## Message from the OSDI '23 Program Co-Chairs

Dear Colleagues,

Welcome to the 17th USENIX Symposium on Operating Systems Design and Implementation (OSDI '23).

Once again, we are co-locating OSDI and the USENIX Annual technical Conference (USENIX ATC '23). We are excited to be back in person in these two forums for such a large gathering of technical experts across academia and industry. We hope you come away from OSDI and USENIX ATC inspired, refreshed and re-engaged with the wider systems research community!

This year, OSDI received 255 submissions. We accepted 50 submissions, which is a 19.6% acceptance rate. This is inline with the 253 submissions and 19.4% acceptance rate from last year. In addition to the 50 papers accepted this year, 5 additional papers were accepted from the OSDI '22 Revise and Resubmit process. This brings the total program to 55 papers presented at OSDI across an incredibly wide breadth of areas of focus. Although this is 6 more papers than last year, we continue to be committed to a single-track conference at OSDI and have put together a 3-day program for all 55 papers.

Given the large number of submissions, we formed a program committee of 86 members in addition to the two program co-chairs. There were also 5 external reviews where a particular area of expertise or evaluation was needed on a single paper. We are very grateful to the program committee for their diligence, focus, and optimism during the review process. OSDI is known for high quality reviews that help and inform the authors to produce their very best work.

The program committee reviewed submissions in two rounds. Every paper received at least three reviews in the first round. Roughly 40% of the papers were rejected during the first round of reviews. One paper was accepted after the first round of reviews concluded, and the remainder advanced to the second round. Papers then received 2 or 3 additional reviews. Subsequently, the PC had an asynchronous online discussion phase where an additional 35 papers were accepted and 77 papers were rejected. Thirty six papers were advanced to a synchronous, online two-day PC meeting. We purposefully organized the PC meeting by topic area, which allowed experts who might not have a paper in a particular area up for discussion, to dial in and participate in the areas most relevant to them. We finished the PC meeting on time, and had a great discussion from PC members all over the world. Each accepted paper was assigned a shepherd to work with the authors to revise the paper in response to reviewer feedback. The committee completed more than 1,000 reviews and posted hundreds of comments as part of the online discussion process. Finally, we did allow one of the program co-chairs to submit a paper. However, the paper was assigned a "paper administrator," and neither co-chair had any involvement in the review of that paper, and both were informed of the paper's outcome after the PC meeting concluded.

The program committee also chose to continue the revise-and-resubmit process. A small set of papers were recommended by the program committee to undergo this process. Those authors will have a much longer period of time (until August) to revise their papers, add important missing details, and/or run additional experiments, as requested by the PC. The original reviewers will review the revised submission. If accepted, the authors will be allowed to submit a "camera-ready" version of the paper in October of 2023 and then the authors will present the paper and have that paper officially included in the OSDI 2024 program. This early camera ready deadline allows authors to discuss the work (and have others cite it) well before the OSDI 2024 program appears.

Once the program was completed and the camera-ready deadline had passed, we began the process of selecting the Jay Lepreau Best Paper Award. We began by asking PC members for nominations and looking at the top-rated papers during the review process. We formed a small group of non-conflicted PC members who read each paper and agreed on the best paper of those chosen for consideration.

OSDI '23 had an artifact-evaluation committee that organized and evaluated the artifacts submitted by authors. The committee co-chairs this year are Jianyu Jiang, Nathan Rutherford, and Cesar A. Stuardo. Thirty-two papers submitted artifacts supporting their research. Twenty-nine papers received the Available badge. Thirty-one papers received the Functional badge, and 27 papers received the Reproduced badge, meaning the results in the paper were independently reproduced by the committee.

OSDI '23 had a poster submission process organized by co-chairs Adriana Szekeres and Ryan Huang. Thirty-three posters were accepted for display at the OSDI poster session.

Finally, as PC chairs, we rely on so many dedicated volunteers and professional staff to make this conference a reality. We thank the authors who submitted such high-quality work. This conference is first and foremost a forum for disseminating, sharing, discussing, and debating world-class systems research. Thank you for your hard work and innovation! We thank the PC members and external reviewers for their significant investment of time, energy, and insight into shaping the program. We thank Pierre Tholoni and Roy Rinberg, who facilitated the PC meeting and made sure we ran the technology and not the other way around. We especially thank the USENIX staff, who have made chairing a conference like this one a well-oiled machine! Finally, we thank you for coming to this conference to engage with each other and with the authors of the accepted papers. This community is one we cherish, and one we are honored to have curated this year through our stewardship as co-chairs.

We hope that you leave this conference energized and inspired.

Onwards!

Roxana Geambasu, *Columbia University*

Ed Nightingale, *Apple*

OSDI '23 Program Co-Chairs

# 17th USENIX Symposium on Operating Systems Design and Implementation (OSDI '23)

July 10–12, 2023  
Boston, MA, USA

## Monday, July 10

### Make Your Bits Go Faster

- Ship your Critical Section, Not Your Data: Enabling Transparent Delegation with TCLocks** ..... 1  
Vishal Gupta, *EPFL*; Kumar Kartikeya Dwivedi, *SRMIST*; Yugesh Kothari, Yueyang Pan, Diyu Zhou, and Sanidhya Kashyap, *EPFL*
- RON: One-Way Circular Shortest Routing to Achieve Efficient and Bounded-waiting Spinlocks** .....17  
Shiwu Lo, Han-Ting Lin, Yao-Hung Hsieh, and Chao-Ting Lin, *National Chung Cheng University*; Yu-Hsueh Fang, *National Cheng Kung University*; Ching-Shen Lin, *National Chung Cheng University*; Ching-Chun (Jim) Huang, *National Cheng Kung University*; Kam Yiu Lam, *City University of Hong Kong*; Yuan-Hao Chang, *Academia Sinica, Taiwan*
- Userspace Bypass: Accelerating Syscall-intensive Applications**..... 33  
Zhe Zhou, Yanxiang Bi, Junpeng Wan, and Yangfan Zhou, *Fudan University*; Zhou Li, *University of California, Irvine*
- Triangulating Python Performance Issues with SCALENE**..... 51  
Emery D. Berger, Sam Stern, and Juan Altmayer Pizzorno, *University of Massachusetts Amherst*
- Relational Debugging — Pinpointing Root Causes of Performance Problems** ..... 65  
Xiang (Jenny) Ren, Sitao Wang, Zhuqi Jin, David Lion, and Adrian Chiu, *University of Toronto*; Tianyin Xu, *University of Illinois at Urbana-Champaign*; Ding Yuan, *University of Toronto*

### Secure Your Bits I

- Accountable authentication with privacy protection: The Larch system for universal login** ..... 81  
Emma Dauterman, *UC Berkeley*; Danny Lin, *Woodinville High School*; Henry Corrigan-Gibbs, *MIT*; David Mazières, *Stanford University*
- K9db: Privacy-Compliant Storage For Web Applications By Construction**..... 99  
Kinan Dak Albab, Ishan Sharma, Justus Adam, Benjamin Kilimnik, Aaron Jeyaraj, Raj Paul, Artem Agvanian, Leonhard Spiegelberg, and Malte Schwarzkopf, *Brown University*
- Encrypted Databases Made Secure Yet Maintainable** .....117  
Mingyu Li, *Shanghai Jiao Tong University*; *Shanghai AI Laboratory*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Xuyang Zhao and Le Chen, *Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Cheng Tan, *Northeastern University*; Huorong Li and Sheng Wang, *Alibaba Group*; Zeyu Mi, *Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Yubin Xia, *Shanghai Jiao Tong University*; *Shanghai AI Laboratory*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Feifei Li, *Alibaba Group*; Haibo Chen, *Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*
- LVMT: An Efficient Authenticated Storage for Blockchain** ..... 135  
Chenxing Li, *Shanghai Tree-Graph Blockchain Research Institute*; Sidi Mohamed Beillahi, *University of Toronto*; Guang Yang and Ming Wu, *Shanghai Tree-Graph Blockchain Research Institute*; Wei Xu, *Tsinghua University*; Fan Long, *University of Toronto*
- Honeycomb: Secure and Efficient GPU Executions via Static Validation**..... 155  
Haohui Mai, *PrivacyCore Inc.*; Jiacheng Zhao, *SKLP, Institute of Computing Technology, CAS*; *Zhongguancun Laboratory*; and *UCAS*; Hongren Zheng, *IIS, Tsinghua University*; Yiyang Zhao, *SKLP, Institute of Computing Technology, CAS*; and *UCAS*; Zibin Liu, *BUPT*; Mingyu Gao, *IIS, Tsinghua University*; Cong Wang, *IDEA Shenzhen*; Huimin Cui, *SKLP, Institute of Computing Technology, CAS*; and *UCAS*; Xiaobing Feng, *SKLP, Institute of Computing Technology, CAS*; *Zhongguancun Laboratory*; and *UCAS*; Christos Kozyrakis, *PrivacyCore Inc. and Stanford*

## Secure Your Bits II

**An Extensible Orchestration and Protection Framework for Confidential Cloud Computing** .....173  
Adil Ahmad and Alex Schultz, *Arizona State University*; Byoungyoung Lee, *Seoul National University*; Pedro Fonseca, *Purdue University*

**Nimble: Rollback Protection for Confidential Cloud Services**..... 193  
Sebastian Angel, *Microsoft Research*; Aditya Basu, *Penn State University*; Weidong Cui, *Microsoft Research*;  
Trent Jaeger, *Penn State University*; Stella Lau, *MIT CSAIL*; Srinath Setty, *Microsoft Research*; Sudheesh Singanamalla, *University of Washington*

**Kerberos: Efficient and Scalable Cloud Admission Control** ..... 209  
Sultan Mahmud Sajal, *Microsoft Research and Pennsylvania State University*; Luke Marshall and Beibin Li, *Microsoft Research*; Shandan Zhou and Abhisek Pan, *Microsoft Azure*; Konstantina Mellou and Deepak Narayanan, *Microsoft Research*; Timothy Zhu, *Pennsylvania State University*; David Dion and Thomas Moscibroda, *Microsoft Azure*;  
Ishai Menache, *Microsoft Research*

**Security and Performance in the Delegated User-level Virtualization** ..... 227  
Jiahao Chen, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Dingji Li, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; MoE Key Lab of Artificial Intelligence, AI Institute, *Shanghai Jiao Tong University*; Zeyu Mi, Yuxuan Liu, and Binyu Zang, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*; Haibing Guan, *Shanghai Key Laboratory of Scalable Computing and Systems, Shanghai Jiao Tong University*; Haibo Chen, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University*; *Engineering Research Center for Domain-specific Operating Systems, Ministry of Education, China*

**Core slicing: closing the gap between leaky confidential VMs and bare-metal cloud**..... 247  
Ziqiao Zhou, *Microsoft Research*; Yizhou Shan, *University of California, San Diego*; Weidong Cui, Xinyang Ge, Marcus Peinado, and Andrew Baumann, *Microsoft Research*

## Tuesday, July 11

### Expanding, Hardening, and Deploying Your Bits

**ExoFlow: A Universal Workflow System for Exactly-Once DAGs**..... 269  
Siyuan Zhuang, *UC Berkeley*; Stephanie Wang, *UC Berkeley and Anyscale*; Eric Liang and Yi Cheng, *Anyscale*;  
Ion Stoica, *UC Berkeley*

**Hyrax: Fail-in-Place Server Operation in Cloud Platforms** ..... 287  
Jialun Lyu, *Microsoft Azure and University of Toronto*; Marisa You, Celine Irvine, Mark Jung, Tyler Narmore, Jacob Shapiro, Luke Marshall, and Savyasachi Samal, *Microsoft Azure*; Ioannis Manousakis and Lisa Hsu, *Formerly of Microsoft Azure*; Preetha Subbarayalu, Ashish Raniwala, Brijesh Warriar, and Ricardo Bianchini, *Microsoft Azure*;  
Bianca Schroeder, *University of Toronto*; Daniel S. Berger, *Microsoft Azure and University of Washington*

**NCC: Natural Concurrency Control for Strictly Serializable Databases by Avoiding the Timestamp-Inversion Pitfall** ..... 305  
Haonan Lu, *University at Buffalo*; Shuai Mu, *Stony Brook University*; Siddhartha Sen, *Microsoft Research*;  
Wyatt Lloyd, *Princeton University*

**Conveyor: One-Tool-Fits-All Continuous Software Deployment at Meta** ..... 325  
Boris Grubic, *Meta*; Yang Wang, *Meta and the Ohio State University*; Tyler Petrochko, Ran Yaniv, Brad Jones, David Callies, Matt Clarke-Lauer, and Dan Kelley, *Meta*; Soteris Demetriou, *Meta and Imperial College London*; Kenny Yu and Chunqiang Tang, *Meta*

### Query Your Bits

**Chardonnay: Fast and General Datacenter Transactions for On-Disk Databases** ..... 343  
Tamer Eldeeb and Xincheng Xie, *Columbia University*; Philip A. Bernstein, *Microsoft Research*; Asaf Cidon and Junfeng Yang, *Columbia University*

**ScaleDB: A Scalable, Asynchronous In-Memory Database** . . . . . 361  
Syed Akbar Mehdi, *The University of Texas at Austin*; Deukyeon Hwang and Simon Peter, *University of Washington*;  
Lorenzo Alvisi, *Cornell University*

**VBASE: Unifying Online Vector Similarity Search and Relational Queries via Relaxed Monotonicity** . . . . . 377  
Qianxi Zhang, Shuotao Xu, Qi Chen, and Guoxin Sui, *Microsoft Research Asia*; Jiadong Xie, *Microsoft Research Asia  
and East China Normal University*; Zhizhen Cai and Yaoqi Chen, *Microsoft Research Asia and University of Science and  
Technology of China*; Yinxuan He, *Microsoft Research Asia and Renmin University of China*; Yuqing Yang, Fan Yang,  
Mao Yang, and Lidong Zhou, *Microsoft Research Asia*

**Detecting Transactional Bugs in Database Engines via Graph-Based Oracle Construction** . . . . . 397  
Zu-Ming Jiang and Si Liu, *ETH Zurich*; Manuel Rigger, *National University of Singapore*; Zhendong Su, *ETH Zurich*

**Take Out the TraChe: Maximizing (Tra)nsactional Ca(che) Hit Rate** . . . . . 419  
Audrey Cheng, David Chu, Terrance Li, Jason Chan, Natacha Crooks, Joseph M. Hellerstein, and Ion Stoica, *UC Berkeley*;  
Xiangyao Yu, *University of Wisconsin—Madison*

## Store Your Bits

**Replicating Persistent Memory Key-Value Stores with Efficient RDMA Abstraction** . . . . . 441  
Qing Wang, Youyou Lu, Jing Wang, and Jiwu Shu, *Tsinghua University*

**eZNS: An Elastic Zoned Namespace for Commodity ZNS SSDs** . . . . . 461  
Jaehong Min and Chenxingyu Zhao, *University of Washington*; Ming Liu, *University of Wisconsin-Madison*;  
Arvind Krishnamurthy, *University of Washington*

**SEPH: Scalable, Efficient, and Predictable Hashing on Persistent Memory** . . . . . 479  
Chao Wang, Junliang Hu, Tsun-Yu Yang, Yuhong Liang, and Ming-Chang Yang, *The Chinese University of Hong Kong*

**No Provisioned Concurrency: Fast RDMA-codedigned Remote Fork for Serverless Computing** . . . . . 497  
Xingda Wei, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai Jiao Tong University, and Shanghai AI  
Laboratory*; Fangming Lu, Tianxia Wang, Jinyu Gu, and Yuhan Yang, *Institute of Parallel and Distributed Systems,  
SEIEE, Shanghai Jiao Tong University*; Rong Chen, *Institute of Parallel and Distributed Systems, SEIEE, Shanghai  
Jiao Tong University, and Shanghai AI Laboratory*; Haibo Chen, *Institute of Parallel and Distributed Systems, SEIEE,  
Shanghai Jiao Tong University*

## Manage Your Bits I

**Johnny Cache: the End of DRAM Cache Conflicts (in Tiered Main Memory Systems)**. . . . . 519  
Baptiste Lepers, *Université de Neuchâtel*; Willy Zwaenepoel, *University of Sydney*

**TAILCHECK: A Lightweight Heap Overflow Detection Mechanism with Page Protection and Tagged Pointers**. . . . . 535  
Amogha Udupa Shankaranarayana Gopal, Raveendra Soori, Michael Ferdman, and Dongyoon Lee, *Stony Brook University*

**SMART: A High-Performance Adaptive Radix Tree for Disaggregated Memory** . . . . . 553  
Xuchuan Luo, *School of Computer Science, Fudan University*; Pengfei Zuo, *Huawei Cloud*; Jiacheng Shen and Jiazhen  
Gu, *The Chinese University of Hong Kong*; Xin Wang, *School of Computer Science, Fudan University*; Shanghai  
Key Laboratory of Intelligent Information Processing, Shanghai, China; Michael R. Lyu, *The Chinese University of  
Hong Kong*; Yangfan Zhou, *School of Computer Science, Fudan University*; Shanghai Key Laboratory of Intelligent  
Information Processing, Shanghai, China

**ORC: Increasing Cloud Memory Density via Object Reuse with Capabilities** . . . . . 573  
Vasily A. Sartakov, Lluís Vilanova, and Munir Geden, *Imperial College London*; David Eyers, *University of Otago*;  
Takahiro Shinagawa, *The University of Tokyo*; Peter Pietzuch, *Imperial College London*

## Manage Your Bits II

**Global Capacity Management With Flux**. . . . . 589  
Marius Eriksen, Kaushik Veeraraghavan, Yusuf Abdulghani, Andrew Birchall, Po-Yen Chou, Richard Cornew, Adela  
Kabiljo, Ranjith Kumar S, Maroo Lieuw, Justin Meza, Scott Michelson, Thomas Rohloff, Hayley Russell, Jeff Qin, and  
Chunqiang Tang, *Meta*

<b>Defcon: Preventing Overload with Graceful Feature Degradation</b> .....	<b>607</b>
Justin J. Meza, Thote Gowda, Ahmed Eid, Tomiwa Ijaware, Dmitry Chernyshev, Yi Yu, Md Nazim Uddin, Rohan Das, Chad Nachiappan, Sari Tran, Shuyang Shi, Tina Luo, David Ke Hong, Sankaralingam Panneerselvam, Hans Ragas, Svetlin Manavski, Weidong Wang, and Francois Richard, <i>Meta Platforms, Inc.</i>	
<b>Cilantro: Performance-Aware Resource Allocation for General Objectives via Online Feedback</b> .....	<b>623</b>
Romil Bhardwaj, <i>UC Berkeley</i> ; Kirthevasan Kandasamy, <i>University of Wisconsin-Madison</i> ; Asim Biswal, Wenshuo Guo, Benjamin Hindman, Joseph Gonzalez, Michael Jordan, and Ion Stoica, <i>UC Berkeley</i>	
<b>Karma: Resource Allocation for Dynamic Demands</b> .....	<b>645</b>
Midhul Vuppapalati, Giannis Fikioris, and Rachit Agarwal, <i>Cornell University</i> ; Asaf Cidon, <i>Columbia University</i> ; Anurag Khandelwal, <i>Yale University</i> ; Éva Tardos, <i>Cornell University</i>	

## Wednesday, July 12

### Train Your Bits I

<b>AlpaServe: Statistical Multiplexing with Model Parallelism for Deep Learning Serving</b> .....	<b>663</b>
Zhuohan Li and Lianmin Zheng, <i>UC Berkeley</i> ; Yinmin Zhong, <i>Peking University</i> ; Vincent Liu, <i>University of Pennsylvania</i> ; Ying Sheng, <i>Stanford University</i> ; Xin Jin, <i>Peking University</i> ; Yanping Huang and Zhifeng Chen, <i>Google</i> ; Hao Zhang, <i>UC San Diego</i> ; Joseph E. Gonzalez and Ion Stoica, <i>UC Berkeley</i>	
<b>Cocktailer: Analyzing and Optimizing Dynamic Control Flow in Deep Learning</b> .....	<b>681</b>
Chen Zhang, <i>Tsinghua University</i> ; Lingxiao Ma and Jilong Xue, <i>Microsoft Research</i> ; Yining Shi, <i>Peking University &amp; Microsoft Research</i> ; Ziming Miao and Fan Yang, <i>Microsoft Research</i> ; Jidong Zhai, <i>Tsinghua University</i> ; Zhi Yang, <i>Peking University</i> ; Mao Yang, <i>Microsoft Research</i>	
<b>Welder: Scheduling Deep Learning Memory Access via Tile-graph.</b> .....	<b>701</b>
Yining Shi, <i>Peking University &amp; Microsoft Research</i> ; Zhi Yang, <i>Peking University</i> ; Jilong Xue, Lingxiao Ma, Yuqing Xia, Ziming Miao, Yuxiao Guo, Fan Yang, and Lidong Zhou, <i>Microsoft Research</i>	
<b>Effectively Scheduling Computational Graphs of Deep Neural Networks toward Their Domain-Specific Accelerators</b> .....	<b>719</b>
Jie Zhao, <i>Information Engineering University</i> ; Siyuan Feng, <i>Shanghai Jiao Tong University</i> ; Xiaoqiang Dan, Fei Liu, Chengke Wang, Sheng Yuan, Wenyan Lv, and Qikai Xie, <i>Stream Computing Inc.</i>	

### Train Your Bits II

<b>EINNET: Optimizing Tensor Programs with Derivation-Based Transformations</b> .....	<b>739</b>
Liyang Zheng, Haojie Wang, Jidong Zhai, Muyan Hu, Zixuan Ma, Tuowei Wang, and Shuhong Huang, <i>Tsinghua University</i> ; Xupeng Miao, <i>Carnegie Mellon University</i> ; Shizhi Tang and Kezhao Huang, <i>Tsinghua University</i> ; Zhihao Jia, <i>Carnegie Mellon University</i>	
<b>Hydro: Surrogate-Based Hyperparameter Tuning Service in Datacenters</b> .....	<b>757</b>
Qinghao Hu, <i>Nanyang Technological University, S-Lab, NTU, and Shanghai AI Laboratory</i> ; Zhisheng Ye, <i>Shanghai AI Laboratory and Peking University</i> ; Meng Zhang, <i>Nanyang Technological University, S-Lab, NTU, and Shanghai AI Laboratory</i> ; Qiaoling Chen, <i>Shanghai AI Laboratory and National University of Singapore</i> ; Peng Sun, <i>Shanghai AI Laboratory and SenseTime Research</i> ; Yonggang Wen and Tianwei Zhang, <i>Nanyang Technological University</i>	
<b>MGG: Accelerating Graph Neural Networks with Fine-Grained Intra-Kernel Communication-Computation Pipelining on Multi-GPU Platforms</b> .....	<b>779</b>
Yuke Wang, Boyuan Feng, and Zheng Wang, <i>University of California Santa Barbara</i> ; Tong Geng, <i>University of Rochester</i> ; Kevin Barker and Ang Li, <i>Pacific Northwest National Laboratory</i> ; Yufei Ding, <i>University of California Santa Barbara</i>	
<b>Optimizing Dynamic Neural Networks with Brainstorm.</b> .....	<b>797</b>
Weihao Cui, <i>Shanghai Jiao Tong University</i> ; Zhenhua Han, <i>Microsoft Research Asia</i> ; Lingji Ouyang, <i>University of Science and Technology of China</i> ; Yichuan Wang, <i>Shanghai Jiao Tong University</i> ; Ningxin Zheng, Lingxiao Ma, Yuqing Yang, Fan Yang, Jilong Xue, Lili Qiu, and Lidong Zhou, <i>Microsoft Research Asia</i> ; Quan Chen, <i>Shanghai Jiao Tong University</i> ; Haisheng Tan, <i>University of Science and Technology of China</i> ; Minyi Guo, <i>Shanghai Jiao Tong University</i>	

**AdaEmbed: Adaptive Embedding for Large-Scale Recommendation Models** . . . . .817  
Fan Lai, *University of Michigan*; Wei Zhang, Rui Liu, William Tsai, Xiaohan Wei, Yuxi Hu, Sabin Devkota, Jianyu Huang, Jongsoo Park, Xing Liu, Zeliang Chen, Ellie Wen, Paul Rivera, Jie You, and Chun-cheng Jason Chen, *Meta*; Mosharaf Chowdhury, *University of Michigan*

## Verify Your Bits

**BWoS: Formally Verified Block-based Work Stealing for Parallel Processing** . . . . . 833  
Jiawei Wang, *Huawei Dresden Research Center, Huawei Central Software Institute, Technische Universität Dresden*; Bohdan Trach, Ming Fu, Diogo Behrens, Jonathan Schwender, Yutao Liu, and Jitang Lei, *Huawei Dresden Research Center, Huawei Central Software Institute*; Viktor Vafeiadis, *MPI-SWS*; Hermann Härtig, *Technische Universität Dresden*; Haibo Chen, *Huawei Central Software Institute, Shanghai Jiao Tong University*

**Spoq: Scaling Machine-Checkable Systems Verification in Coq** . . . . . 851  
Xupeng Li, Xuheng Li, Wei Qiang, Ronghui Gu, and Jason Nieh, *Columbia University*

**Verifying vMVCC, a high-performance transaction library using multi-version concurrency control** . . . . . 871  
Yun-Sheng Chang, *MIT CSAIL*; Ralf Jung, *ETH Zurich*; Upamanyu Sharma, *MIT CSAIL*; Joseph Tassarotti, *New York University*; M. Frans Kaashoek and Nickolai Zeldovich, *MIT CSAIL*

**Automated Verification of Idempotence for Stateful Serverless Applications** . . . . . 887  
Haoran Ding, Zhaoguo Wang, and Zhuohao Shen, *Institute of Parallel and Distributed Systems, SEITEE, Shanghai Jiao Tong University*; Rong Chen, *Institute of Parallel and Distributed Systems, SEITEE, Shanghai Jiao Tong University*; *Shanghai AI Laboratory*; Haibo Chen, *Institute of Parallel and Distributed Systems, SEITEE, Shanghai Jiao Tong University*

**Sharding the State Machine: Automated Modular Reasoning for Complex Concurrent Systems** . . . . . 911  
Travis Hance and Yi Zhou, *Carnegie Mellon University*; Andrea Lattuada, *VMware Research*; Reto Achermann, *University of British Columbia*; Alex Conway, *VMware Research*; Ryan Stutsman, *VMware Research and University of Utah*; Gerd Zellweger, *VMware Research*; Chris Hawblitzel, *Microsoft Research*; Jon Howell, *VMware Research*; Bryan Parno, *Carnegie Mellon University*

EPFL \*SRMIST

## Abstract

Today’s high-performance applications heavily rely on various synchronization mechanisms, such as locks. While locks ensure mutual exclusion of shared data, their design impacts application scalability. Locks, as used in practice, move the lock-guarded shared data to the core holding it, which leads to shared data transfer among cores. This design adds unavoidable critical path latency leading to performance scalability issues. Meanwhile, some locks avoid this shared data movement by localizing the access to shared data on one core, and shipping the critical section to that specific core. However, such locks require modifying applications to explicitly package the critical section, which makes it virtually infeasible for complicated applications with large code bases, such as the Linux kernel.

We propose *transparent delegation*, in which a waiter automatically encodes its critical section information on its stack and notifies the combiner (lock holder). The combiner executes the shipped critical section on the waiter’s behalf using a lightweight context switch. Using transparent delegation, we design a family of locking protocols, called TCLocks, that requires zero modification to applications’ logic. The evaluation shows that TCLocks provide up to  $5.2\times$  performance improvement compared with recent locking algorithms.

## 1 Introduction

Synchronization mechanisms are the basic building blocks for today’s high-performance concurrent applications. In fact, applications heavily rely on locks as a concurrency control mechanism, as they provide a set of simple programming APIs for users to mediate concurrent access to shared data. Besides ensuring program correctness, locks also affect the scalability of applications [33, 34, 49]. For instance, various high-performance applications, such as the Linux kernel, have moved from coarse-grained to fine-grained locks [52] for minimizing the length of the critical section. However, thanks to diverse workloads and applications, the scalability problem due to lock algorithms still remains at large [41, 55, 62, 70].

**Figure 1:** Impact of locks on a file-system micro-benchmark [62]. We compare three traditional lock algorithms: Linux’s `qspinlock` (*Stock*) [41], `CNA` [43] and `SHFLOCK` [52] with our proposed `TCLock`. (a) Enumerating files in a shared directory on an 8-socket 224-core machine. (b) Time spent in the critical section: moving the critical section context (`TCLock`) compared with moving critical section shared data (*Stock*, `CNA`, and `SHFLOCK`).

As a result, research in lock algorithms focuses on minimizing the contention on cache-lines containing the lock word and shared data. The most widely used algorithms always move the shared data to the core executing the critical section [30, 41, 43, 52, 53, 60]. Lock evolution within this design philosophy has focused on reducing contention on the lock word. However, such a lock design still moves shared data across cores for every lock acquisition. **Figure 1** shows that such shared data access cost increases with increasing cores, thereby limiting the scalability of applications.

On the other end of the design spectrum, some algorithms adopt the request-response style of communication, also called delegation-style locking [37, 47, 51, 56, 64, 67]. Specifically, waiters delegate their critical section execution context to a dedicated core [56, 67] or a *combiner* [47, 51] that executes that function on behalf of each waiter in a specific order. **Figure 1** illustrates that this design outperforms traditional locks and improves application performance. In particular, such a lock design minimizes the shared data movement, and ensures almost constant critical section latency regardless of the number of threads.

Despite potential performance gains, the practical design and implementation of delegation-style locks faces several challenges. First, applications require major rewriting to ex-

explicitly encapsulate and pass the critical section as a function pointer [51, 56, 67]. Unfortunately, this rewriting becomes impractical for applications with large code bases, such as the Linux kernel, which has over 180k lock API call sites [52]. Second, every delegation-based work focuses on situations involving a single lock contention. However, today's applications often employ fine-grained locking and may acquire multiple locks for operations, such as memory, scheduler, and storage management in the Linux kernel [4, 12, 13, 20]. Finally, the third challenge involves managing the per-CPU or per-thread variables, which applications heavily depend on for either performance or correctness.

In this paper, we take the first step towards making delegation-based locks practical for concurrent applications with large code bases. We introduce the idea of *transparent delegation*, which enables developers to utilize delegation-style locking without rewriting the application. Our transparent delegation approach encapsulates the critical section using two observations: First, a thread's stack and CPU registers contain the state of the waiter's thread. Second, using the lock/unlock API pushes the thread's context on its stack. Thus, a waiter *saves its critical section context using CPU registers and stack pointer, and calling the lock API as a function*. Finally, the combiner executes the waiter's critical section on its behalf by assuming the role of the waiter using a lightweight context switch mechanism [29, 59]. This context-switch mechanism is transparent to the application.

Using transparent delegation, we design a new family of locks called TLocks that augment existing locks, such as test-and-set (TAS) and MCS, by employing the combining technique for batching waiters' requests [47]. Our first lock is a spinlock, where waiters continuously spin while awaiting the lock. The combiner can execute multiple waiter's critical section before passing its role based on a counter-based mechanism. Similar to our prior work (SHFLocks) [52], our algorithms can enforce hardware and software policies on the fly. In particular, our spinlock version also incorporates NUMA-awareness policy. We then integrate the core over-subscription policy [52] to design a blocking lock, where the waiter can sleep while waiting for the lock. Lastly, we design a phase-based readers-writer lock built on top of our blocking lock.

Applying TLocks directly in highly concurrent systems presents its own set of challenges. First, transparent delegation violates the single-writer property of a thread's stack, meaning that two threads (the combiner and the waiter) writing to the same stack can cause data races and stack corruption. Waiters need access to a stack due to specific events, such as interrupts in the kernel space, signals in userspace, and scheduling of waiting threads. We address the data-race issue using a *per-thread ephemeral stack* that a waiter switches to between the acquire and release phases.

Second, most concurrent applications use multi-level locking [4, 20, 28] and out-of-order (OOO) unlocking [12, 13]

for higher concurrency and better scalability. TLocks handle the arbitrary level of nested combining by maintaining combiner-specific state on the ephemeral stack before acquiring the nested lock. Meanwhile, we handle OOO unlocking by keeping track of the order of acquired locks. We delay the release of OOO unlocked locks until the order is the inverse of acquired locks. This effectively flattens the release of locks.

We evaluate TLocks in both kernel space and userspace on NUMA machines. TLocks improve the performance within and across sockets. Specifically, TLocks boost application throughput by 1.7–5.2× compared to the locks used in the Linux kernel and state-of-the-art locks, respectively.

In summary, this paper makes the following contributions:

- **Design technique.** We introduce a new design technique called transparent delegation. Locks with this technique allow developers to use the same APIs as traditional locks while benefiting from the scalability improvements provided by delegation-style locking.
- **Delegation-based lock family.** We implement TLocks that employ transparent delegation. We first design a spinning lock and extend it to blocking and readers-writer locks, utilizing per-thread ephemeral stacks to manage the parking of waiters.
- **Practical application.** TLocks incorporate various lock use scenarios, including nested locking and out-of-order unlocking. This approach allows us to realize the potential of delegation-style locking for the Linux kernel without modifying any code.

## 2 Background

While executing a critical section, a thread accesses three types of memory locations (data):

1. **Lock word**, *i.e.*, its structure that determines the exclusive access for a thread.
2. **Shared data** among threads guarded by a lock word, accessible only to the thread holding the lock.
3. **Thread-local data** like stack and per-thread variables.

Most lock designs minimize the contention on the lock word, while some minimize the movement of shared data. Hence, there are two design philosophies based on shared data movement: traditional and delegation-style. We now discuss the evolution of locks based on these design philosophies. Later, we touch upon the systems-level challenges that are specific to delegation-style locks.

### 2.1 Traditional Locks

Traditional lock design adheres to the principle of moving data to computation. A core executes the critical section by moving shared data into its cache. Consequently, this design moves cache lines of both the lock word and shared data across cores while executing the critical section. The evolution of traditional lock algorithms [50] has focused on minimizing cache-line movement of the lock word. For example, queue-based locks [41, 42, 44, 58, 60, 68] minimize

cache-line contention due to the lock word. Hierarchical locks [39, 46, 57, 66] further reduce the cache-line contention on non-uniform memory access (NUMA) machines, where accessing a local-socket memory location is faster than a remote one. These locks amortize the remote access cost of the lock word by reordering the wait queue to pass the lock within the same socket. SHFLLOCK [52] and CNA [43] further generalize hierarchical lock design by reordering the wait queue based on various hardware and software policies. Moreover, our recent work [65] has also shown that the reordering policy can be changed dynamically without kernel compilation.

Readers-writer locks also follow traditional lock design, with most locks aiming to minimize contention on the lock word [36, 54, 61]. These locks augment mutually exclusive locks with different types of read indicators based on workload requirements. Some examples include centralized [61], per-socket [38], and per-CPU [40, 63, 71] indicators. These locks also require moving shared data across cores, even though they offer a broader semantics of mutual exclusion.

Traditional locks do not require modifying applications since the lock/unlock programming APIs remain consistent. However, these locks move shared data cache lines among cores while executing the critical section. Unfortunately, this lock design incurs shared data movement for every critical section execution, thereby increasing critical section execution latency. Moreover, this latency grows with increasing core count (Figure 1 (b)), which saturates the throughput without efficiently utilizing hardware.

## 2.2 Delegation-style Locks

Delegation-style locks follow the principle of moving computation to data [45, 47, 51, 56, 64, 67]. These locks use an old technique called combining that has been used in hardware and software to mitigate memory contention by combining requests for the same memory location. In this approach, waiters pack their critical section as a function and pass that function pointer to the combiner as a request. The combiner then executes the waiter's function and notifies it upon completion. Executing the critical section on the same core eliminates shared data movement, leading to improved application throughput with increasing core count (Figure 1).

However, this lock design has a critical limitation. It does not provide the same lock/unlock APIs as traditional locks [47, 67]. Consequently, we need to modify applications, which involves identifying each critical section in the code, wrapping it as a function, and modularizing the application logic for delegation. Modifying application logic to encapsulate the critical section as a function is quite challenging and even impossible in some cases [46]. For instance, Roghanchi *et al.* [67] reported modifying  $\sim 1,500$  lines of code (LoC) to enable delegation for Memcached. This limitation, unfortunately, prevents the scalability offered by delegation-style locking from being applied to existing real-world applica-

tions, such as Linux, which comprises 28M LoC with more than 180k static lock call sites.

## 2.3 The Incompatibility of Delegation in Concurrent Applications

Real-world applications, such as the Linux kernel, employ fine-grained locking in multiple execution contexts. Fine-grained locking mostly involves acquiring multiple nested locks when working with several objects. To prevent deadlocks, the nested locks are acquired in a specific order, but they can be released in arbitrary order to enhance concurrency [12, 13]. However, none of the delegation approaches handle such common, but challenging cases. We measured that both nested locking calls and OOO unlocking calls are quite prevalent. For instance, booting Linux results in  $\sim 80k$  nested locking calls and  $\sim 20k$  OOO unlock calls. Thus, addressing these cases is essential to make delegation-style locks practical for every concurrent systems software.

In addition, the Linux kernel can call locks from various contexts. These contexts comprise of task [25] and interrupts (*e.g.*, non-maskable interrupt context [11], HardIRQ context [6, 7], or SoftIRQ context [23]). The kernel code typically executes in the task context. Depending on the kernel configuration, a scheduler can preempt or migrate a task to another CPU. Nevertheless, in special execution contexts, such as interrupts, or code regions that disable CPU preemption and migration, the scheduler prohibits the migration of such contexts. The Linux kernel code also heavily utilizes per-CPU variables and implicitly relies on stable access to these variables in such special execution contexts. Traditional lock design does not require any handling for special execution contexts because the critical section executes on the core that acquires the lock. In contrast, delegation-style locks break this property, necessitating special handling for these cases, *i.e.*, special contexts and stable access to per-CPU variables.

**Goal.** In accordance with the general design principle of minimizing data movement [43, 52], our objective is to reduce data movement for both lock word and shared data. Unlike existing delegation-style locks, we avoid making any code modifications. Hence, we take the initial step towards achieving the goal of transparently enabling delegation-style locking for any real-world application, including the OS.

## 3 TLocks

We propose transparent delegation, a practical lock-design technique for real-world applications that allow developers to use the same lock/unlock APIs as traditional locks without modifying the application code. Transparent delegation involves two steps: First, it automatically encapsulates a critical section of arbitrary length in a set of registers and the thread stack. Second, waiters pass this encapsulated information to the combiner for execution. As a result, our approach enables applications to enjoy scalability without any modification. We apply this technique to design a family

of lock algorithms called TLocks, that transparently delegate waiters' requests to the combiner. TLocks comprises spinning (§3.2) and blocking (§3.4) locks. We extend the blocking lock with read indicators to design a phase-based readers-writer blocking lock (§3.5) incorporating hardware and software-based optimizations (§3.6).

### 3.1 TLock Design

We first discuss a set of insights and techniques that allows us to design and implement TLocks.

**Transparent delegation.** When executing a critical section, a thread can access both shared data (e.g., global variables, heap) and thread-local data (e.g., registers, stack, and per-thread variables). In delegation-style locking, although shared data is globally available to all threads, the combiner requires access to the waiter's thread-local data and the set of instructions for executing its critical section.

Our technique overcomes the challenge of thread-local data and critical section context using three key insights.

1. A thread's execution context is well-defined by hardware, with thread-specific CPU registers and the stack containing all information for executing the critical section [2, 8, 10].
2. A waiter busy-waits without modifying its state once it sends its request to the combiner. It exits only after receiving the response from the combiner.
3. Calling the lock API as a function<sup>1</sup> ensures that hardware pushes the next instruction onto the stack, making the critical section's start address available to the combiner for executing the critical section.

Using these insights, the combiner pops the start address of a critical section from the waiter's stack using a *return* instruction and executes it. After completing the critical section, calling the unlock API pushes the first instruction of the non-critical section onto the waiter's stack. The waiter resumes executing the non-critical section after receiving a notification from the combiner. Thus, transparent delegation allows waiters to seamlessly pass context and resume after the critical section's execution.

**Avoiding concurrent stack access with an ephemeral stack.** To ensure program correctness, transparent delegation must prevent concurrent accesses to a thread's execution stack. Ideally, a waiter busy-waits for notification during its critical section execution. However, certain events, such as interrupts in kernel space, signals in user space, and the waiter's parking and wake-up mechanism [32] can access the waiter's stack during the execution of its delegated critical section. As a result, naive transparent delegation via stack switching violates the fundamental single-writer stack principle, leading to potential stack state corruption.

To address this issue, we introduce an initially empty, separate stack called the *ephemeral stack*. Each waiter switches to its ephemeral stack during lock acquisition, and delegates

<sup>1</sup>For example, the `call` instruction in x86.

**Figure 2:** Lock and qnode structures of the TLock. (a) Initially, the lock is in the unlock state.  $t_1$  first switches from its main stack ( $M_1$ ) to the ephemeral stack ( $E_1$ ), and (b) joins the waiting queue. (c)  $t_1$  being at the head of the queue, becomes the combiner. Meanwhile,  $t_2$  and  $t_3$  join the queue. They also switch their stack to  $E_2$  and  $E_3$ , respectively. (d)  $t_1$  begins the combining process by traversing the queue and finds  $t_2$ . (e)  $t_1$  switches to  $t_2$ 's main stack ( $E_1 \rightarrow M_2$ ) and executes  $t_2$ 's critical section. (f) Once finished,  $t_1$  first switches back to  $E_1$  and then notifies  $t_2$  that  $t_1$  has finished executing its critical section. (g)  $t_2$  then switches back to  $M_2$  and exits its unlock phase. Meanwhile,  $t_1$  finds  $t_3$  as the last waiter. (h)  $t_1$  notifies  $t_3$  that it is now at the head of the queue, then  $t_1$  switches its stack to  $M_1$ , executes its critical section, and finally exits the unlock phase.

its critical section to the combiner. The waiter then busy-waits using the ephemeral stack while the combiner accesses the waiter's main stack to execute the critical section. Importantly, the use of an ephemeral stack does not introduce any new stack overflow bugs since it is a separate memory from the thread's execution stack. By incorporating the ephemeral stack, TLocks maintain the single-writer principle, thereby preventing concurrent access and the corruption of waiters' stack.

### 3.2 Spinlock: TLock<sup>SP</sup>

TLock<sup>SP</sup> augments the TAS and MCS lock by adopting the combining technique from MCS-style combining works [45, 47]. It involves a waiting thread becoming a combiner and batch waiters' requests up to a set threshold. Specifically, TLock extends the DSM-Synch lock, using TAS as a top-level lock, and an MCS-style waiting queue for waiters. The waiter's queue node (qnode) maintains additional states: 1) request and wait flags for synchronizing between a waiter and the combiner and selecting the next combiner. 2) Socket ID for NUMA lock design (§3.6.3). 3) Batch count to limit

excessive waiters, causing starvation or long-term fairness issues. And, 4) a pointer to the waiter's thread context for transparent delegation, which includes all registers and the stack pointer.

**Transparent delegation invariants.** Our lock algorithm maintains four invariants: 1) A combiner is always at the head of the waiting queue. 2) A waiter never uses its main stack while busy waiting. 3) All instructions in a critical section are executed only once, either by a waiter or the combiner executing on the waiter's behalf. 4) A combiner exclusively executes the waiter's critical section instructions defined between the lock and the unlock phase.

**Workflow.** Figure 2 presents a running example of  $\text{TCLock}^{SP}$ . Before requesting a lock, every thread executes in its main context (a). When a thread requests a lock, it switches to an ephemeral stack, saves its main context in its `qnode`, and joins the queue (b). Now, the head of the queue ( $t_1$ ) becomes the combiner, while other threads ( $t_2$  and  $t_3$ ) join the queue after switching to their respective ephemeral stacks. They wait for notification from the combiner, while processing any interrupts and signals on their ephemeral stacks. The combiner iterates through the queue and finds  $t_2$ 's request (d).  $t_1$  context-switches to  $t_2$ 's main context using  $t_2$ 's `qnode`, and starts executing  $t_2$ 's critical section (e). Reaching the unlock API of  $t_2$ ,  $t_1$  switches back to its ephemeral stack, notifies  $t_2$ , and checks for other requests (f). Once  $t_2$  receives notification, it switches back to its main context, which now points to the end of the critical section. It then continues executing its non-critical section (g). Finally, the combiner iterates through the entire queue, it passes the combining role to  $t_3$ , switches to its main context, and executes its critical section (h). Finally,  $t_1$  unlocks the lock, allowing  $t_3$  to acquire it and continue the combining process.

**Algorithm.** Listing 1 presents the  $\text{TCLock}^{SP}$  pseudocode. A thread  $t$  first attempts to acquire the TAS lock on the fast path (line 17). On success,  $t$  executes its critical section directly. Otherwise,  $t$  finds its thread-local combining structure (line 21), saves its register state on the main stack, switches to the ephemeral stack, and begins the slow path (lines 26–27). The slow path comprises four phases: 1)  $t$  joins the queue and busy-waits locally. 2)  $t$  then waits to acquire the TAS lock after becoming the head of the queue. 3) After acquiring the TAS lock,  $t$  checks the combining conditions. 4) Finally,  $t$  combines waiters' critical sections.

*Phase 1: Busy-waiting phase.* Upon entering the slow path,  $t$  initializes its `qnode` (line 32). Specifically, it sets the `wait` field to `True`, `request` field to `UNPRCSD`, and the `next` pointer to `None`. The combiner notifies a waiter with the `wait` flag and uses the `request` flag to specify whether it executed a waiter's critical section.  $t$  then adds itself to the waiting queue by atomically swapping the `tail` with the `qnode`'s address (line 36). After that,  $t$  checks for any preceding waiters

in the queue. If true,  $t$  joins the queue as a waiter (line 38) and waits for the combiner's notification (lines 39–40); otherwise, it proceeds to phase 2. While in the queue,  $t$  busy-waits for the combiner to execute its critical section. After reaching the end of  $t$ 's critical section, the combiner pushes the first instruction after the unlock API (line 107) on  $t$ 's main stack. It then marks  $t$ 's request as complete (*i.e.*, `PRCSD`) (line 28), which switches to its main context and begins the non-critical section (line 107). If, however,  $t$ 's request is not completed,  $t$  reaches the head of the queue and moves to phase 2.

*Phase 2: Global lock acquisition phase.*  $t$  now tries to acquire the TAS (global) lock using the CAS operation (lines 46–50).

*Phase 3: Combining-role decision phase.* After acquiring the global lock,  $t$  checks whether it can be a combiner (lines 52–56). If  $t$  is the only one in the queue, it resets the queue tail, (lines 52–53), switches to its main stack (line 28), executes its critical section, and releases the lock. Otherwise,  $t$  checks if there are at least two waiters in the queue. If true,  $t$  proceeds to phase 4 as a combiner. Otherwise,  $t$  passes the combining role to the next waiter (lines 58–60) by setting the `wait` bit to false, and releases the lock after executing its critical section.

*Phase 4: Combining phase.*  $t$  begins the combining phase by disabling the fast path, thereby forcing new waiters to join the queue (line 63).  $t$  iterates over the queue to execute each waiter's critical section (lines 65–75). Within the loop,  $t$  selects the next waiter (4a line 67), and records the waiter's information (`qnode`) in its thread-local combiner struct (`cst`) to later use it for resuming the combining process. Then  $t$  switches from its ephemeral stack to the waiter's main stack, and executes the waiter's critical section (4b line 70). Once finished,  $t$  notifies the waiter by first setting the `request` flag to `PRCSD` and resetting the `wait` flag (4c line 72).  $t$  continuously iterates until it reaches the combining threshold or cannot find two subsequent waiters in the queue (4d lines 73–75). After exiting the loop,  $t$  ends the combining phase by changing the locking mode to the non-combining mode (line 77).  $t$  then notifies the next waiter to be the head of the queue (line 78), and finally executes its critical section.

During the unlock phase,  $t$  can be in one of the two states: `G_LOCKED`:  $t$  unlocks the TAS lock by resetting its value and returns (lines 92–94). `G_LOCKED_COMBINER`:  $t$  does not release the TAS lock. It context switches from a waiter to the combiner by switching from the waiter's main stack to the combiner's ephemeral stack (lines 98) After switching,  $t$  resumes the combining loop and notifies the waiter about the completion of the critical section (line 72).

### 3.3 Proof Sketch of Correctness

**Mutual exclusion.**  $\text{TCLock}$  ensures mutual exclusion by maintaining two invariants: First, only one thread can hold the global TAS lock, which can also be a combiner; Second, the main stack of a thread is active on only one thread at any time.  $\text{TCLock}$  piggybacks on the mutual exclusion property

```

1  PRCSDB = 0 # Waiter's request is processed by the combiner
2  UNPRCSDB = 1 # Waiter's request is not processed until now
3  G_UNLOCK = 0, G_LOCKED = 1 # TAS known states
4  G_LOCKED_COMBINER = 2 # State to mark combining phase
5  WAITERS_TO_COMBINE = 1024 # Combining batch count
6
7  class thread_local_combiner_struct:

83         return qnode.next
84
85     def notify_next_queue_head(qnode):
86         qnode.wait = False
87
88     def notify_waiter(qnode):
89         qnode.request = PRCSDB
90         qnode.wait = False
91
92     def spin_unlock(lock):
93         if lock.glock == G_LOCKED:
94             lock.glock = G_UNLOCK # Only true for no combining phase
95             return
96         # Jump back to combiner
97         cst = this_cpu_comb_struct()
98         # Waiter's stack → combiner's ephemeral stack
99         switch_stack_from_waiter_to_combiner(cst.qcurr, cst)
100        return

```

**Listing 1:** Pseudocode of TLock along with the algorithm flow. In the bottom figure, Shade of the boxes show which stack is currently active and the numbers ①–⑤ shows stack switching locations in the algorithm. At each of these locations, following return addresses are present on the outgoing stack: ① Outgoing: Waiters’ main stack → line 23. ② Outgoing: Combiner’s ephemeral stack → line 71. ③ Outgoing: Waiter’s main stack → line 99. ④ and ⑤ Outgoing: waiter’s and combiner’s ephemeral stack → contents are discarded.

of the TAS lock as it uses atomic compare-and-swap (CAS) to guarantee thread exclusivity. Hence, thanks to the TAS lock, only one thread can hold the global lock at any given point and only one thread can access shared data at a time. Finally, our transparent delegation invariants ensure that a waiter never touches its own main stack while waiting for a combiner’s notification. Moreover, TLock ensures that

the switch from the waiter’s main stack to the combiner’s ephemeral stack (line 98) occurs at the end of the critical section, i.e., at the end of the unlock function. Thus, after the waiter restores its context from the main stack (line 28), it never enters its critical section.

**Correct thread state.** TLock preserves the correct waiter’s state using a lightweight context switch mechanism

and avoids concurrent stack modification. Specifically, a waiter yields ownership of its main stack (line 26) before joining the waiting queue (line 36). Thus, a combiner thread can only obtain the ownership of a waiter thread's main stack after the waiter gives up the ownership. Finally, the combiner thread concedes its ownership of the waiter's main stack (line 98) before notifying the waiter (line 72). Therefore, our approach ensures that when a waiter reacquires the ownership of its main stack (line 28), the combiner is not using that stack.

### 3.4 Blocking Lock: $\text{TCLock}^B$

$\text{TCLock}^B$  follows a similar design philosophy of the blocking  $\text{SHFLock}$ , where waiters use the spin-then-park strategy. In this approach, a waiter spins locally until its time quota expires. Upon expiration, it schedules itself out if the system is oversubscribed; otherwise, it yields to the scheduler, which eventually reschedules the waiter. In addition, the lock queue maintains both active and passive waiters.

We design  $\text{TCLock}^B$  by augmenting  $\text{TCLock}^{SP}$  to support the parking/wakeup policy. We extend the combiner's role, which now wakes up sleeping waiters while executing their critical sections. The use of an ephemeral stack becomes critical for  $\text{TCLock}^B$  because parking of waiters requires calling a function, which pushes the function frame on the waiter's stack. Hence,  $\text{TCLock}^B$  uses the thread-local ephemeral stack to prevent concurrent accesses. The stack switching protocol remains the same as in  $\text{TCLock}^{SP}$ . To enable efficient parking and wakeup, we add two new states to the request field of the  $qnode$ : `PARKED`, in which a waiter is scheduled out, and `PRCSING`, which indicates that the combiner has started executing a waiter's critical section.

In the slow-path phase, while spinning locally (*i.e.*, phase 1), a waiter  $t$  checks if its time quota is up. If so,  $t$  attempts to park itself out. Specifically,  $t$  tries to change its request field from `UNPRCSD` to `PARKED` atomically. If successful,  $t$  parks itself out; otherwise, it continues spinning as the combiner has changed  $t$ 's state. In phase 4c, while selecting the next head of the queue (`notify_next_queue_head()`), the combiner atomically swaps  $t$ 's state to `PRCSING` to prevent the waiter from going to sleep. Furthermore, after executing the critical section, the combiner atomically swaps  $t$ 's state to `PRCSD`. In both cases, the combiner checks the old state of the request field. If it is `PARKED`, the combiner wakes up  $t$ . We use atomic instructions for changing the state to prevent the lost wakeup problem.

### 3.5 Readers-writer Version: $\text{TCLock}^{RW}$

$\text{TCLock}^{RW}$  is a combining-aware readers-writer lock that allows readers to execute in parallel, while writers are combined.  $\text{TCLock}$  uses a phase-based mechanism [35, 36] that alternates between readers and combined writers.  $\text{TCLock}^{RW}$  comprises the following: 1) A counter that includes the reader count (`RCNT`), writer present byte (`WP`) to indicate if a writer is holding the lock, and writer waiting

```

1 RCNT = 1 << 16; WW = 0x100; WP = 0x1;
2 WCOMBINER = G_LOCKED_COMBINER
3 class rwlock: (32 byte lock)
4   # rwcounter → [RCNT: 17-63; WW: 8-16; WP: 0-7]
5   rwcounter = 0 # 8-byte readers-writer rwcounter
6   tail = None # Writers enqueue in this queue
7   wlock: mutex # Coordinate bw readers & first writer
8
9 def down_read(rwlock): # Acquire read lock
10  atomic_inc(&rwlock.rwcounter, RCNT) # Increment reader count
11  if !(rwlock.rwcounter & 0xffff): # Check the first two bytes
12    return # Lock acquired, if writer not present or waiting
13  atomic_dec(&rwlock.rwcounter, RCNT) # Decrement reader count
14  read_lock_slowpath(rwlock) # execute read slowpath
15
16 def read_lock_slowpath(rwlock):
17  mutex_lock(&rwlock.wlock) # Acquire mutex
18  atomic_inc(&rwlock.rwcounter, RCNT) # Increment reader count
19  while (rwlock.rwcounter & 0xffff) > 0: # Check first two bytes
20    continue # Wait for writer to finish
21  mutex_unlock(&rwlock.wlock) # Release the mutex
22
23 def up_read(rwlock): # Release read lock
24  atomic_dec(&rwlock.rwcounter, RCNT) # Decrease reader count
25
26 def down_write(rwlock): # Acquire write lock
27  # The writer tries to set the WP byte (as 1)
28  if CAS(&rwlock.rwcounter, 0, WP) == 0:
29    return # Writer fastpath
30
31  # Switch to the ephemeral stack and acquire lock in slowpath.
32  cst = this_cpu_comb_struct() # Get the per-CPU comb struct
33  switch_stack(rwlock, cst)
34  return
35 def lock_slowpath(lock, cst): # Write lock slowpath
36  ...
37  - # Waiter → queue's head; get the TAS lock
38  - while True: # Wait for the glock to be unlocked
39  -   while lock.glock != G_UNLOCK:
40  -     continue
41  -   if CAS(&lock.glock, G_UNLOCK, G_LOCKED) == G_UNLOCK:
42  -     break # Got the TAS lock
43
44  + # Replace spinning on glock with rwcounter
45  + mutex_lock(&lock.wlock) # Acquire mutex
46  + if CAS(&lock.rwcounter, 0, WP) == 0:
47  +   goto unlock # Success if no readers are present.
48
49  + atomic_inc(&lock.rwcounter, WW) # Indicate writer waiting
50  + while True: # Spin until all readers finish CS
51  +   if CAS(&lock.rwcounter, WW, WP) == WW:
52  +     break
53  +   unlock:
54  +   mutex_unlock(&lock.wlock) # Release mutex
55  +   # MCS unlock phase
56  +   ...
57
58  - # Now, qnext is the combiner, indicated by glock word
59  - lock.glock = G_LOCKED_COMBINER
60  + # Now, qnext is the combiner, indicated by rwcounter word
61  + lock.rwcounter = WCOMBINER
62
63  - # Combiner phase is over, now combiner will run its CS
64  - lock.glock = G_LOCKED # Reset TAS lock to normal lock
65  + lock.rwcounter = WP
66
67 def up_writer(rwlock): # Release write lock
68  + if rwlock.rwcounter == WP:
69    rwlock.rwcounter = 0
70  ...

```

Listing 2: Pseudo-code for  $\text{TCLock}^{RW}$ .

byte (`WW`) indicating a writer waiting to acquire the lock. 2) A writer queue (`tail`) for combining and parking waiting writers. This queue is similar to our  $\text{TCLock}^B$ 's queue. 3) A

mutex, called `wlock`, that synchronizes the phase between readers and the head of the writers queue. Hence, `wlock` handles the parking of readers and the head of the write queue. We use the `ShflLockB` algorithm [52]—a traditional NUMA-aware queue-based mutex—for `wlock` than `TCLockB` because maintaining a centralized count of readers (shared data) contradicts the design of combining that tries to localize the access to the shared data.

**Algorithm.** Listing 2 shows the necessary changes to `TCLockSP`. A reader first atomically increments `RCNT` and executes its critical section if no writer is present (lines 10–11). Otherwise, it decreases the `RCNT` (line 13), and enters the slow-path phase. The reader first acquires `wlock` (line 17), it then increments the `RCNT` (line 18) to mark that a reader phase should begin soon, and waits for existing writers to exit (line 20). Finally, it unlocks `wlock` (line 21) and executes its critical section. In the unlock phase, a reader releases the lock by atomically decreasing `RCNT` (line 24).

A writer enters the critical section if it successfully switches `WP` from 0 to 1 (line 28). Otherwise, it switches to the ephemeral stack and begins the slow path phase (line 33). This slow path follows the same protocol as `TCLockSP` except that the head of the waiting queue (line 44) acquires the `wlock` (line 45). After acquiring `wlock`, the writer tries to enter the critical section by atomically setting the value to `WP` (line 46). On failure, it sets the `WW` byte to 1 to prevent new readers from entering the critical section (line 49) and waits for other readers to leave. Once they leave, the writer atomically modifies the `rwcounter` from `WW` to `WP` (line 50–52), releases `wlock`, and starts the combining process. In the unlock phase, a writer resets the `rwcounter` to 0 if the value is `WP`.

### 3.6 Optimizations

We propose three key optimizations to minimize further the data movement between the combiner and a waiter, and the cache-line bouncing of the lock word.

#### 3.6.1 Direct stack switching: waiter → waiter

In the current `TCLockSP` version (§3.2), the combiner switches stack twice before executing the next waiter’s critical section. Specifically, it first switches to its own context, finds the next waiter to combine, and then switches to the next waiter’s context. To avoid the switch to the combiner’s context, we split the combining loop. In particular, after switching the stack to a waiter’s context, the combiner tries to select the next waiter to combine after the current waiter (4a), and notifies the previous waiter that its critical section execution is over (4c). The combiner then exits the lock function call and executes the critical section of the current waiter. After executing the critical section, *i.e.*, in the unlock phase of the current waiter, the combiner checks the combining loop conditions (4d). If the condition holds, the combiner directly switches to the next waiter’s context (4b).

Otherwise, it marks the end of the combining phase, switches back to its context, notifies the previous waiter, and finally executes its own critical section.

#### 3.6.2 Minimizing context switch overhead

Our combining approach suffers from saving, transferring, and restoring a thread’s contexts while executing the critical section. We leverage both compiler and hardware techniques to minimize extra latency incurred inside the critical section.

**Leveraging function’s caller-callee convention.** Our basic context-switch algorithm saves, transfers, and restores all CPU-specific registers. We minimize this overhead by leveraging the function calling convention. Specifically, we explicitly make the slow-path of lock acquisition as a function to prevent compiler inlining. This has two benefits: First, this phase is triggered only in the case of contention, as in the uncontended case, the thread acquires the TAS lock. This approach is similar to the Linux spinlock implementation [41]. Second, we leverage the function calling convention. In particular, we save, transfer, and restore only the callee-saved registers, while the compiler saves and restores the necessary caller-saved registers [3]. The compiler, using its register liveness information, knows exactly which caller-saved registers are in use when the slow-path function is called, and spills only those registers to the stack. Moreover, the number of callee-saved registers is small [1, 8, 10]. For example, with `x86_64`, there are only six callee-saved registers compared with 16 general-purpose registers. Thus, the combiner only transfers at most one cache line to encapsulate any critical section of arbitrary length.

**Prefetching thread-local data.** Accessing thread-local data within the critical section requires moving the waiter’s specific code and data residing on its CPU to the combiner’s CPU. Unfortunately, this movement extends the length of the critical section. We find that most of the local data resides on the stack due to aggressive compiler optimizations that a thread either accesses or modifies in the critical section. Thus, we prefetch contiguous cache lines from the top of the stack<sup>2</sup> to minimize the critical section latency. The combiner issues the prefetch requests before executing the current waiter’s critical section. Traditional lock designs cannot adopt this approach because, unlike the combining approach, the lock holder already has access to its local data. Meanwhile, shared data cache lines are always going to move to the CPU holding the lock, and their movement is only possible at the end of the critical section.

#### 3.6.3 NUMA awareness

Similar to `SHFLock`, `TCLock` can adopt different policies to choose the next waiter (`select_next_waiter()` in §3.2). `TCLock` currently employs a NUMA-aware policy that minimizes cache-line bouncing among NUMA nodes. In particular, the combiner only executes critical sections of waiters

<sup>2</sup>We prefetch data in the write mode using the `prefetchw` instruction.

belonging to the same NUMA node. Upon reaching the combining limit, the combiner passes the role to a waiter residing on another NUMA node. TLock adopts the dynamic queue-splitting approach from the CNA algorithm. Specifically, TLock maintains a combiner-local waiting queue for remote NUMA node waiters and uses the primary queue for local NUMA node waiters. Initially, all waiters join the primary queue (same as before), and the selection of the next waiter happens as follows: The combiner tries to find the next waiter from the same socket. If it succeeds, it executes that waiter's critical section; otherwise, it adds the remote waiter's node to its local queue. While passing the role, the combiner first enqueues the local queue waiters at the beginning of the primary queue and then passes the combining role to the primary queue head.

## 4 TLocks with Real-World Applications

Although TLocks offer a compelling case to minimize overall shared data movement, applying them to real-world applications introduces two major challenges. The first challenge involves fine-grained locking, which requires support for multi-level locking [4, 20, 28] and out-of-order unlocking [12, 13]. The second challenge stems within the OS kernel, such as Linux, in which locks can be acquired within special execution contexts, which guarantees stability about per-CPU variables while executing within these contexts. We now discuss our approaches to overcoming these challenges in the context of the Linux kernel.

### 4.1 Multi-level Locking

Multi-level locking leads to two notable usage patterns that require additional effort to design and implement correctly in the context of combining. First, a combiner thread can be a waiter while executing a nested lock (henceforth called *waiter-combiner*). Second, locks can be released in arbitrary order leading to out-of-order unlocking. Although out-of-order unlocking does not affect traditional locks, TLock requires extra care in handling such cases, as it can lead to data corruption as well as deadlocks. We now present our approach to supporting these usage patterns.

**Nested combining.** For handling nested combining, TLock adopts the same interrupt processing mechanism by OSes. Interrupt handlers, before processing the interrupt, push the current thread state on the stack. When the interrupt handler finishes, it restores the thread's state from the stack. This allows for handling nested interrupts without affecting the execution of the interrupted thread. There are three cases that occur when TLocks interplay in the context of nested locking: First is the case of nested locks when both locks are in their combining phase. The second one is when the outer level lock is a combiner and the inner one is the fast-path TAS lock. Finally, the third case is the opposite of the second scenario.

Listing 3 shows the changes required to implement the first case, which works similar to the interrupt processing

```

1 + G_UNLOCKED_000 = 4
2 # Extra state to handle out-of-order unlocking
3
4 def switch_stack(lock, cst):
5     switch_to_ephemeral_stack(cst.node) # Main → ephemeral
6 - lock_slowpath(lock, cst)
7 + ret_val = lock_slowpath(lock, cst)
8 + if ret_val == G_UNLOCKED_000: # Only for nested combiner
9 +     switch_to_combiner_previous_stack_frame()
10 + else:
11 +     switch_from_ephemeral_stack(cst.node) # Ephemeral→main
12
13 def lock_slowpath(lock, cst):
14     ...
15     if qprev is not None: # Waiters are in the queue
16         ...
17         if qnode.request == PRCSO : # Waiter rqst is processed
18 +         if lock.glock == G_UNLOCKED_000: # 000 unlock
19 +             return G_UNLOCKED_000
20             return 0 # Combiner executed my CS
21         ...
22
23     # For handling nested combining
24 + save_on_curr_stack_frame(lock.glock, cst.qcurr, qnode.rsp)
25
26     lock.glock = G_LOCKED_COMBINER
27 + j = find_first_empty_index(cst.lock_addr)
28 + cst.lock_addr[j] = lock # Record the current lock address
29     # Combiner loop ...
30     # Combiner phase is over, now combiner will run its CS
31 + cst.lock_addr[j] = None # Remove the current lock address
32
33     # For handling nested combining
34 + restore_from_curr_stack_frame(lock.glock,
35 +                               cst.qcurr, qnode.rsp)
36     notify_next_queue_head(qnext) # Next waiter is the combiner
37
38 def spin_unlock(lock):
39     if lock.glock == G_LOCKED:
40         lock.glock = G_UNLOCK # Only true for no combining phase
41         return
42 + max_idx = find_last_not_empty_index(cst.lock_addr)
43 + my_idx = find_my_lock_index(cst.lock_addr, lock)
44 + if my_idx < max_idx : # Acquire order != release order
45 +     lock.glock = G_UNLOCKED_000
46 +     return
47     # Jump back to combiner
48     cst = this_cpu_komb_struct()
49     # Waiter's stack → combiner's ephemeral stack
50     switch_stack_from_waiter_to_combiner(cst.qcurr, cst)
51     return

```

Listing 3: Out-of-order (OOO) unlocking protocol.

approach. Specifically, a combiner may acquire a nested lock inside the critical section. Before acquiring that lock, the combiner pushes its state onto its ephemeral stack (line 24), which it restores after releasing that nested lock (line 35). This allows TLocks to handle arbitrary levels of nesting without violating application correctness.

TLocks also supports the last two scenarios, in which one of the locks is in the combining phase. We do not require any additional support for these cases because each lock is independent and the underlying lock mechanism doesn't interact with each other, which is exactly the same in the traditional lock design. Specifically, every lock has its own lock word and its underlying lock mechanism only interacts with its own lock word. Thus, acquiring the lock in the fast-path (TAS lock), does not interact with the lock which is held by the combiner thread.

**Out-of-order (OOO) unlocking.** The algorithms discussed thus far for TLocks incorrectly handle OOO unlocking, leading to wrong program execution. We illustrate this through an example: Suppose multiple threads acquire  $L_A$  and then  $L_B$ , which leads to contention. As a result, the combining phase becomes active, and  $C_A$  and  $C_B$  hold locks  $L_A$  and  $L_B$ , respectively.  $C_A$  becomes a waiter-combiner when it tries to acquire lock  $L_B$ . Now, if  $L_A$  is released before  $L_B$ —unlocked OOO—the combiner  $C_B$  will return to its own combining loop, as the unlock function does not track of the order of unlocked locks. Therefore, the combiner  $C_B$  breaks application semantics by starting to execute the next waiter’s critical section, while the lock  $L_B$  which it holds is not unlocked yet.

To handle OOO unlocking, we rely on a simple insight: we can release a lock at a later point in time without affecting the correctness of the application. Specifically, we do not release  $L_A$ ; we only release it once  $L_B$  has been released. This approach is similar to the handling of nested transactions, in which we effectively flatten the out-of-order lock hierarchy and release all the locks at the same time.

Listing 3 shows the changes required to TLocks for handling OOO unlocking. We make three specific changes in the lock and unlock function of TLocks:

- To identify OOO unlocks, we maintain a per-thread `lock_addr` array to record the acquisition order of locks. Before starting the combining loop, a combiner stores its lock’s address in the `lock_addr` array (line 28), and removes it once the combiner loop finishes (line 31).
- In the unlock function, the combiner checks if the lock that is being unlocked is the last entry in the `lock_addr` array. This is because the last entry in the `lock_addr` array is the lock holding which the current combiner is executing the critical section. We have two cases now: The first one is the non-OOO case (line 47): The combiner follows the original algorithm and returns to the combiner’s ephemeral stack (line 50) and continues with its combiner loop. While the second one is an OOO case (line 44): We simply mark the lock as *OOO-unlocked* (line 45) and let the current combiner continue executing until the unlock function for its lock is called. The waiter-combiner for the OOO-unlocked lock waits for the notification from the current combiner which doesn’t happen until the current combiner reaches its combiner loop. Therefore, delayed notification effectively flattens the lock hierarchy for out-of-order unlocked locks as the waiter-combiner cannot progress until it gets the notification.
- After receiving the notification, the waiter-combiner checks if its lock is unlocked OOO (line 18) and if true, it return `G_UNLOCKED_OOO` (line 19). The combiner switches to its previous state (line 9) which was saved when the nested lock was called (line 5). The combiner returns to its combiner loop (line 29), notifies the current waiter and continues combining the next waiter.

The waiter for the outermost lock will get the control back once the outermost lock and all the nested locks are released. The waiter then starts executing its non-critical section.

## 4.2 Special Execution Contexts and Per-CPU Variables

Delegation via transparent combining breaks assumptions of Linux kernel code about the stability of access to per-CPU variables under special execution contexts. This includes interrupt handlers, non-preemptible contexts, non-migratable contexts, etc. This raises a critical question for our design: How do we enable delegation-style locking transparently in the kernel without compromising on correctness?

A potential solution involves the combiner accessing the per-CPU variables of the waiter’s CPU while executing the critical section. For example, on x86, we can save and restore the `gs` registers that allows access to per-CPU variables of the waiter’s CPU [14]. Unfortunately, this approach leads to data races when waiters are busy-waiting, as interrupts on the waiter’s CPU may still access per-CPU variables. Moreover, this approach further leads to additional overhead of accessing per-CPU data of a remote CPU. Besides that, it requires annotating parts of the kernel code that access per-CPU variables for functional correctness, such as scheduler [22], RCU [18], and many more during the combining phase. As a result, these challenges make it very difficult to enable transparent combining in special execution contexts within the kernel.

We adopt a more conservative approach of disabling combining for such execution contexts and falling back to default kernel locking (currently `qspinlock` [41]). We leverage the property that any part of a critical section requiring stable access to per-CPU variables ensures appropriate protection against CPU migration for that region of code. For example, the Linux kernel’s `spinlock_t` APIs do not guarantee stable access to per-CPU variables, as they do not disable preemption for the critical section. This is because the `spinlock_t` type is transparently replaced with a mutex on real time kernels [19]. Hence, the scheduler is allowed to preempt threads and migrate them to a different CPU when they are holding such a lock. To ensure that preemption is disabled within the critical section regardless of the kernel configuration, developers use specific `raw_spinlock_t` APIs [17].

When invoking the TLock APIs, we only enable combining for threads that can migrate from one CPU to another. Otherwise, we disable combining and fallback to the existing traditional lock. We identify these code regions by leveraging well-defined APIs of the Linux kernel. In particular, we enable combining for the following cases: 1) the kernel thread executes in the *task* context [27]; 2) it does not disable *migration* or *preemption* [9, 16], and 3) it does not execute in a context where *HardIRQs* and *SoftIRQs* are disabled [5, 24]. It is safe to execute traditional and combining queue-based lock because mechanism for both types of locks are inde-

pendent and only one of them will be active for a particular instance of lock at any given point.

## 5 Implementation

We implement TLocks in the Linux kernel v5.14.19 and replace all *spinlock*, *mutex*, and *rwsem*. We add 1349, 955, and 1652 LoC for spinlock, mutex, and readers-writer lock (rwsem), respectively. For userspace applications, we use LiTL [50] library. It uses the LD\_PRELOAD mechanism to interpose different POSIX locks used by userspace applications.

We implement TLock for the x86 architecture, but it is easily extensible to other architectures as well. x86-64 has six callee-saved registers: *rbx*, *rbp*, and *r12-r15*. We push these registers on the stack along with the stack pointer on the waiter’s qnode. When the combiner switches to the waiter’s main stack, it uses the stored stack pointer and pops the callee-saved registers from the stack. We mark the stack-switch function as *nonline* and *noipa* to prevent any compiler optimizations and function inlining. Our code is publicly available here: <https://github.com/rs3lab/TLocks>.

## 6 Evaluation

We evaluate TLocks by answering the following questions:

- Q1. How does the kernel-based TLock implementation impact micro-benchmarks (§6.1) and real applications (§6.2)?
- Q2. How does each design decision affect TLocks’ performance (§6.3)?
- Q3. How does the userspace TLock implementation impact an application’s performance (§6.4)?

**Evaluation setup.** We use micro-benchmarks that mostly stress a lock and application benchmarks that stresses various kernel subsystems. In addition, we use a hash-table nano-benchmark [69] to show the effectiveness of TLock design decisions. We evaluate on an 8-socket, 224-core Intel machine with hyper-threading disabled. We use *tmpfs* in all experiments to minimize the file system overhead. We evaluate three traditional locks within the Linux kernel: Linux’s stock locks, CNA, and SHFLLOCK. CNA replaces the stock *qspinlock*, while we replace all locks with SHFLLOCK.

### 6.1 TLock Performance Comparison

We evaluate TLocks using a set of micro-benchmarks [31, 62]. Each micro-benchmark instantiates a set of threads and pins them to cores. These threads mostly contend on a single lock (sometimes two) while performing specific tasks (Table 1) for 30 seconds.

**Spinning TLock.** Figure 3 ((a) and (b)) show that TLock<sup>SP</sup> outperforms the Linux version (Stock) by 3.7× and 4.4× on MRDM and lock1, respectively. TLock performs similarly to Stock from two to eight cores for two reasons. First, the stack switching adds an average of 47 ns latency. Second, the combiner is unable to perform effectively at such a low core count. As a result, TLock does not reach its potential. On the other hand, the benefit of

Lock type	Workload	Lock: Usage
Spinlock	MRDM [62] lock1 [31]	<b>rename seqlock:</b> Rename files within a directory <b>files_struct.file_lock:</b> fd allocation / fcntl
Blocking	MWRM [62]	<b>sb-&gt;s_vfs_rename_mutex:</b> Rename a file across directory <b>dentry-&gt;d_lock:</b> Directory lock
RW Blocking	mmap1 [31]	<b>mm_struct-&gt;mmap_lock:</b> Memory map file within a directory

Table 1: Lock usage in various micro-benchmarks [31, 62].

TLock<sup>SP</sup> is evident after eight cores where the gains from localizing shared data cache lines outweighs the overhead of stack-switch. TLock<sup>SP</sup> combiner on average batches 950 waiter’s request. Thus, even within a socket (up to 28 cores), TLock<sup>SP</sup> maintains consistent throughput.

Compared to NUMA-aware locks, TLock<sup>SP</sup> outperforms SHFLLOCK and CNA by 2-3× across sockets. The combining-based NUMA-aware policy of TLock<sup>SP</sup> minimizes the cache-line bouncing of both the lock word and the shared data. On average, 190K combiners execute during a 30-second run where every TLock<sup>SP</sup> combiner batches ~980 waiter’s request before passing the lock to different NUMA socket. In essence, every combiner is reducing extra coherence traffic for accessing shared data within the waiter’s critical section, which would be generated in a traditional lock design.

**Blocking TLock.** We compare TLock<sup>B</sup> with Linux *mutex* and SHFLLOCK. Figure 3 (c) shows that TLock<sup>B</sup> is 1.8× faster than both *mutex* and the blocking version of SHFLLOCK. Both *Stock* and SHFLLOCK suffer from shared data movement at a high core count. In addition, SHFLLOCK’s performance degrades similarly to that of *Stock* due to its lock stealing, which renders its NUMA-policy ineffective. Whereas, TLock<sup>B</sup> retains performance because it reduces cache-line bouncing for both the lock word and shared data.

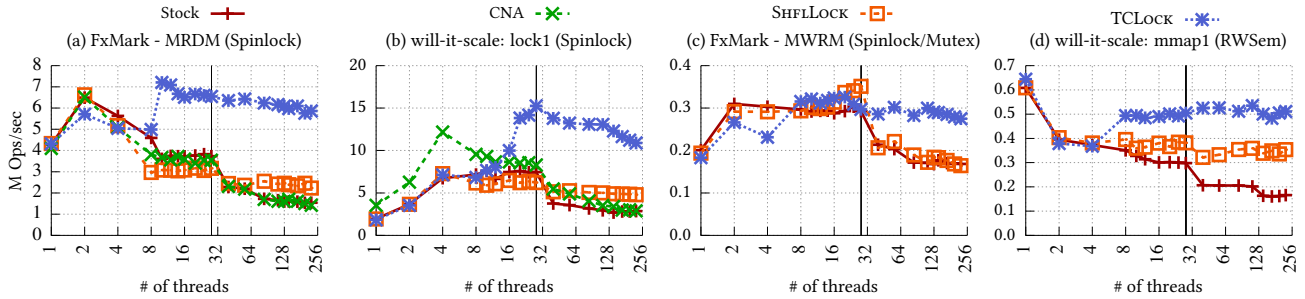

**Readers-Writer Blocking TLock.** Figure 3 (d) shows the impact of TLock when stressing the writer side of *rwsem*. We use the *mmap1* benchmark [31], which populates and deletes VMAs within an address space. TLock maintains the best throughput irrespective of contention after eight cores. Within a socket, TLock<sup>RW</sup> outperforms *Stock* by 1.7×, as a combiner combines ~1000 waiter’s request, thereby minimizing cache-line movement of shared data cache lines. Moreover, across the socket, TLock<sup>RW</sup> combiner batches similar number of waiter’s request resulting in 3.1× and 1.5× better throughput than *Stock* and SHFLLOCK.

### 6.2 Application-level Benchmarks

We evaluate two applications that extensively stress various subsystems of the Linux kernel. Figure 4 reports applications’ throughput. The kernel subsystem uses a mix of blocking locks and spinlocks, which are present in several data structures such as inodes, task structures, and memory mappings.

**Psearchy** is a parallel version of *searchy* that does text indexing. It is *mmap* intensive, which stresses the memory subsystem with multiple userspace threads. It does around 96,000

**Figure 3:** Impact of spinlock, blocking locks and read-write semaphore on the scalability of micro-benchmarks [31, 62].

**Figure 4:** Impact of kernel locks on application scalability.

small and large mmap/munmap operations from 96,000 files with multiple threads. It stresses the writer side of the `rwsem` in the memory subsystem and inode allocation in the file system layer. Figure 4 (a) shows that TLOCK outperforms existing locks up to  $2.2\times$ . Because of its effective combining strategy, TLOCK<sup>RW</sup> is able to localize access to shared data. We find that SHFLLOCK and Stock have similar performance as they inefficiently use up hardware bandwidth. Moreover, we observe that psearchy’s performance drops with increasing core count, which happens due to the contention in the file stream glibc library.

**Metis** is an in-memory map-reduce framework, representing a page-fault-intensive workload that stresses the readers’ side of the `mmap_sem` (`rwsem`) in the Linux kernel. Figure 4 (b) shows that TLOCK outperforms both SHFLLOCK and Stock by  $1.3\times$ . The reason is due to the phase-based design of TLOCK<sup>RW</sup>, which improves the performance by batching the writers in one phase, meanwhile executing readers in parallel in the next phase. Across sockets, it improves performance compared to SHFLLOCK and Stock by  $1.7\times$  and  $1.4\times$  at 140 cores, respectively.

### 6.3 Nano benchmark: RCUHT

We now do an in-depth analysis of TLOCKS using a hash-table benchmark in the kernel [69]. A global lock guards the hash table. For TLOCK<sup>SP</sup> and TLOCK<sup>B</sup>, we generate 100% writes, whereas for TLOCK<sup>RW</sup> (readers-writer blocking lock), we generate 1% and 20% writes on the hash table. Figure 5 presents the results and the factor analysis of TLOCKS.

**Spinning TLOCK.** Figure 5 (a) and (b) shows the throughput and 99.99% latency of spinlocks, respectively. (a) We find that TLOCK<sup>SP</sup> maintains similar performance within and across sockets because of the effective combining pol-

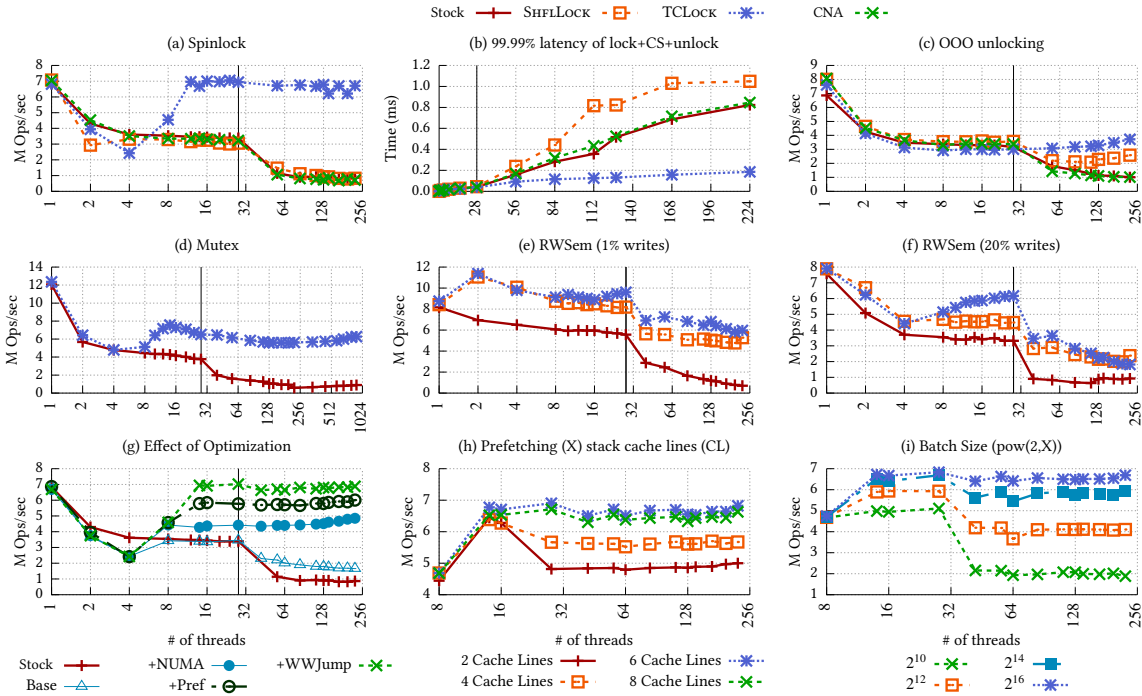

icy. In particular, the combining batches up to 50,000 waiter requests, thereby localizing the requests for that many invocations. In addition, the average and 99%ile latency of the critical section is 188 ns and 474 ns at 28 cores, respectively, whereas both stock and SHFLLOCK have up to  $2.5\times$  and  $2.1\times$  higher average and 99%ile latency, respectively.

In the case of NUMA, TLOCK<sup>SP</sup> outperforms SHFLLOCK and Stock by up to  $9.4\times$ . The improvement occurs because of minimizing cache-line bouncing and Localizing shared data, which reduces the time spent in critical section. For example, at 168 cores, the average latency of TLOCK is 213ns, which is similar to average latency at 28 cores. Whereas SHFLLOCK and Stock have  $10.5\times$  and  $11\times$  higher latency, respectively. The 99%ile latency increases to 1516 ns for TLOCK. This happens because of NUMA-aware moving of the shared data, which increases the 99.9% latency of TLOCK. However, this latency is still  $3\times$  lower than that of SHFLLOCK.

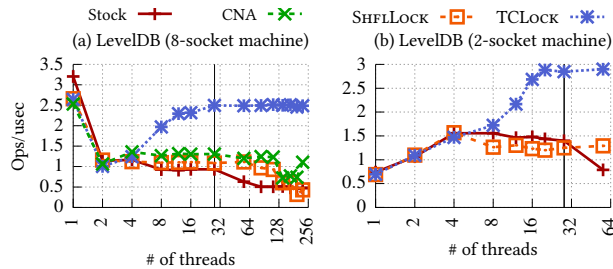

Figure 5 (b) shows the combined latency for the lock function, critical section execution, and the unlock function. TLOCK<sup>SP</sup>, even with batching 50,000 waiters, has up to  $5.6\times$  and  $4.4\times$  lower latency compared to SHFLLOCK and Stock, respectively. This is because of lower critical section latency, which reduces the overall latency of the whole system as the critical sections are executed sequentially.

**Nested Locking and OOO unlocking.** We evaluate the impact of our OOO unlocking with a hash-table nano-benchmark that acquires nested lock and can release locks in an OOO manner. Specifically, every bucket has a lock and nested locks are acquired when moving an entry from one bucket to another. Figure 5 (c) shows that, within a socket, TLOCK<sup>SP</sup> performs similar to other locks. At 28 cores, TLOCK<sup>SP</sup> is 5% slower than Stock. This is because the overhead of saving/restoring the combiner state with nested lock along with delaying the unlock degrades TLOCK<sup>SP</sup> performance within a socket. Across socket, TLOCK<sup>SP</sup> outperforms Stock by up to  $3.7\times$ . The performance gains with localization of shared cache lines outweighs the overhead of TLOCK<sup>SP</sup> implementation of nested locking.

**Blocking TLOCK.** Figure 5 (d) shows the throughput with blocking locks. TLOCK<sup>B</sup> outperforms stock in both under-subscribed and over-subscribed scenarios. With the help of its efficient spin-then-park strategy, TLOCK<sup>B</sup> outperforms Stock by up to  $9.5\times$  in under-subscribed scenarios. More-

**Figure 5:** (a – f) Impact of spinning, blocking and read-write lock on the hash-table nano benchmark with an eight-socket Intel machine. (b) Latency of executing lock function+CS+unlock function with different spinlocks. (c) Performance with nested locking and OOO unlocking. (g) Impact of different optimization introduced in  $\text{TCLock}^{SP}$ . On top of baseline, we add NUMA-awareness, stack prefetching, and waiter-to-waiter jump. (h – i) Impact of prefetching and batch size on  $\text{TCLock}^{SP}$ 's performance.

**Figure 6:** Impact of locks on userspace applications.

over,  $\text{TCLock}^B$  maintains the same performance even after crossing the socket boundary. Although latency to wake up a waiter on a remote socket costs more than that of the local socket,  $\text{TCLock}^B$ 's usage of NUMA-aware design amortizes the overhead of waking up waiters from other socket.

**Reader-writer  $\text{TCLock}$ .** Figure 5 ((e) and (f)) show that the  $\text{TCLock}^{RW}$  has higher throughput than the stock version by 6.8 $\times$  and 2.2 $\times$  for 1% and 20% writes, respectively.  $\text{SHFLock}$  and  $\text{TCLock}^{RW}$  use similar design for readers. Because of using the phase-based design,  $\text{TCLock}^{RW}$  is able to improve performance by up to 1.28 $\times$  and 1.37 $\times$  at 1% and 20% writes, respectively. We further observe that combining is not effective with centralized readers counting, as the readers counter cache line is always moving across cores.

**$\text{TCLocks}$  optimizations.** Figure 5 (g) shows the effect of

different optimizations used by  $\text{TCLock}^{SP}$ .  $\text{TCLock}^{SP}$  without any optimizations outperforms Stock by 2.2 $\times$  because it localizes the shared data access. The overhead of stack switch is apparent at lower core count because jumping to a waiter's critical section requires access to the stack which needs to be fetched from a waiter's core. On adding NUMA-awareness to the current design, we improve the performance by 2.6 $\times$ , as we now prevent moving the waiter's stack cache line across sockets. It also helps within a socket because checking the socket ID of the next waiter's node fetches the next waiter's node in the combiner's cache. As a result, this simple check reduces the time spent in the combiner loop.

In addition, our stack prefetching approach, on top of NUMA-awareness policy, further improves performance by 1.3 $\times$ , as it reduces the time spent in starting the execution of critical section. Finally, our waiter  $\rightarrow$  waiter jump (WWJump) further improves the throughput by 1.2 $\times$  as it reduces the overhead of stack switch ( $\sim 50$  ns) from two switches to one. Overall, our optimizations reduce the overhead of stack switching and improve performance compared to the baseline by 4 $\times$ .

**$\text{TCLocks}$  sensitivity.** Figure 5 ((h)–(i)) shows the impact of changing the number of prefetched cache lines and the number of waiter's combined. Figure 5 (h) shows that prefetching up to six cache lines provides the best performance for this

benchmark. It depends entirely on what is accessed inside the critical section. We can write a compiler pass to tune this parameter, as the compiler has the information on what is accessed within the critical section. Figure 5 (i) shows the impact of batching. Higher batch count improves throughput at the expense of short-term fairness, but TLocks maintain long-term fairness. Batching is also able to reduce the latency for all requests, if it can reduce the time spent per request as shown in Figure 5(e).

#### 6.4 Performance With Userspace TLock

We evaluate TLocks on the LevelDB benchmark [49]. We integrate both TLock, CNA and SHFLock into LiTL [50] for evaluation. LevelDB is an open-source key-value store [48]. We use the readrandom benchmark with 1M key-value pairs, that contends on the global database lock. Figure 6 (a) shows the performance with spinlocks on an 8-socket machine. Within a socket, TLock<sup>SP</sup> improves throughput compared to other locks by  $1.9\times$ – $2.6\times$ . Localizing shared data movement helps to achieve better performance than traditional locks. Across sockets, NUMA-awareness coupled with minimal shared data movement helps TLock<sup>SP</sup> outperform other locks by up to  $5.2\times$ . Figure 6 (b) shows the performance on a 2-socket machine. TLock<sup>SP</sup> performs similar to the 8-socket machine and improves throughput compared to other locks by  $2.1\times$ – $3.6\times$ .

### 7 Discussion and Limitations

TLocks implement transparent delegation, which enables developers to use delegation-style locking without rewriting the application. However, TLocks have limitations both in terms of algorithm design and kernel implementation. We discuss them below.

**Overhead at two–four cores.** We observe overhead with TLocks when very few threads (two–four) contend for a lock. Contending threads execute slowpath after stack-switching, but combining is only enabled when more than two waiters are present in the queue. Waiters pay the cost of two stack-switching but their critical section is not executed by the combiner. This can be solved by disabling combining when we have less than four threads in the queue. The challenge lies in efficiently identifying the size of the queue without using extra memory or traversing the queue.

**Resource accounting.** The kernel requires accurate accounting of resources like CPU usage, allocated memory, etc. Kernel subsystems, such as the scheduler or cgroup, are guided by the accounting of resources used by a particular thread. Delegation-based techniques can break this accurate accounting for resources used within the critical section. Thus, TLocks complicate resource accounting. Even though a combiner thread executes the critical section on behalf of other waiter threads, resources like CPU time or allocated memory in the critical section need to be accounted to the waiter thread, for maintaining broader kernel

semantics. We leave this extension as future work.

**TLock vs ‘current’.** Apart from per-CPU variables, Linux also uses a macro named *current*, which resolves to a per-CPU pointer variable to the currently executing thread’s task structure. This pointer is used to access the task structure for multiple purposes, including but not limited to resource accounting with cgroups [21], permission checks using credentials [15], thread scheduling [26], etc. While executing a waiter’s critical section on the combiner’s CPU, if this pointer is not switched to the waiter’s task structure, then it could lead to subtle bugs. For example, if a combiner thread has higher privileges than the waiter thread, and the permission checks are done within the critical section, it may lead to privilege escalation bugs, since the combiner thread’s credentials will be inspected.

One possible solution is to modify *current* macro’s implementation to resolve to the waiter’s task structure while executing waiter’s critical section on combiner CPU. Unfortunately, this will also lead to bugs. For example, if a thread sleeps within its critical section, the scheduler code uses the *current* macro to put the running task to sleep. When combining a waiter’s critical section, we want the combiner thread to sleep. However, if we switch the *current* macro to use the waiter’s task structure, it will lead to confusion within the scheduler as the waiter task is already seen to be running on another CPU.

We currently keep the *current* macro unchanged, and suggest judicious use of the TLock APIs in cases where a different thread identity within the critical section may lead to unexpected behavior.

### 8 Conclusion

Delegation based techniques are known to offer better scalability and provide better performance for highly contended scenarios, but prior work requires application changes to enable delegation. In this paper, we propose a new technique called *transparent delegation* that makes delegation-style locking practical. We design the first-ever transparent delegation based locks, called TLocks, for both userspace applications and the Linux kernel. This is achieved by lightweight context switching and using ephemeral stacks to maintain consistency. Using transparent delegation, we design spinning, blocking and phase-based readers-writer locks. We replace all the locks in the Linux kernel with TLocks, and discuss the technical challenges involved. Our evaluation shows that TLocks provide better performance and scalability compared to traditional lock design.

### 9 Acknowledgment

We thank Changwoo Min for his comments on the initial draft. We also thank Dave Dice, Alex Kogan, the anonymous reviewers, and our shepherd, Geoffrey M. Voelker, for their helpful feedback. This work is supported by the SNSF project grant 212884.

## Abstract

As the number of processor cores increases, the efficiency of accessing shared variables through the lock-unlock method decreases. A NUMA-aware algorithm, which only considers the transmission delay between processors, may not fully utilize the connection network of a multi-core processor. This limits the scalability of a multi-core processor due to the large amount of low- and variable-cost data sharing between cores. The problem is that the reduction in communication cost cannot compensate for the increase in the time complexity of the spinlocks, and the farthest transmission distance becomes longer with more cores.

We propose a method called Routing on Network-on-chip (RON)<sup>1</sup> to minimize the communication cost between cores by using a routing table and pre-calculating an optimized locking-unlocking order. RON delivers locks and data in a one-way circular manner among cores to (1) minimize global data movement cost and (2) achieve bounded waiting time. Microbenchmarks provide quantitative analysis, while multi-core benchmarks show performance under various workloads.

In terms of user space performance, RON improves the performance of Google LevelDB by 22.1% and 24.2% compared to ShflLock and C-BO-MCS, respectively. In the kernel space, RON is 1.8 times faster than using ShflLock for Google LevelDB. RON-plock solves the problem of oversubscription with constant space complexity and achieves 3.7 times and 18.9 times better performance than ShflLock-B and C-BO-MCS-B, respectively.

## 1 Introduction

This paper primarily focuses on addressing the lock-unlock problem under high contention. Despite the significant increase in the number of cores in a *central processing unit* (CPU), a fully shared cache memory system can limit the bandwidth of the cache memory, creating a performance

bottleneck. To overcome this issue, CPUs can maintain private caches, and processors sharing these private caches are referred to as *Cache Coherent Non-uniform Memory Access* (NUMA) processors (abbreviated as ccNUMA).

Spinlocks and atomic operations are provided to ensure the coherency of shared data in the cache, and programs access shared data in *critical sections* (CS) [5, 6]. However, minimizing data access latency is a crucial issue that can significantly impact CPU performance in accessing shared data in ccNUMA [12, 13]. This depends on the topology of the *Network on Chip* (NoC) and the movement of data between caches, which is triggered by tasks executing in the CPU.

When multiple tasks compete to enter a CS, granting the closest task to the one that just released the lock access can reduce data access latency. However, this can still be costly as core-to-core transmission latencies vary in a CPU [14]. Additionally, allowing the core with the shortest transmission latency to enter the CS may lead to adjacent cores having exclusive access, leading to poor throughput [41].

Inter-core communication limits multicore processor scalability [19, 20]. Transmission latency can be fixed or distance-dependent. While monolithic die processors such as Intel Xeon [2] exhibit similar inter-core communication latency, *Multi-Chip-Module* (MCM) processors like AMD EPYC [2] and Apple M1 Pro [2] use MCM technology to increase the number of cores on a processor affordably and at scale. Next-generation Intel Xeons also use MCM [3], but MCM processors may have varying transmission latency between and within chips.

NUMA-aware spinlocks [25–31] enable cores from the same “NUMA node” to enter the CS in batches. This approach is suitable for multi-core processors, such as AMD EPYC, that have different transmission latencies. We can minimize handover costs by dividing the cores in a multi-core processor into mini-nodes, such as the east and west parts shown in Figure 1, and using a NUMA-aware approach to schedule them. However, transferring locks between cores in a mini-node is not considered in these algorithms. A layered approach (e.g., cohort [25]) can address this, but using too many layers

<sup>1</sup>The source codes of RON can be found at <https://github.com/shiwulo/ron-osi2023>.

(e.g., C-TKT-TKT-TKT) can make spinlocks complex and expensive. Modern processors have non-uniform computing power [47], where higher computing power implies a greater ability to acquire locks. Batch-based algorithms often set a “maximal batch size” periodically to prevent starvation and maintain fairness. However, reducing the batch size for fairness can decrease performance. Unfair lock allocation causes unbalanced resource distribution and reduces throughput, as discussed in Section 2.3.

The optimization principle for low-cost communication is similar to that of data routing in computer networks. Although computer networks can use complex algorithms to produce the best route, such methods are often too expensive for small CS in multi-core processors. Therefore, we pre-calculate the shortest circular route including all cores, and the spinlock algorithm generates a path of threads to enter the CS according to the pre-calculated route. The “one-way circular shortest routing” shortens the distance between cores, while the “shortest routing” produces a local optimal solution for handover cost. The “one-way” optimizes handover costs by transferring locks in the direction where more threads are waiting, and the “circular” approach limits the number of times a thread waits to enter the CS. Thus, we schedule tasks on the cores to enter CS in a “one-way circular shortest routing” manner to improve the performance and fairness.

This paper makes three main contributions. Firstly, we propose the simple yet effective concept of “one-way circular shortest routing” to solve the fairness and efficiency issues in spinlocks. Secondly, we identify that long-term fairness alone is insufficient for modern processors, which have cores with varying capabilities to grab locks due to differences in computing frequency. Finally, we provide insights on how single-core spinlocks can work alongside multi-core spinlocks without compromising efficiency and fairness.

In Section 2, we discuss the limitations of NUMA-aware spinlocks in minimizing transmission latency in multi-core processors and the negative impact of unfair spinlocks on throughput. Section 3 presents related work in the field. In Section 4, we propose our fair and efficient spinlock algorithm for ccNUMA. Section 5 addresses performance under oversubscription, while Section 6 compares RON with two well-known algorithms. Section 7 discusses the advantages and disadvantages of RON compared to ShflLock and Linux’s qspinlock, and Section 8 concludes the paper.

## 2 Preliminary and Motivation

### 2.1 Data Coherence in ccNUMA

Figure 1 shows an example of the multi-core architecture, in which the connection network of each core group is similar to the *CPU Complex (CCX)* of Advanced Micro Devices, Inc. (AMD). In a multi-core architecture, data stored in the cache memory can be shared among the cores. *Cache coher-*

*ence non-uniform access (ccNUMA)* uses snoop-based and/or directory-based cache coherence algorithms to maintain consistency of shared data in each cache memory [42]. The snoop method broadcasts messages such as “some shared data has been updated”, whereas the directory-based method allows point-to-point communication between nodes. A node can be a core or a group of adjacent cores.

Figure 1: An example NoC architecture of ccNUMA.

### 2.2 Cost of Spinlocks on Multi-core CPUs

We define the *serializing cost* as the cost of allowing multiple threads to have mutually exclusive access to shared data. Serializing costs are divided into “*contention*” and “*handover*”. The contention cost is the cost for determining the next task that can enter the CS. It depends on the data structure and data access method used by a spinlock. For example, the ticket lock [43] is centralized, while MCS spinlock (or called “MCS” for short) [44] is decentralized. In the ticket lock, all threads continuously monitor a variable of the ticket lock, and this can generate a lot of traffics in the NoC. The contention cost also depends on how the threads are granted to enter the CS. The raw spinlock (e.g., GNU’s `pthread_spin_lock` [46], abbreviated as “*Plock*”) relies on the NoC to determine when the first thread can enter the CS. The MCS spinlock [44] allows each thread to wait on a different variable. Therefore, MCS spinlocks prevent atomic operations from triggering excessive bus traffic.

The handover cost depends on the speed of transferring shared data between the lock-holding thread and the successive thread. Because spinlock is a shared data structure, a smaller handover cost can also slightly reduce the contention cost. As the example in Figure 1 shows, the processor is divided by two parts, i.e., the west and east parts. The two parts are connected through a system bus. The handover cost of using the C-to-C bus only is 1. The handover cost between the core and the system bus is related to the distance between the core and the system bus. B, C, and F are far away from the system bus, so the handover cost is 3, and the handover cost of A, D, and E is 2.

In conventional NUMA-aware spinlocks, the order of entering the CS can be arbitrary, for example,  $A \rightarrow D \rightarrow B \rightarrow C \rightarrow F \rightarrow E$ . Since A, B, C, and D have the same communication cost, they belong to the same group (i.e., mini-node). The same goes for E and F. The handover cost of this order is (A, 1, D, 1, B, 1, C, 3, 3, F, 1, E)=10. This paper proposes to use one-way circular shortest routing to minimize

handover costs. By scheduling the order of entering the CS as  $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow F$ , the handover cost is reduced to (A, 1, B, 1, C, 1, D, 2, 2, E, 1, F)=8. In this example, the one-way circular shortest routing improves the performance by 20% (i.e.,  $\frac{10-8}{10}$ ).

### 2.3 Throughput or Fairness? Take Both !

Various locking techniques have been proposed [39] to improve system throughput in varying levels of contention. Lock algorithms such as Test-And-Set (TAS) [46] and Test-and-Test-and-Set (TTAS) [46] can be used in low-contention systems. Algorithms like *C-BO-MCS* [25] and *Shuffling (ShflLock)* [26] were designed to reduce the handover cost under high contention with hierarchical design or local spinning.

Moreover, the fairness is an issue that needs to be considered to better utilize the protected resources. According to the level of fairness, we define fairness as follows:

1. *Probabilistic fairness*: The chance of each task entering the critical section is the same in probability.

2. *Bounded waiting*: The number of waiting tasks does not exceed a certain multiple of the number of tasks.

Take Test-Test-And-Set (TTAS) [46] as an example. The probability of each thread obtaining a lock on a single core processor system is related to the proportion of the CPU time that the thread can acquire. In such a situation, the TTAS spinlock satisfies probabilistic fairness. Currently, GNU's Pthread library use TTAS spinlock to implement `pthread_spin_lock()`.

A spinlock algorithm is conformed to bounded waiting when it can limit the number of times that other tasks are inserted before a specific task. Ticket lock and MCS [44] are bounded waiting spinlocks. Both of them are based on first-in-first-out (FIFO) mechanism. Although FIFO allows all tasks to enter CS in a fair manner, FIFO also limits the performance of spinlocks on multi-core/NUMA machines. This is because FIFO cannot shorten the data transmission latency.

Most NUMA-aware spinlocks algorithms balance performance and fairness by preventing threads from waiting too long, but some cores may have higher computing power than others due to differences in manufacturing processes [47]. The slight difference in speed will result in the core with the advantage always being able to acquire the lock successfully. Just like in a 100-meter race, the one who gets first place is always Jamaica's Usain Bolt, even though he is only 0.1 seconds faster than the second-place runner. In modern multi-core processors like the AMD 2990WX, some cores have significantly higher lock acquisition capabilities than others. For instance, the lock acquisition capability of cores 0-7 is 20.6 times greater than that of cores 8-31 (refer to Section 6.2.2). As a result, conventional NUMA-aware algorithms may not be able to ensure equal access to the critical section for all threads/cores within a reasonable period.

With joint consideration of both throughput and fairness, we propose a spinlock method that creates one-way circular shortest path and uses this path to minimize the handover cost and ensure bounded waiting time.

### 3 Related Work

While TTAS spinlock [46] is a simple method to implement POSIX spinlocks in GNU (abbreviated as "Plock") and ensures the consistency of shared data, it is unfair because it tends to provide locks to neighboring cores [21]. Unfairness doubles the execution time of a multi-thread program and causes starvation as shown in [41]. It also increases the variability of latency, making it difficult to guarantee the service quality. The non-scalability of Plock is another serious problem. As shown in [22, 23], although most critical sections are short, increasing the number of cores can cause a system to collapse due to non-scalable locks.

Cohort [25] is a software framework that can combine two NUMA-oblivious locks into a scalable NUMA-aware lock. NUMA nodes compete for the global lock, and unless all threads on the NUMA node leave the CS, the NUMA node will not release the lock. Therefore, threads belonging to the same NUMA node are grouped to enter the critical section, reducing handover costs. Shuffle lock [26] and CNA [27] also use grouping to improve performance. Both are suitable for use with a Linux kernel. However, they cannot effectively reduce the latency of data transmission nor avoid unfairness in a multi-core processor. To obtain good performance under the more complex NUMA architecture, HMCS [28] is based on the concept of Cohort [25] and changes the number of lock levels from 2 to 4. The AHMCS [29] and CLoF [48] algorithms include a mechanism for managing contention and multiple locking methods, allowing different locking methods to be used in different situations. CST-semaphore and CST-mutex locks are applicable to NUMA that support parking [31].

Only dedicated threads or the threads currently holding the lock can execute the code of the CSs of each thread in [32]. In [33], the researchers further proposed turning CSs into an asynchronous execution. Although these methods can optimize data access latency to global data, they take longer to access local data because the code of a CS executes on a specific core.

Programmers can optimize software to better utilize the NoC of ccNUMA when the software uses data-level parallelization and pipe-lining [7, 34, 37, 38]. Stefan Kaestle et al proposed broadcast trees [4] to reduce the communication cost of NUMA machines. However, for multi-threaded programs that use locking mechanisms to protect shared data, these methods may not be suitable.

### 4 Routing On Network-on-Chip (RON)

In Section 4, we introduced RON, a NUMA-aware algorithm that is specifically designed for highly competitive and multi-core environments. In Section 5, we combined RON with simple spin locks, such as plock or ticket lock, to achieve scalability when the number of threads exceeds the number of cores. As most applications typically have more threads than cores, we utilized the RON-plock combination algorithm in our application-level benchmarks.

## 4.1 The Idea

In this section, we propose a design called *Routing On Network-on-Chip* (RON) that aims to minimize the handover cost between cores with low contention cost while ensuring fairness in scheduling the threads waiting to enter a CS. Minimizing handover costs can also improve the efficiency of atomic operations, which are based on atomic operations, which rely on cache coherence protocols (such as snoop+dictionary) on multi-core systems. This, in turn, can improve the performance of locks that suffer from contention.

We propose a concept of reducing the total handover cost by scheduling threads waiting to enter the CS in a specific order. This order can be compared to a train passing through all stations. The ownership of the lock is like the train, and each core is like a station. All waiting threads acquire the lock ownership in order, reducing the total handover cost. Engineers optimize train tracks to pass through all stations in the most efficient way possible, even though the route from station A to station B may not be the shortest. Please note that the train track is a *one-way circular route*. Similarly, we define a global schedule for all cores with waiting threads in the system based on the minimum total handover costs, instead of determining the scheduling order using handover costs alone. One-Way Circular Routing can often achieve global optimization. By minimizing total handover costs, we can also improve the efficiency of atomic operations, thereby improving the performance of locks that suffer from contention.

Since the code of spinlocks cannot be too complicated, it is impractical to dynamically calculate the priority of threads waiting to enter the CS. We assume that there is a thread on each core waiting to enter the CS, and then pre-calculate an optimal lock transfer path. The pre-calculate lock transfer path called the *Traveling Salesman Problem Order* (TSP ORDER) of the cores with an efficient TSP algorithm [40]. For the same processor model, the TSP ORDER is the same. RON follows the TSP ORDER to let threads that want to access shared data enter the CS one by one.

To find the TSP ORDER for a multi-core processor, we created a benchmark program to calculate the transmission latency between cores (see Section 6.2.1). Using this information, we built a fully connected weighted graph of cores and solved the TSP problem with a widely-used algorithm [40]. This allowed us to obtain the TSP ORDER that passes through all cores in the graph, which we use for lock ownership trans-

fer to reduce the handover cost with low contention cost.

## 4.2 The Algorithm

Algorithm 1 presents the RON procedure for one spinlock. We use an array-based method and assume that each core has at most one thread. This method can achieve higher performance under high load compared to using a linked list (similar to MCS [44]). For each spinlock, the array-based RON not only has a “wait flag” for each core, but also places wait flags of adjacent cores, so as to increase the cache efficiency. The data structure of RON is similar to queue spinlock [24] and Linux’s qspinlock with constant space complexity. However, queue spinlock [24] cannot handle the situation in which there are more threads than cores (i.e., oversubscription). In the case of oversubscription, Linux’s qspinlock does not support all tasks to enter CS in the FIFO order to guarantee bounded waiting. Note that we will introduce how to support oversubscription based on an array-based RON in Section 5. It should be noted that RON is a heuristic algorithm and can provide decent solutions but cannot guarantee optimal solutions. The worst case of RON occurs in low contention scenarios where multiple cores access the same memory locations. To mitigate this issue, cache prefetching can be used to predict and fetch the data, reducing the number of cache misses and improving performance.

The first four lines of Algorithm 1 define the variables:

- `NUM_core`: This variable indicates the total number of cores on the system. It is a *system-scope variable*.
- `TSP_ID_ARRAY[]`: This array stores the mapping of each core ID to its corresponding “TSP ORDER ID” (i.e., `TSP_ID`), where `TSP_ID` is the lock transfer order of a core. When a lock is transferred to a core, the thread on this core can be checked to see whether it can enter the CS. This is a *per-process variable*, and each process can have its own routing path (TSP ORDER) because each process owns a different number of cores and can have a different TSP ORDER
- `TSP_ID`: This is the “TSP ORDER ID” of a core, and each thread has its “local version” of `TSP_ID`. Thus, each thread on a different core will get a different value when it accesses the `TSP_ID`. This is a *per-thread variable*. We used “thread\_local”, a C11 keyword of C language, to declare per-thread variable in Algorithm 1 (Line 2).
- `InUse`: If this is “false”, there is no thread in the CS. This is a *per-lock variable*.
- `WaitArray[]`: This array is to indicate which cores’ threads are waiting to enter the CS protected by this lock. When a thread wants to enter a CS, its corresponding `WaitArray[TSP_ID]` is set to 1. When the other threads set their corresponding flag in `WaitArray[]` to

0, the thread can enter the CS. *This is a per-lock array.* In Section 7, we will provide an algorithm for sharing `WaitArray[]` between different locks.

In Algorithm 1, Lines 3 and 5–8 initialize the variables. Line 5 uses `getcpu()` to get the core ID of the running thread, and uses the core ID to get the TSP ID of the core by looking up the `TSP_ID_Array[]`. The `spin_lock()` in Line 10 informs other threads that the caller thread wants to enter the CS. When no other thread is in the CS, the caller thread can enter the CS (Lines 14-16). Otherwise, it waits for the previous thread in the TSP ORDER to leave the CS (Lines 12-13). Because “checking whether there is no thread in CS (lines 19-21)” and “setting `InUse` (line 22)” cannot be executed atomically, it is necessary to simultaneously check `InUse` and `waitArray[TSP_ID]` in a while loop. Additionally, Line 14’s `cmp_xchg()` uses TTAS, a technique commonly used in spinlock implementation to reduce coherence traffic on the cache line.

---

**Algorithm 1** The RON Algorithm

---

```
1  int TSP_ID_ARRAY[NUM_core]; /*per-process*/
2  thread_local TSP_ID; /*thread-local-storage*/
3  atomic_bool InUse=false; /*per-lock*/
4  atomic_int WaitArray[NUM_core]; /*per-lock*/
5  TSP_ID = TSP_ID_ARRAY[getcpu()]
6  void spin_init()
7      for (each element in WaitArray)
8          element = 0;
9  void spin_lock()
10     WaitArray[TSP_ID]=1;
11     while(1)
12         if (WaitArray[TSP_ID]==0)
13             return;
14         if (cmp_xchg(&InUse, false, true)):
15             WaitArray[TSP_ID] = 0
16             return;
17 void spin_unlock()
18     for (int i=1; i<NUM_core; i++)
19         if (WaitArray[(i+TSP_ID)%NUM_core]==1)
20             WaitArray[(i+TSP_ID)%NUM_core]=0;
21         return;
22     InUse=false;
```

---

The `spin_unlock()` in Lines 18-21 finds the next thread that wants to enter the CS. Lines 18-20 treat `WaitArray[]` as a circular queue. From the next position of the caller thread (where `i` is between 1 and `NUM_core`.), it searches for the first thread wanting to enter the CS. Because the thread that wants to enter the CS will set `WaitArray[]` based on its `TSP_ID` (Line 10), the first thread found in the loop of Lines 18-20 is the next thread in the TSP ORDER. In Line 20, `WaitArray[]` of the next thread is set to 0, and the next thread leaves `spin_lock()` (Lines 12-13) to enter the CS. If no thread is waiting, `InUse` is set to false (Line 22).

### 4.3 Correctness

A method must satisfy the following three conditions to ensure the correctness of a CS: (1) mutual exclusion, (2) progress, and (3) bounded waiting. At a minimum, the algorithm used in a software system must satisfy conditions 1 and 2. For instance, GNU’s `pthread_spin_lock` satisfies only conditions 1 and 2, while RON satisfies all three. However, we provide proof of bounded waiting only due to space limitations.

*Bounded Waiting:* We will prove that the maximum number of waits is the number of threads when each core has at most 1 thread. Each core has a unique `TSP_ID`, and these `TSP_ID`s of cores form a circular queue. RON allows all threads to enter a CS in the order of the TSP ORDER. In the worst case when thread `X` is ready to enter a CS, all threads on the cores whose TSP ORDERS are before the core of thread `X` want to enter the CS. Assuming that the total number of threads is “num,” thread `X` needs to wait for (num - 1) threads to leave the CS. In Section 5, RON can support multiple threads on a core. In this case, the maximum number of waits is also the number of threads minus one.

### 4.4 An Example

RON does not prioritize threads for entering the CS based on arrival order, but instead uses the TSP ORDER of each core. While this approach may not generate the optimal solution in all cases, it provides a heuristic algorithm that works efficiently. Let us use the CPU architecture of AMD as an example to illustrate the mechanism of RON. As Figure 2 shows, two CPU Complexes (CCXs) are connected by two point-to-point buses. Each CCX contains four cores that are fully connected by a high-speed network. First, we assume that the TSP ORDER of the cores is  $3 \rightarrow 0 \rightarrow 1 \rightarrow 2 \rightarrow 5 \rightarrow 6 \rightarrow 7 \rightarrow 4$ . The TSP ORDER of a core can be obtained by `TSP_ID_ARRAY[]`. Taking core 3 as an example, we can find that its TSP ORDER is 0 in `TSP_ID_ARRAY[3]`. We also assume that at time  $t_0$ , the thread on core 3 is ready to enter the CS. Therefore, `InUse` is set to true (Line 14 in Algorithm 1) and this thread on core 3 enters the CS. Then, all entries of `WaitArray[]` in the graph are null (value 0) at time  $t_0$ . At time  $t_1$ , the threads on cores 1, 5, 2, and 6 arrive and are in the Lock Session (LS). Taking the thread on core 1 as an example, its TSP ORDER is `TSP_ID_ARRAY[1] = 2`. Therefore, `WaitArray[2]` is set to 1 (Line 10), and the thread waits for either `WaitArray[2]` (Line 12) or `InUse` (Line 14) to become 0. The `TSP_ID`s of cores 1, 5, 2, and 6 are 2 (`TSP_ID_ARRAY[1]`), 4 (`TSP_ID_ARRAY[5]`), 3 (`TSP_ID_ARRAY[2]`), and 5 (`TSP_ID_ARRAY[6]`), respectively, and their `WaitArray[]` values are set to 1 accordingly.

At time  $t_2$ , the thread on core 3 leaves the CS. Because the TSP ORDER of core 3 is 0, the search will start from next TSP ORDER (i.e., `TSP_ID` 1 in this case). Thus, the

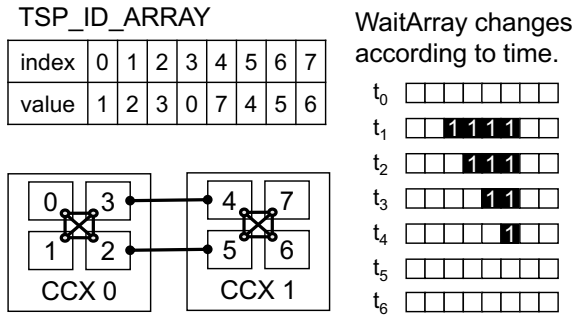

Figure 2: An example of RON.

value of `WaitArray[1]` is examined (Lines 18-21), and the first “1” appears in `WaitArray[2]`. Therefore, the thread in core 3 sets `WaitArray[2]` to 0. Since the thread in core 1 has been waiting for `WaitArray[2]` to become 0 (Line 12), it can now enter the CS. Similarly, at times `t3` and `t4`, the threads in cores 2 and 5 enter the CS, respectively. At time `t6`, the thread in core 6 wants to leave the CS, so it finds all entries of `WaitArray[]` equal to 0. Therefore, it sets `InUse` to false (Line 22).

In this example, we assume that the handover cost within the same CCX is 1 and that across CCXs is 3. If the CS is entered in the FIFO order (3, 1, 5, 2, 6) as in MCS and Ticket, the total handover cost will be  $1 + 3 + 3 + 3 = 10$ . However, according to RON, it will be entered in the order 3, 1, 2, 5, 6, so the total handover cost is only  $1 + 1 + 3 + 1 = 6$ .

## 5 More Threads than Cores

In real applications, there may be a situation where the number of running threads is more than the number of cores. We call this oversubscription. RON approach proposed in Section 4.2 cannot handle oversubscription. In this section we propose two methods to solve this problem: RON-ticket and RON-plock. The former provides better fairness (i.e., bounded waiting), while the latter provides better performance and probabilistic fairness. In the following, we first point out that it is not necessary to run all threads with NUMA-aware spinlock algorithms in Section 5.1. By utilizing this observation without violating fairness, we present our solution on supporting oversubscription in Section 5.2.

### 5.1 Lock Contention Problems on a Core

In oversubscription, multiple threads can run on a single core, which differs from the situation where competing threads are spread across multiple cores. In Figure 3-(a), `Thr1` to `Thr4` correspond to `core1` to `core4`. `core1` and `core2` belong to NUMA `node1`, and the other cores belong to `node2`. If Plock is used and `Thr4` releases the lock, `Thr3` has more probability of entering the CS because `Thr3` and `Thr4` are in the same node.

When `Thr3` and `Thr4` continue to request entering the CS, then `Thr1` and `Thr2` may not have the opportunity to enter the CS. In ticket lock, these threads enter the CS in FIFO order.

Figure 3: Threads on NUMA nodes vs. threads on a core.

Figure 3-(b) is the same as Figure 3-(a), but all threads belong to the same core. Taking Linux as an example, the execution order of threads on the same core depends on the scheduler. If Plock is used, when `Thr4` (abbreviation for thread 4) releases the lock, the next task that enters the CS is the task executed after `Thr4`. Therefore, the chance of `Thr1` to `Thr3` entering the CS is proportional to their chance of getting CPU time. Because RON guarantees that each core has an equal chance of obtaining the lock, the fairness of threads obtaining the lock on different cores depends on whether the scheduler is fair. The fairness of the ticket lock is the same as in the example shown in Figure 3-(a).

### 5.2 RON with Oversubscription Support

In RON, the element in `WaitArray` indicates whether a thread on that core is waiting to enter the CS. In this section, each element of `WaitArray` indicates how many threads are waiting for the lock on that core (for RON-ticket and RON-plock) and the order in which they enter the CS (for RON-ticket).

The RON-ticket is given in Algorithm 2. Each lock has an array consisting of the elements corresponding to each core and the elements consist of two variables: grant and ticket.

Each core has its own `nWait` variable, which behaves more like thread-local storage. When a thread is waiting to enter the CS from the LS, it uses the `atomic_fetch_add(nWait, 1)` operation to check whether there is a thread in the CS or not. This operation is performed on the `nWait` variable of the core that the thread is running on. If no thread is in the CS, then the waiting thread can enter. To enter the CS, the thread uses the `atomic_fetch_add(ticket, 1)` operation to set the `l_ticket` variable (Line 6). The thread then waits on the while loop (Lines 7-10) until it is its turn to enter the CS. If the thread is not the next thread that should enter the CS of the core (that is,  $grant - l\_ticket \neq 1$ ), the thread releases the CPU (Lines 8-9) and tries again later. When a thread leaves the CS, it first checks to see if there is any waiting thread (Line 13). If there is a waiting thread, it searches for a core with a waiting thread (Lines 14-19). Once a core with a waiting thread is found, it increases the grant of that core by 1 (Line 17), allowing the waiting thread to enter the CS.

The RON-plock is shown in Algorithm 3. Each lock has an array consisting of the elements corresponding to each core and the elements consist of two variables: `numWait` and `lock`.

---

**Algorithm 2** The RON-ticket Algorithm

---

```
1 struct TicketLock {grant=0, ticket=1;}
2 atomic_int nWait=0; //per-lock variable
3 TicketLock WaitArray [NUM_CORE]; //per-lock
  variable
4 TSP_ID = TSP_ID_ARRAY[getcpu()]
5 void spin_lock()
6 if(atomic_fetch_add(&nWait, 1) == 0) return;
7 l_ticket = atomic_fetch_add(&WaitArray[TSP_ID
  ].ticket, 1);
8 while(1)
9 if(WaitArray[TSP_ID].grant-l_ticket≠1)
10 sched_yield();
11 if(l_ticket==WaitArray[TSP_ID].grant) return;
12 void spin_unlock()
13 if(atomic_fetch_sub(&nWait, 1) == 1) return;
14 next = (TSP_ID+1)%NUM_core;
15 while(1)
16 if(WaitArray[next].grant - WaitArray[next].
  ticket ≤ -2)
17 atomic_inc(&WaitArray[next].grant, 1);
18 return;
19 next = (next+1)%NUM_core;
```

---

Each thread that wants to enter the CS must use `atomic_inc()` to set the `numWait` to which it belongs. When the lock of a core is `HAS_LOCK`, the thread currently executing on the core can enter the CS (Lines 7-8). To increase cooperation between the lock-unlock algorithm and the scheduler, `yield()` can be used when multiple threads are executing on a single core. Although `yield()` is a system call and can have overhead equivalent to `futex()`, for user-mode threads, it can be a user-mode function that transfers control to other threads on the same core. When the thread leaves the CS, it searches for the next core whose `numWait` is not equal to 0 and sets the lock of that core to `HAS_LOCK`. If necessary, `yield()` can be used again to allow other waiting threads on the same core to proceed. The proof of correctness is shown in the supplementary material.

## 6 Performance Evaluations

### 6.1 Evaluation Platform and Settings

In the performance evaluation experiments, we used a AMD Threadripper 2990WX with 64 cores (/32 physical cores) with a GNU/Linux operating system. The kernel version was 5.4. The compiler used `gcc-9.3` with the optimization parameter `-march=znver1 -O3`, which enabled `gcc-9.3` to perform the optimization for the Threadripper microarchitecture. All experiments were conducted 100 times, and their results were averaged. The source codes of RON in this section can be found at <https://github.com/shiwulo/ron-osdi2023>.

For a more complete comparison with other methods, we used the LiTL framework [39]. We compiled RON as a shared library. We wrote Algorithm 3 into a program that is compiled

---

**Algorithm 3** The RON-plock Algorithm

---

```
1 struct PLock {numWait=0, lock=MUST_WAIT;}
2 atomic_bool InUse=false; //per-lock variable
3 PLock WaitArray[ NUM_core]; //per-lock variable
4 void lock()
5 atomic_inc(&WaitArray[TSP_ID].numWait);
6 while(1)
7 if (cmpxchg(&WaitArray[TSP_ID].lock, HAS_LOCK,
  MUST_WAIT))
8 return;
9 if (cmpxchg(&InUse, false, true))
10 return;
11 void unlock()
12 atomic_dec(&WaitArray[TSP_ID].numWait);
13 for(int i = 1; i < NUM_core+1; i++)
14 if (WaitArray[(TSP_ID+i)%NUM_core].numWait>0)
15 WaitArray[(TSP_ID+i)%NUM_core]=HAS_LOCK;
16 return;
17 InUse=false;
```

---

with LiTL. By using `LD_PRELOAD`, RON can be compared with other methods on different benchmarks. AMD Threadripper is a chip-NUMA. There are four dies in the chip. Each die has two CCXs, each of which has four cores. Moreover, the Linux `numastat` command shows that 2990WX has 4 NUMA nodes.

The cache coherence protocol operates at the cache line granularity, which means that low latency also implies high bandwidth. Therefore, the transmission latency obtained from the experiments shown in Figure 4 not only informs the design of inter-core locking algorithms but also provides insights into the underlying hardware’s performance characteristics. By profiling the inter-core latency, an operating system can optimize the lock-unlock algorithms accordingly. Furthermore, detailed microarchitecture information about the NoC from CPU vendors can lead to even better performance. In calculating the transmission latency from core X to core Y, we make core X read 100 integers (2 cache lines in this case) from DRAM, and then we calculate the time for core Y to read the 100 integers from core X’s cache. As 2990WX is a ccNUMA architecture, Y will read 100 integers from X’s cache. It should be noted that not all dies on a 2990WX are the same due to differences in the manufacturing process. AMD puts the best cores on die 0, which means that the transmission latency of die 0 is lower. AMD and Intel support “AMD Turbo Core” and “Turbo Boost Max 3.0”, respectively. The operating system can learn how to make better use of the CPU by being aware of the best die. However, traditional NUMA-aware spinlocks cannot achieve the fairness they claim in such processors, which will be discussed in Section 6.2.2.

After obtaining the handover time (i.e., transmission speed) for each pair of cores, we used Google OR-Tools [40] (A solver for NP-complete problems, providing a usable solution.) to determine the TSP ORDER for the cores as shown in Figure 4. We see that the TSP-ORDER first visits all the cores

in the same CCX and then the CCXs on the same die. Finally, the TSP-ORDER visits each die in the clockwise direction. Then, we generate TSP\_ID\_ARRAY[] according to the TSP ORDER for Algorithm 1.

Figure 4: The core-to-core communication latencies and TSP ORDER of AMD 2990WX

We used microbenchmarks in Section 6.2 to analyze the characteristics of the algorithm, and used general benchmarks in Section 6.3 to understand the performance under various usage scenarios. We compared RON with the following algorithms. Please note that what we describe below are the performance characteristics of each algorithm, not the implementation details.

1. Plock: The GNU Pthread’s spinlock. A thread that intends to enter a CS will test the lock until its value equals to 0. When a thread leaves a CS, it sets the lock to 0. The first core that observes that the lock is 0 can enter the CS. The closer to the core the lock is released, the more likely it is for the core to enter the CS.
2. Ticket: This method allows each task waiting to enter the CS to have a “ticket” number. The thread waits until the “grant” is equal to its ticket number. The wait loops of all waiting threads use atomic instructions to continually query the value of the “grant”, which consumes limited NoC bandwidth.
3. MCS: Because all tasks waiting to enter the CS are queued in a linked list, when a thread leaves the CS, it only needs to set the “wait flag” of the next task to false. Setting the wait flag of next thread is more efficient than multicasting when the CPU supports a directory cache coherence algorithm. MCS does not optimize the interconnect latency in multi-core architectures.
4. C-BO-MCS: The thread should first acquire the MCS lock of the NUMA node to which the thread belongs. Then, it must compete with threads on other NUMA nodes to obtain a back-off lock. If a core neighbors to the core that obtains the C-BO-MCS lock, it has a higher priority to enter the CS. With this method, threads belonging to the same node can be grouped together to reduce handover costs.
5. ShflLock (also known as Shuffle Lock): This also uses grouping to improve performance. Shuffle can specify

that a thread in the queue is responsible for shuffling. However, when the task that is allowed to enter the CS is shuffling the queue, the thread cannot enter the CS immediately and system performance may decrease.

## 6.2 Microbenchmarks for Quantitative Analysis

### 6.2.1 Evaluation Platform and Settings

Here, we analyzed each spinlock method in a quantitative manner through a controllable microbenchmark. In each set of experiments in this section, each thread is bound (i.e., `sched_setaffinity()`) to a hardware thread and executes Algorithm 4. Because we have SMT (Simultaneous multi-threading) enabled, there are 2 hardware threads per core. The total number of software threads is 64. In the while loop (Lines 2–9), a thread in the *lock section* (LS) (Line 3) requests entry into the *critical section* (CS) (Lines 4–5). After the thread enters the CS, each entry in `SharedData` is read and written, and the lock is released into the *unlock section* (US) (Line 6) when the thread leaves the CS. The `clock_gettime()`, defined in the POSIX.1-2001 standard, is called in the *non-critical section* (nCS) (Lines 7–9) until the elapsed time of the nCS exceeds the value of `nCS_size±15%` in Line 9. We first evaluate the throughput (Figure 5) and fairness (Figure 6) of each algorithm, and then analyze their efficiency in terms of handover (Figure 7) and contention (Figure 8). Please note that in these 4 experiments, except for adding the code for measuring time (i.e., `clock_gettime()`) and the code for statistics, the experimental parameters are the same.

---

#### Algorithm 4 Testing Program and Measurements

---

```

1 void thread():
2     while(1):
3         spin_lock(); //LS
4         for (each element in SharedData): //CS
5             element = element + 1; //CS
6         spin_unlock(); //US
7         t = clock_gettime(); //nCS
8         //syscall overhead, rdtscp implement in userspace
9         while(clock_gettime()-t > nCS_size*rand(0.85~1.15));

```

---

### 6.2.2 Results of Microbenchmarks

As shown in Algorithm 4, a shorter nCS implies a heavier workload because the lock request rate is higher. The upper and lower parts of Figure 5 are the performance when the contention is low and high, respectively. RON can provide the best locking efficiency in both cases. Under low load conditions (`nCS = 400K~120K`), the performance of Plock

is second only to RON. When nCS is lower than 40K, the performance of Plock drops rapidly when the load is heavy. The performance curves of MCS and ShflLock are similar, which may be because they queue tasks waiting for CS in a linked list.

ShflLock and C-BO-MCS perform worse than MCS in some cases (i.e., nCS > 10K). This is because these two algorithms implicitly treat the handover costs between cores belonging to the same die as equal. Therefore, they cannot optimize the handover costs of different cores in different dies (Please see the example in Section 2.2). Further, since the difference in communication cost between 2990WX cores is only 3.13 times at most, an algorithm with too-high time complexity reduces the benefits that can be obtained. Because RON uses a pre-calculated TSP ORDER that is optimized for all cores, it can achieve higher performance at a lower cost. According to our simulation results (in the supplementary material), ShflLock and C-BO-MCS performs better when the transmission latency between cores on the same chip/die is almost the same. In other situations, RON performed best.

Figure 5: Locks per second under different loads

Figure 6 shows the number of locks acquired by each core in the case of short-term (1 second) and long-term (10 seconds). The lower the coefficient of variation (CV), the better the fairness. In Figure 6, we see that RON, MCS, and Ticket perform equally well, in terms of CV. That is almost equal to 1%. In long-term fairness, when non-critical section (nCS) < 80K ns, the CV of Plock starts to rise. When nCS < 20K ns, the CV of ShflLock and C-BO-MCS both starts to rise. In order to better understand the performance of spinlock algorithms in long-term fairness, we let the ShflLock, C-BO-MCS, and Plock execute for 1,000 seconds with nCS = 10K and their CVs are 35%, 71% and 96%, respectively. *Fairness factor* is described by Dice et al. [25]. It is the most common metric to measure fairness. The value of fairness factor is between 0.5 and 1. A complete fair spinlock's factor is 0.5 and a complete unfair spinlock's factor is 1. The fairness factor of the ShflLock, C-BO-MCS and Plock are 0.68, 0.85 and 0.8, respectively.

In terms of software design, each thread in Plock competes fairly for locks. C-BO-MCS is based on two fair spinlocks, namely backoff [44] and MCS. ShflLock allows threads on

the same node (i.e., die) of the lock holder to elevate their positions in the queue for a limited number of times. Note that it is difficult to analyze in detail why these algorithms do not meet long-term fairness perfectly, so only Plocks is analyzed to provide insights into the interaction between multicore processors and spinlocks.

In the past, the multi-core processor had to execute at a frequency that all cores could run correctly. The worst core determines the maximum clock frequency that a multi-core processor can run. Now each core can run on its highest frequency [47]. According to the experimental results of the Plock with nCS=10k, the ability of cores 0-7 and 32-39 to obtain locks is 20.6 times that of cores 8-31 and 40-63. Therefore, we roughly conclude that when the load becomes heavier, algorithms that meet long-term fairness may not achieve the expected fairness on modern multi-core processors. [47].

Figure 6: Long-/short- fairness of different algorithms.

The experimental parameters of Figure 7 are the same as Figures 5 and 6, but we changed the X coordinate from nCS (Line 8 in Algo. 4) to the number of threads waiting to enter CS (i.e., the number of threads in LS, Line 3 in Algo. 4). The more the number of threads waiting, the better the performance of an algorithm that can optimize the handover cost. In Figure 7, the Y axis is the time required to access the shared data. For example, in the case of RON under load nCS = 10K, the number of threads in LS is 45, and the handover time is 100 ns. Under the same load, the number of threads of C-BO-MCS in LS is 52, and handover time is 190 ns. RON is almost the best spinlock in terms of handover time. With more tasks in the LS, the path formed by each task selected by RON is closer to TSP ORDER, because each core has a higher probability to have a thread waiting for entering the CS. When the number of tasks in LS increases from 0 to 15, the efficiency of accessing shared data doubles (from 210ns to 100ns). When the LS changes from 60 to 62, the efficiency is reduced by 7%. This is the reason for the reduced efficiency when the nCS is 1K in Figure 5.

Plock is slightly better (0.07%) than RON when the lock contention is very low (nCS=120K). Although Plock's handover cost is low, its performance is not good. Since Plock uses `cmp_xchg` (`compare_exchange`) to solve the lock contention problem, The hardware may need to execute `cmp_xchg` continuously until the return value of only one task is equal to true. This wastes the limited bandwidth of

NoC and is time consuming. The handover time of C-BO-MCS and ShflLock is better than MCS. However, these two methods are too complicated, resulting in the performance lower than expected. Both Ticket and MCS arrange tasks to enter the CS in the order of their arrival. Since Ticket does not give each thread a wait flag, all threads will constantly monitor the wait flag, thus consuming a lot of NoC bandwidth. Ticket has the worst handover cost.

Figure 7: Handover cost and the number of thread in LS.

In Figure 8, we set the size of the shared data accessed in the critical section to 0 (Line 4 in Algorithm 4). The X axis is the number of tasks waiting to enter the CS, and the Y axis is the time of each thread executing one round (including LS, US, CS and nCS, i.e., Lines 2-8). The size of the non-critical section (Lines 7 and 8) ranges from 160K to 1K. Therefore, the main factor in performance is the locking and unlocking efficiency of an algorithm. RON is almost the best algorithm. Its performance is slightly worse than that of Plock (0.2%) when the loading is extremely light. RON has a better performance for two reasons. First, TSP ORDER is pre-calculated. Second, the lower handover cost makes atomic operations more efficient. We use experiments to analyze the efficiency of atomic operations of RON. When we schedule threads to perform atomic operations through TSP ORDER, the efficiency of atomic operations is 1.6 times that of random order.

Figure 8: Contention cost.

### 6.2.3 Oversubscribe

In each set of experiments of this section, each thread binds (i.e., `sched_setaffinity()`) to a core and executes Algorithm 4. Each core has at most  $\lceil \text{num\_thread} \div \text{num\_core} \rceil$  threads. Because RON-ticket shares a key property with RON, that is, bounded waiting, RON-ticket was used for performance evaluation in the previous section. In this section,

microbenchmarks are used to evaluate the performance of RON-ticket and RON-plock. In the case of oversubscription, two factors affect performance. The first one is whether the thread holding the lock is scheduled out. Second, if the algorithm specifies the next thread entering the CS, and whether it is scheduled out.

In Figure 9, RON-plock and RON-ticket perform better in the case of overbooking, where the y-axis denotes “millions locks” per second. Although C-BO-MCS(-B) and ShflLock(-B) also support oversubscription, the number of lock-unlock operations per second is dropped quickly.

Figure 9: Performance of algorithms under oversubscribe.

RON-plock and Plock use intuitive methods (e.g., test-test-and-set) to solve the problem of oversubscribe. As long as the lock-holder is not scheduled out, Plock will allow a thread to enter CS (it is because that all threads wait on the same variable.). RON-plock is similar to Plock, except that all threads on the next core are scheduled out. Because RON-plock is based on RON, the performance of RON-plock is better than Plock. RON-ticket, ShflLock-B, and C-BO-MCS-B use system calls (i.e., `futex()` and `yield()`) to prevent the thread from spinning meaninglessly. ShflLock-B’s `unlock()` directly wakes up the next thread. However, C-BO-MCS-B’s `unlock()` may wake up all threads that can enter CS. RON-ticket makes the next thread that can enter the CS busy waiting, and other threads on that core enter the sleep state. For the same reason as RON-plock, RON-ticket has better performance.

### 6.2.4 Scalability

In this section, we investigate how algorithm performance changes with an increase in the number of threads used. Our experiment was conducted on the 2990WX, which has SMT technology. During the experiment, each thread accesses 100 integers in the critical section, while the non-critical section takes  $10,000 \pm 15\%$  nanoseconds.

As shown in Figure 10, it indicate that the performance of the RON-plock improves with an increase in the number of threads when the thread count is less than 64. This experiment yields results similar to those in Figure 5 because “executing more threads simultaneously” and “having shorter non-critical sections” both lead to greater competition for entering the

critical section. However, when the number of threads exceeds 64, the performance of these algorithms is determined by their ability to handle the oversubscribe problem.

Figure 10: Locks per second under different number of threads

### 6.3 Application-level Benchmarks

We pick five different application-level benchmarks representing different performance bottlenecks. For the consistency of the experiment, the RON implementation here uses RON-ticket, which has identical features to RON (bounded waiting).

#### 6.3.1 LevelDB (Key-value Database)

Here, we used Google’s LevelDB to test the performance of the spinlock. The Horizontal axis of Figure 11 is the algorithm tested, and the vertical axis is the time cost for every operation reported by LevelDB. Because of the difference data scales, “fillsync” is normalized to MCS and others normalized to Ticket.

Figure 11: Google’s LevelDB.

We use the db\_bench in LevelDB to evaluate performance with 1 million entries and 64 threads. For each spinlock, fillseq, fillsync, fillrandom, overwrite, and readrandom have been tested. The last one is the geometric average of LevelDB’s 5 tests. RON-ticket, ShflLock and C-BO-MCS are spin locks optimized for ccNUMA or NUMA. Please note that RON-ticket is RON with oversubscribe support and it also satisfies bounded waiting. Compared with ShflLock and C-BO-MCS, the performance of RON is better by 22.1% and 24.2%, respectively.

MCS is slightly better than ShflLock and C-BO-MCS for LevelDB, although the latter two are optimized for NUMA.

This may be because these two algorithms are designed to overcome the huge transmission overhead between two CPUs. However, there is not much difference in the communication cost between the cores on AMD 2990WX. When the load is high, ShflLock and C-BO-MCS may only perform local optimization.

Consider the situation with four NUMA nodes, where ShflLock and C-BO-MCS serve node X, and the load on node X always has a thread waiting to enter the CS. At this time, although there are many threads waiting for the CS on other NUMA nodes to enter, ShflLock and C-BO-MCS tend to let tasks on node X enter the CS. Since RON uses TSP ORDER to arrange the cores to enter the CS, RON does not suffer from the problem of local optimization.

#### 6.3.2 Benchmarks in Different Contention Levels

We applied an additional four different application benchmarks to evaluate the performance of different algorithms. These algorithms are selected from LiTL [39] and cover both high and low contention scenarios. Volrend and Raytrace are from the SPLASH2x benchmark set representing extreme and high levels of contention, respectively. For the extreme level, more than 40 threads are waiting to acquire the same lock instance. For the high level, there are about 10 to 40 threads waiting to acquire a lock. Dedup and Ferret are from the PARSEC3.0 benchmark set and respectively represent pressure on the memory and relatively low levels of contention [39]. In Figure 12, the vertical axis is the elapsed time of the benchmark task (including geomean of LevelDB Figure 11). Because of the different data scales, the numbers are the percentage to where the algorithm performs the worst for each task.

Figure 12: Applications with different contention level.

The bottleneck of Raytrace is a lock contention, protecting a single counter with about a million acquisitions every second. RON-ticket, MCS, and Plock accomplished the task with around 70% of elapsed time. MCS is optimized for multi-core systems with dedicated caches for each core to reduce the overhead of lock contention and well fitted in high level of contention. The code of Plock is not optimized for multi-core. However, the core adjacent to the core that released the lock is more likely to successfully perform the atomic operation compare\_exchange() to acquire the lock. Thus, Plock is implicitly optimized for multi-core platforms.

In the case of extreme levels of contention, the performance of Plock and MCS starts to drop while the ShflLock and RON-ticket can handle the stress. Under extreme level of contention (Volrend), RON-ticket achieved its best performance, taking only 24.3% of the elapsed time of the ticket to accomplish task. The bottleneck of Volrend is the lock contention for protecting different task queues with around 40 threads waiting. This benchmark verified that the RON algorithm generally performs best under higher contention. With more cores possessed by threads spinning for the lock instance, the routing path can massively reduce the handover cost.

However, under low levels of contention, RON-ticket only performs second best in all six algorithms. Ferret is a parallelized software with about 2000 times of acquisition for every second. While RON-ticket uses around 20% of the elapsed time, Plock takes only around 15.6% of the elapsed time of C-BO-MCS, outperforming RON in this specific benchmark. The lower contention of the lock leads to the sparseness of the `WaitArray`, which results in leaping on the routing path and lowers the benefit. Ticket guarantees fairness as threads keeping querying the global variable to know whether they can enter the CS. Ticket fits the task with low level of contention. However, under higher pressure, the bandwidth consumed by lock contention limits the bandwidth that can be used by handover.

Moreover, according to the results of Dedup, RON-ticket and Plock gave low memory pressure. Dedup allocates numerous locks (266k) [39], which puts pressure on the memory if the components of the lock are not reusable. The reusability of components like `WaitArray` and `Get_TSP_ID` gives RON-ticket the ability to handle numerous lock allocations.

In summary, RON algorithms can handle different levels of contention, especially higher levels. With higher contention RON algorithms achieve better performance relatively, but Plock remains a better algorithm for low levels of contention. With reusable components, Both Plock and RON put low pressure on the memory while allocating numerous lock instance.

## 7 RON in GNU/Linux Kernel

### 7.1 Implementation

As shown in the performance evaluation section, RON is more suitable for multi-core computers than methods that support NUMA in user space applications. In this section, we shows whether RON is suitable for Linux kernel. In our implementation, the line of code (LoC) is 47.

In the Linux kernel, the lock-acquire and lock-release are implemented by `queued_spin_lock(struct qspinlock *lock)` and `queued_spin_unlock(struct qspinlock *lock)`, respectively. Both functions have only one parameter, `lock`. By rewriting these two functions, we implement RON in the Linux kernel. We use `*lock` as `InUse` in the RON algorithm (Line 3 in Algorithm 1).

In order to achieve the same space efficiency as `qspinlock`, only one `WaitArray` (Line 4 in Algorithm 1) is in kernel. In user space, a task sets `WaitArray[TSP_ID]` (Line 10 in Algorithm 1) to wait for entering the CS. In the Linux kernel, the task writes the address of `lock` (that is the parameter of `queued_spin_lock`) to `WaitArray[TSP_ID]` for entering the CS. When the thread leaves CS, the thread will check one by one whether there is an element with a value equal to `lock` in `WaitArray`. Therefore, a busy-waiting task is only awakened by the task holding the same `lock`.

If the space of the `WaitArray` has been used up, the other tasks wait on `InUse` (that is `*lock` in kernel space). Tasks waiting for `InUse` do not enter CS in TSP ORDER. This design method is the same as Linux's `qspinlock`, though it is not perfect but good enough (compromise to  $O(1)$  space complexity). In terms of memory usage, RON requires 4 bytes for each lock (that is the size of `struct qspinlock`) and 28 bytes for each core ( $28 \times 64 = 1792$  bytes for AMD 2990WX).

### 7.2 Evaluations

In this section, the Linux kernel version is 5.12.1. We apply the patch of ShflLock into the `qspinlock.c` of Linux. Therefore, in this section, we will compare the performance of the Linux kernel using `qspinlock`, ShflLock and RON. We use a microbenchmark and `db_bench` of Google LevelDB to measure the performance of RON in Linux kernel. In the experiment, we do not use `LD_PRELOAD` to change the behavior of LevelDB. The purpose of microbenchmark is to measure performance under high load conditions. The microbenchmark is implemented by forking 64 child processes, and every child process creates 2048 threads to execute 64 `mmap()` and `munmap()` function calls. We use `strace` to evaluate the time taken for each system call.

As shown in Figure 13, ShflLock doesn't perform well on both microbenchmark and LevelDB. ShflLock is suitable for multi-socket NUMA machines but ours is a single-socket machine. RON performs better than `qspinlock` under high load conditions. In terms of geometric average of microbenchmark, the performance of Linux kernel with RON is 1.35 times that of Linux kernel with `qspinlock`. In terms of LevelDB, RON and `qspinlock` are about the same in terms of geometric average. In these five experiments, the performance of these three algorithms on `readseq` are almost the same. RON performs better than `qspinlock` in `fillsync` because the contention is high. RON and `qspinlock` both have their own strengths.

Intuitively we can combine `qspinlock` and RON to achieve better performance. `qspinlocks` can encode the first two tasks that want to enter CS into the `lock` variable (the parameter of `queued_spin_lock()`). In this way, the performance of `qspinlock` is very good under low contention. The purpose of this experiment is to explore the effectiveness of RON, so we did not use Linux optimization techniques to improve

performance under low contention conditions.

microbenchmark (microseconds)					
system call	mmap	clone	mprotect	munmap	geomean
qspinlock	923	183	252	43	207
ShflLock	2029	206	456	39	294
RON	592	185	264	19	153

(a)

LevelDB						
	fillseq	fillsync	fillrandom	overwrite	readseq	geomean
	MB/sec	op/sec	MB/sec	MB/sec	MB/sec	
qspinlock	20.2	511.4	17.8	17.2	487.3	68.8
ShflLock	7.9	390.5	7.5	7.1	485.3	38.1
RON	18.3	687.1	16.3	15.7	482.7	68.9

## 8 Conclusion

We propose a RON spinlock algorithm that delivers locks and data in a one-way circular manner among cores with the awareness of the performance differences of cores, so as to minimize the system-level handover cost and achieve bounded waiting for threads among cores. In particular, “one-way” is for minimized system-level handover cost and “circular” is for bounded waiting of threads to enter CS. In addition, the proposed RON algorithm can also resolve the oversubscription issue without losing its scalability. A series of experiments were conducted to evaluate the efficacy of the proposed algorithm. Compared with ShflLock and C-BO-MCS, the performance of RON in google leveldb has increased by 22.1% and 24.2% respectively. In terms of kernel space performance, compared with using ShflLock, RON can improve the performance of Google LevelDB by 1.8 times.

## 9 Future work

This paper addresses the issue of unfairness caused by different execution frequencies on multi-core processors, as well as the efficiency of inter-core data transfer. The proposed method is particularly suitable for highly competitive scenarios. Although high competition can be a bottleneck for performance, low competition is a more common scenario where simple algorithms often have good performance. Therefore, in future research, we will investigate how to dynamically switch algorithms (such as plock and RON) at runtime. We will also evaluate the performance of RON by implementing it using linked-list methods to offload the runtime of unlocking to the locking process.

## Abstract

Context switching between kernel mode and user mode often causes prominent overhead, which slows down applications with frequent system calls (or syscalls), e.g., those with high I/O demand. The overhead is further amplified by security mechanisms like Linux kernel page-table isolation (KPTI). To accelerate such applications, many efforts have been put in removing syscalls from the I/O paths, mainly by combining drivers and applications in the same space or batching syscalls. Nonetheless, such solutions require developers to refactor their applications or even update hardware, which impedes their broad adoption.

In this paper, we propose another approach, userspace bypass (UB), to accelerate syscall-intensive applications, by transparently moving userspace instructions into kernel. Userspace bypass requires no modification to userspace binaries or code and achieves full binary compatibility. Specifically, to avoid overhead caused by frequent syscalls, kernel identifies the short userspace execution path between consecutive system calls, and converts the instructions in the path into code blocks with Software-Based Fault Isolation (SFI) guarantee. According to our evaluation, I/O micro-benchmark can be accelerated by 30.3 – 88.3%, Redis GET Requests Per Second (RPS) can be improved by 4.4 – 10.8% for 1B – 4KiB data sizes, when the application is executed in a virtualized setting with KPTI turned on. The performance boost will be reduced when KPTI is turned off.

## 1 Introduction

System call (syscall) is widely used by a userspace application to access the resources provided by the hosting operating system (OS) and extensively used for I/O operations. However, syscall could incur prominent performance overhead [43] when mechanisms like Linux kernel page-table isolation (KPTI) [47] are turned on. Arguably, syscall is one of the major performance bottlenecks for applications pursuing high I/O requests Per Second (IOPS), e.g., those requesting over a million IOPS [7].

**Syscall-refactoring approaches.** In the recent literature, there are mainly two streams of work in achieving higher IOPS by changing how syscalls are processed from the I/O path, which we call syscall-refactoring approaches: 1) The first stream of approaches integrate drivers and data processing logic in the same address space by moving data processing logic into kernel [26, 36, 53] or moving drivers responsible for I/O into userspace (kernel bypass) [21, 51]. In this way, the processing logic can directly talk to I/O devices and avoid the overhead caused by the switching between user mode and kernel mode [51]. 2) The second stream of approaches batch syscalls and allow userspace processes to queue multiple I/O requests and issue them together with only one single syscall [43]. However, these solutions require developers to change their code, which is usually a non-trivial task.

**Our approach.** In this paper, we propose *userspace bypass* (or UB for short), which reduces the overhead introduced by syscall-related I/O and achieves *binary compatibility* (i.e., no application code needs to be changed or rebuilt) at the same time. UB is motivated by the observation that applications with high IOPS do not execute many instructions between two consecutive syscalls (see Section 3.1). As a result, we can transparently instrument the instructions between syscalls under pre-defined security requirements (i.e., translating the instructions into sanitized code blocks), and let kernel execute the blocks without returning to userspace. In this way, the overhead caused by consecutive syscalls can be avoided. Figure 1 illustrates this idea.

Yet, a few challenges should be addressed. First, only those instructions that will potentially be executed between *frequently* invoked consecutive syscalls deserve userspace bypass. However, without explicit information provided by the developer, it is difficult to find such syscall sequence. As elevating the instructions to kernel also introduces overhead, the syscalls to be optimized need to be carefully chosen to offset such overhead. Second, malicious applications may exploit UB to steal kernel data and even execute privileged instructions. In addition, buggy applications may pollute kernel memory. Hence, it is critical for UB to guarantee kernel

Figure 1: Invoking system calls without and with UB.

safety by performing comprehensive sanitization on userspace code and data. Finally, to achieve binary compatibility, the elevated application code should be oblivious about whether they are executed in kernel mode or user mode. The identical execution outcomes with and without UB should be guaranteed, including memory order and atomicity for multi-thread applications.

We address these challenges by adapting Dynamic Binary Translation (DBT) [52] and Software-Based Fault Isolation (SFI) [44] techniques. First, we profile syscalls by hooking their entries, to learn which syscall invocations are frequent (i.e., “hot” syscalls). Inspired by Just-In-Time (JIT) compilation [17, 22, 48], we can obtain the userspace instructions following the hot syscalls in the runtime. The instructions, if within the same function, will be translated into Binary Translation Cache (BTC). Next, we iteratively execute the BTC and extend the BTC from the exit instruction until we meet the next syscall invocation. We perform instruction and address sanitization to restrict the behaviors of BTC, and achieve kernel control-flow integrity (CFI) and data integrity on the BTC. UB does not re-order instructions or split memory access. As a result, other threads can execute concurrently and safely with the thread optimized by UB.

We implement a prototype of UB and evaluate its performance gain in I/O micro-benchmark and real-world applications including Redis and Nginx. Under our default setting (the tested application runs in a virtual machine (VM) and the Linux KPTI is turned on), I/O micro-benchmark threads can be accelerated by 30.3% to 88.3%. For Redis GET, the acceleration ratio ranges from 4.4% to 10.8% for 1B – 4KiB data sizes. Nginx can be accelerated by 0.4% – 10.9%. UB can accelerate raw socket-based packet filters by 31.5% – 34.3%. We also evaluate the impacts of KPTI and virtualization on UB’s performance gain. Since turning off KPTI reduces the syscall overhead, UB is less effective. For example, the acceleration ratio for I/O micro-benchmark drops from 88.3%

to 41.6% for the smallest I/O size. Hence, future processors, which are expected to eliminate Meltdown and Spectre vulnerability in hardware, will benefit much less from UB. When the applications run in the physical machine, UB achieves higher upper-bound acceleration ratios in most settings compared to VM, because IOPS is usually higher in this case, which results in more syscalls that can be optimized.

We also compare UB with other systems that optimize syscalls, including `io_uring` [23], F-Stack DPDK [45] and eBPF [34] in our experimental study. The results show that UB is less advantageous, comparing with `io_uring` in the micro-benchmark, F-Stack for the Redis macro-benchmark, and eBPF for raw sockets. However, UB has a unique advantage that no code change is required for the application developers.

Finally, we acknowledge UB might introduce new security risks under side-channels, undocumented x86 instructions, and kernel races. We accordingly suggest a few defense ideas.

The code of our UB prototype is published at [15]. We summarize the contributions of this paper as follows.

- We propose userspace bypass (UB), which directly executes the instructions between syscalls in kernel mode, to accelerate syscalls.
- We provide a concrete design that transparently translates userspace instructions to kernel-safe, sanitized BTC. With this method, existing applications can be executed without modification and enjoy the performance gain.
- We implement a prototype and evaluate it against several high IOPS apps. The results prove the effectiveness of UB.

## 2 Background

In this section, we first overview the syscall mechanisms and their introduced overhead. Then, we describe the prior efforts in reducing such overhead.

### 2.1 Syscalls and Their Costs

Syscall presents the default interface between userspace applications and kernel services. Software interrupt (e.g., `int 0x80`, which has been deprecated) and special instructions (e.g., `syscall/sysret` created by AMD and `sysenter/sysexit` created by Intel) can be leveraged to transfer the control from user space to kernel space and vice versa after syscall.

Previous studies have shown that syscall invocation can introduce prominent overhead on various applications and scenarios [16, 35, 43], including *direct costs* and *indirect costs* [43]. For the first case, because of switching between user mode and kernel mode, extra procedures have to be executed to save registers, change protection domains, and handle the registered exceptions. For the latter case, the state of processor structure, including L1 cache data and instruction

Figure 2: IPC after no-op syscall and `pwrite` syscall, measured on our platform (Intel Skylake and Linux).

caches, translation look-aside buffers (TLB), etc., can be *polluted* by syscalls, and the Out of Order Execution (OOE) of CPU has to be stalled for the order guarantee. As a result, the user-mode instructions per cycle (IPC) would be decreased after syscall.

A widely-used technique called kernel page-table isolation (KPTI) [47] makes syscalls even slower. To defeat transient execution attacks, e.g., Meltdown [29] and Spectre v3a [49], OS kernel uses two sets of page tables for user space and kernel space. As a consequence, CPU should switch to kernel page table upon entering syscall, and switch back when returning to userspace. Besides KPTI, virtualization may also increase the context-switching overhead. For example, the overhead of TLB miss (part of indirect overhead) inside VM can be larger, as more page table entries have to be examined than inside physical machines.

Below we summarize the observations from previous studies and our measurement about the concrete syscall overhead.

- A no-op system call with KPTI enabled can cost 431 CPU cycles, as measured by Mi et al. on Intel Skylake and `seL4` [35].
- As measured in our experiment platform (Intel Skylake and Linux), the kernel prologue and epilogue (direct costs) take 197 instructions (992 CPU cycles) for a no-op syscall, suggesting the issue of syscall overhead persists a decade after the study of Soares et al. [43].
- Also on our platform, a `pwrite` syscall can degrade the IPC of the following userspace instructions from 2.9 to 0.2 (indirect costs). The IPC slowly goes back to 2.1 after executing 20,000 instructions. Figure 2 shows the trend of IPC by time elapsed.

## 2.2 Performance Optimization on Syscalls

The research community is actively working on mitigating the overhead resulting from syscalls. Below we describe the related work with a comparison to our approach (also summarized in Table 1).

**Asynchronous syscalls.** Syscall introduces a synchronous execution model, as the user-mode execution is resumed after a syscall is finished. Brown proposed non-blocking Linux syscalls [5] that can be completed asynchronously parallel

Scheme	Develop Cost	Async Needed	Acceleration	Popularity
<b>eBPF</b>	++	✓	++	++
<b>DPDK</b>	++	✓	+	++
<b>io_uring</b>	++	✓	+	+
<b>UniKernel</b>	+++	-	+++	-
<b>FlexSC</b>	+	-	+	-
<b>UB</b>	-	-	+	

Table 1: Comparison of schemes for optimizing syscalls.

to the userspace execution flow. But, this approach does not completely decouple the syscall invocation from its execution. So far, most of the syscall implementations on Linux are still synchronized.

**Syscall batching.** As locality is a major performance factor, executing syscalls in a batch has also been investigated. Rajagopalan et al. proposed to group consecutive syscalls into one (the result of a syscall is directly fed to the next) [38]. This approach is effective under the assumption that no computation happens between two syscalls. Soares et al. proposed to batch syscalls of multiple co-routines and asked the developers to change the thread model to M-on-N (“M user-mode threads executing on N kernel-visible threads, with  $M \gg N$ ”) [38]. Thus, it only works when the task can be split into many threads. Modern kernel provides native queues, i.e., `io_uring` [23], to batch I/O requests from userspace processes and reduce the occurrences of syscalls. In particular, userspace code can issue multiple requests to the queue and invoke one syscall to let kernel process the queue<sup>1</sup>.

**Unikernel.** To mitigate the overhead of context switching, the Unikernel solutions run application code in kernel space instead of user space. Examples include Loadable Kernel Module (LKM) [42] and library OS [31, 40].

**In-kernel sandbox.** To reduce the occurrences of context switching caused by syscalls, in-kernel sandbox allows application code to run in privileged mode. For instance, eBPF [34] allows developers to attach code into kernel trace points. When kernel reaches these points, it will use a VM to execute the attached code. However, eBPF places many restrictions on the code, and kernel verifies if all the requirements are met before execution, during which legal codes may be rejected because of false positives in verification. Recently, Dmitry et al. propose to use in-kernel sandbox to execute applications entirely in kernel [27], in which context switching overhead can also be mitigated.

**Kernel bypass.** Observing that kernel does not always have to be involved in I/O tasks like packet handling, some researchers proposed the kernel bypass approaches. One prominent example is the Data Plane Development Kit

<sup>1</sup>`io_uring` also supports a kernel polling mode if the application has root privilege, where no syscall is required.

(DPDK) [11], which takes over I/O devices in userspace. Specifically, I/O requests are submitted to devices via a shared ring buffer, instead of syscalls. The buffer is maintained in userspace, involving no kernel activity for I/O.

We find that existing approaches all require noticeable development efforts. Different coding paradigms have to be followed in order to use the syscall-refactoring primitives. Most kernel bypass and syscall batching solutions (e.g., DPDK, RDMA, io\_uring) require application code to interact with a queue pair asynchronously. Nonetheless, developers still prefer to write program logic in the synchronous style. Refactoring the legacy code is also labor-intensive. As an example, we compare the unofficial Redis with DPDK support [2] to its official version (version 3.0.5). We find that the former includes 9,984 extra lines of code (LoC) to support DPDK, which accounts for 10% of the LoC of the official version. Another example is Unikernel: It requires developers to write kernel-mode code, which is unfortunately difficult to debug and prone to errors like memory corruption (there is no memory isolation). In addition to changing the application code, special userspace drivers may be required for kernel-bypass solutions [24].

### 3 Design Overview

To address the aforementioned issues, we propose userspace bypass (UB), a new primitive for syscall optimization. UB aims to fulfill the following three design goals (DG).

**DG1: Minimizing the manual efforts of developers.** Different from syscall-refactoring approaches, which require developers to change their legacy code or adjust to asynchronous programming, UB optimizes the syscalls at the *execution time*, which meanwhile does not impact application’s functionality.

**DG2: Minimizing changes to system architecture.** Syscall-refactoring approaches may change the current system architecture, e.g., mapping and binding devices to userspace. In contrast, UB keeps the current system architecture unchanged, including device driver and I/O harvesting models.

**DG3: Comparable performance to syscall-refactoring approaches.** UB aims to reduce the direct and indirect costs of syscalls, and achieve similar performance boost compared to syscall-refactoring approaches.

#### 3.1 Syscall-intensive Applications

We focus on optimizing applications of high IOPS, e.g., Redis and Nginx, which are also syscall-intensive. By analyzing their code and runtime behaviors, we identify the following two insights that guide the design of UB.

**Lightweight userspace instructions in I/O threads.** We find that the computation workloads between I/O events are usually lightweight for the examined applications. Moreover, the number of instructions between two consecutive syscalls

is usually small. One explanation is that such applications follow a popular I/O model that separates I/O-intensive workload from CPU-intensive workload in different threads. For example, Redis server has a main thread that dispatches accepted sockets to I/O threads [10], which conduct I/O from/to kernel and let the main thread complete the CPU intensive computation. With such a design, the instructions between I/O events simply handle buffer movement. We also profiled syscalls invoked by Redis (in total 3M), and found half of them are followed by less than 400 userspace instructions (around 200 cycles when IPC is 2) before the next syscall, which is faster than executing a syscall itself (e.g., 431 cycles [35] as described in Section 2.1).

**Amplified direct and indirect costs.** Section 2.1 overviews the direct and indirect costs of syscall in general, and those costs can be amplified in syscall-intensive applications. As shown in Figure 1, the frequency of entry and exit rises linearly following the frequency of syscall invocation. The indirect costs due to TLB misses, OOE stalls and cache misses are also non-negligible, especially when the syscall handles lighter tasks (IPC drops to 0.74 for no-op syscall, and 0.21 for `pwrite`, as shown in Figure 2).

#### 3.2 UB Modules

Based on the above considerations, we are motivated to design UB in a way that it can detect the occurrences of syscalls, and elevate the userspace instructions between consecutive syscalls to kernel through binary transformation. Figure 1 illustrates our idea. Although the idea seems simple at the high level, a few challenges should be addressed to enable UB for real-world, full-fledged applications.

- The application code is less trustworthy compared to the kernel code. Hence, necessary *isolation* should be performed to confine its capability after being moved to kernel. However, identifying the untrusted regions and governing them with the right policies are non-trivial.
- Given that isolation would incur extra costs, it is not always beneficial to transform every chunk of userspace instructions. But, when to perform transformation and how to reduce its overhead are unknown.

UB addresses these challenges with three key components. 1) A “hot” syscall identifier that monitors the execution of the target application, profiles the invoked syscalls, and determines when userspace instructions need to be elevated; 2) a *Just-in-Time (JIT)* translator that converts the userspace instructions into *Binary Translation Cache (BTC)* that is instrumented with isolation policies; 3) a *kernel BTC runtime* that executes the translated code. Figure 3 overviews the design of UB.

Note that the components in UB are not fundamentally new concepts. BTC is a standard component for Dynamic Binary Translation (DBT) [3, 22]. The JIT translator follows the guideline of Software-Based Fault Isolation (SFI) [44] in

code instrumentation and isolation policies. Yet, we find that the existing systems cannot be directly used in our problem setting. Below we briefly discuss the main modules in UB.

Figure 3: Overview of the UB framework. Every time a thread calls syscall (S1), hot syscall identifier hooks it (S2) and dispatches it to `do_syscall` (S3), after which kernel may return to user mode if the syscall is not hot (S6), or send it to BTC runtime for UB (S5).

**Hot syscall identifier.** This module runs in kernel mode and hooks each syscall. By analyzing the runtime statistics, it can identify which syscall instructions are *hot*, i.e., ones with high chances to be followed by another syscall shortly. The userspace instructions between two consecutive hot syscalls will be elevated to kernel and accelerated next time when the application runs. To avoid introducing large overhead due to runtime monitoring, this module runs intermittently.

**BTC translator.** The BTC translator converts the userspace instructions marked by the previous modules to BTC and has it executed by the kernel BTC runtime. Under the SFI guidelines, it converts dangerous instructions (e.g., indirect control-flow transfer) to the safe ones (e.g., direct jumps), and instrument checks to constrain memory access and control-transfer behaviors. The translator runs in a separate, independent userspace process to avoid introducing its code to kernel. The translation does not block the application execution, and the translated code is executed *next time* when the same code path is visited.

In addition to optimizing userspace instructions between a pair of hot syscalls, we also consider the acceleration on a *sequence* of hot syscalls. We call the enclosed userspace code *fast path*. UB aims to chain such userspace code and accelerate them altogether. The fast path is discovered incrementally by watching the jump targets. The details will be discussed in Section 5.

## 4 Hot Syscall Identifier

**Criteria of userspace bypassing.** A region of userspace instructions should be elevated when its performance gain out-

weighs the translation and instrumentation overhead by BTC translator. We measure the performance gain against different userspace path length (i.e., the number of instructions), and consider the regions with *short* path. The major reason is that the instrumentation costs increase rapidly for longer paths, because more instructions have to be monitored. We consider 1,000 instructions (termed  $T_{path}$ ) as the threshold for the short path length<sup>2</sup>. Through an empirical study, we observe obvious performance gain (over 20%) with this path length (see Section 6.2).

**Module design.** This module aims to discover hot syscalls that enclose a short userspace path. We resort to online analysis to achieve seamless profiling. Specifically, this module hooks syscall entry and counts the number of instructions between two consecutive syscalls. The two syscalls are classified as candidates of hot syscalls when the instruction number is less than  $T_{path}$ . Below we describe the detailed steps.

- **Syscall sampling.** Monitoring every syscall invocation will introduce high performance penalty to the application execution. Hence, we sample syscalls and conduct the follow-up analysis only when a thread is issuing syscalls frequently (e.g., I/O threads). According to our measurement on syscall-intensive applications (e.g., Redis and Nginx), at least 100K syscalls (termed  $T_{sys}$ ) are issued per second (6M per minute), and we choose to profile less than 10% of  $T_{sys}$  syscalls (up to 500K syscalls every minute). Therefore, most syscalls are not sampled and not interfered.
- **Coarse-grained profiling.** To further reduce the profiling overhead, we check whether a monitored thread invokes syscalls at high frequency. If the thread invokes less than 50K syscalls per second (half of  $T_{sys}$ ), the module will not conduct the next fine-grained syscall profiling. In this, the threads with low IOPS will be skipped.
- **Fine-grained profiling.** For a thread invoking syscalls frequently, this module further analyzes which syscall instructions are invoked frequently. The frequent ones deserve userspace bypassing as more performance boost can be gained. We monitor 15K syscalls (15% of  $T_{sys}$ ) of each round, and maintain a table recording, for each invoked syscall instruction, its location register (RIP) and a counter of how many times the next syscall is invoked within 4 microseconds (approximately the time of executing  $T_{path}$  instructions). We consider a syscall frequent when the counter is larger than 900 (6% of the profiled 15K syscalls). These syscalls and their enclosed userspace instructions will be handled by BTC translator in the next stage.

One might wonder if the performance of this module is sensitive to the parameter selection. To test the sensitivity, we

<sup>2</sup>Soares et al. consider the invocation of a syscall frequent if it is invoked once every 2,000 or less instructions [43]. We use a more conservative number to accommodate different platforms.

check if hot syscalls of Redis and Nginx, two applications used by our experiments, can be correctly discovered on three different machines: a PC with Core i5 10500 (year 2021), two servers with Xeon 8175 and 8260 (year 2017 and 2019). All hot syscalls can be correctly identified, suggesting parameter tuning could be skipped in most cases.

## 5 BTC Runtime and Translator

In this section, we describe how the BTC translator converts userspace instructions into kernel BTC and meets the security requirements. Our BTC translator follows the procedure of Dynamic Binary Translation (DBT) [19, 22, 48]. In general, given a path consisting of basic blocks in binary and triggering an event (e.g., hot syscall in our case), DBT disassembles it, translates it with a SFI rulebook, and compiles it to BTC for the future execution. Due to SFI, the malicious or unwanted behaviors of the translated code can be contained, and safely run by the BTC runtime.

### 5.1 BTC Runtime

The translated code block is executed by a BTC runtime in kernel. The BTC runtime holds local variables in kernel stack, which can be accessed by the instrumentation instructions within the BTC for policy enforcement and context switching. The local variables include: 1) the saved kernel context, i.e., callee-saved registers, 2) the values of reserved registers, and 3) the indirect jump destination information which is used to build the fast path.

Before executing the BTC, the runtime prepares the return status for userspace, i.e., through restoring the userspace context saved on syscall entry (e.g., `pt_regs` for x86\_64). After a block is finished, the runtime processes the return status of the BTC and takes further actions. The execution of a BTC might exit the runtime in the middle when the jump target is missing, e.g., when a new path is encountered. In this case, the runtime records the information about this jump and immediately returns to userspace, i.e., the jump target. We make the userspace memory accessible to the BTC runtime, so all changes on memory are kept. Changes made to registers are updated to userspace context (i.e., `pt_regs` for x86\_64), which will be written to registers when kernel returns to userspace. Therefore, userspace state changes made by the BTC are also preserved and visible to other threads, which ensures the application logic is not changed under UB.

The execution of the BTC might also exit when a syscall instruction is encountered. In this case, a fast path between two consecutive syscalls has been completely executed in kernel, which indicates a successful userspace bypass. The BTC runtime emulates the syscall trap, by looking up the syscall number against the syscall table and dispatching syscall parameters to the corresponding `do_syscall` function (i.e., executing the syscall). After `do_syscall` returns, the BTC run-

time checks if the next syscall instruction is again hot. If the answer is yes, the runtime tries to conduct another userspace bypass. In this way, `do_syscalls` and userspace bypass can be chained, which is similar to direct branch chaining of DBT. In an ideal case, *a whole thread can be executed in kernel*.

**Fast path discovery.** The performance of UB highly depends on the identification accuracy of fast path, and we leverage an incremental, JIT-style approach to achieve high accuracy. Given an entry address, i.e., the instruction next to a hot syscall, the BTC translator first discovers a part of the fast path, by disassembling the code segment of the target thread from the entry address iteratively. The potentially unreachable paths are skipped by the translator in each iteration. Specifically, the translator only follows *direct jumps* and stops at the call instructions, which forces the translator to handle code only within a function at one iteration and consider it fast path. When an indirect jump or call is indeed made later, the target information will be collected by the BTC runtime and sent to the translator to extend the fast path after replacing the jump instructions (see Section 5.2.1). Such an approach is similar to the one adopted by QEMU [9], but we do not lift the binary to its intermediate representation.

### 5.2 BTC Translator

Below we describe how the security policies are instrumented into the userspace code. We follow the SFI principles to provide *data-access policies* and *control-flow policies* [44] on *kernel*, and the implementations are inherited and extended from Nacl [52], which sandboxes the untrusted x86 native code in browser. Noticeably, Nacl assumes source code is available so SFI rules can be enforced under static compilation. In contrast, UB performs DBT on the binaries. As such, the SFI rules have to be adjusted and extended.

**Threat model.** We assume the userspace code is untrusted, which could contain *arbitrary* code and data, and the side-effects include unmediated access to kernel memory, privileged functions, etc. The goal of UB is to ensure the userspace code cannot gain more privilege (and do more harm) after it is elevated to kernel, i.e., protecting kernel's control-flow integrity. Noticeably, this goal is different from guaranteeing control-flow integrity [1] on the userspace application (elaborated in Section 5.3). We take a *conservative* approach in designing UB and avoid elevating a fast path when the consequences can not be immediately determined (e.g., the jump targets are unknown during translation). We focus on x86\_64 platform but the proposed techniques could be easily generalized to other platforms. Below we describe the implementations related to jump, register, instruction, and memory access that ensure security under this threat model.

### 5.2.1 Jump Sanitization

The inner sandbox of Nacl checks the *explicit* control flow expressed with calls and jumps, and disallows memory dereferencing on indirect jump and call instructions. The targets of jumps are confined within the sandbox. In contrast, the entire kernel memory space is open to elevated userspace code under UB. Therefore, we take different approaches to sanitize jumps.

**Direct jump.** To prevent the code in BTC from jumping to an arbitrary address, the translation only happens when the jump target is known. In other words, only direct jumps whose targets are known are processed. The address sanitization is described in Section 5.2.3.

**Indirect jump.** Yet, userspace fast path may contain indirect jumps, and we deter BTC from processing such path till the targets are known. In particular, the translator inserts checks that compare the targets against a *target address table* (similar to jumptable [22]) when encountering the associated code at first. If the target address is not in the table, the control flow will exit BTC runtime. When such an exit is triggered during executing a BTC block, the BTC runtime sends the jump instruction address (i.e., RIP of the address) and the target address to the BTC translator, and extends the fast path, as described in Section 5.1.

We show an example in Figure 4. The indirect jump (jump to RAX, located at 0x123) is initially translated to writing down the jump target (saving RAX to stack) and exiting to BTC runtime (jump to `exit_indirect_jump`). When the path P1 is firstly executed, the BTC runtime learns a target 0x456, and the information is sent to the translator, which updates the BTC by adding a target table entry. After that, the path P1 is added to the BTC, and it will not trigger `exit_indirect_jump` for the next time. If P2 is reached later, another destination 0x789 can be learnt and the BTC will be updated, so the fast path is further extended.

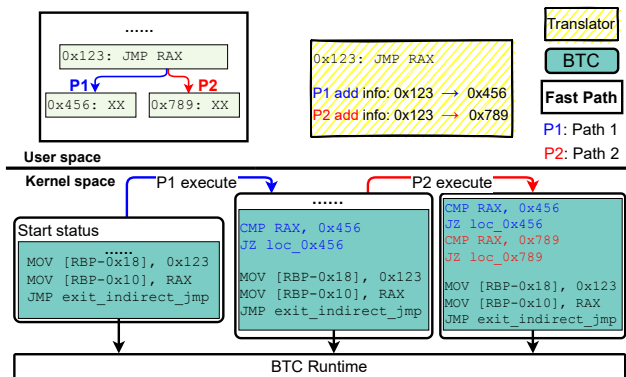

Figure 4: An example of translation under jump sanitation.

As the application runs longer, more indirect jump targets can be learned. The resulting BTC can eventually cover

the entire fast path. The checks inserted into the BTC can perform efficiently because: 1) indirect control-flow transfer instructions do not appear frequently, based on our empirical analysis on the syscall-intensive applications and previous studies [18]; and 2) CPU is allowed to speculatively jump to the destination under out-of-order execution without waiting for the destination check.

### 5.2.2 Register Remapping

To protect kernel registers and stack, the BTC translator disallows the BTC code to access stack registers (i.e., RSP, RBP, and RIP). Besides, some registers are reserved for BTC runtime and cannot be accessed by the BTC code as well. Hence we develop this module to manage the registers.

Specifically, the BTC translator uses the  $M$  reserved registers in BTC to serve the potential access to  $N$  registers ( $N = M + 3$ , 3 are for stack registers). As  $M < N$ , the translator needs to schedule registers. The  $N$  registers have their values stored in local variables, and the translator chooses one from the  $M$  reserved registers to temporally act as a special register with *renaming*. The translator also inserts code to synchronize the  $N$  registers to local variables on stack. As a result, the behaviour of the BTC code is the same as the fast path in the user space.

**Register reservation.** The translator reserves R12- R15 ( $M = 4$ ) for BTC runtime use, as they are the least frequently used in common userspace applications (less than 1% usage frequency [18]). When they appear in the fast path, renaming will occur. We also optimize our renaming mechanism for frequently-used special registers (i.e., RSP), by letting the translator fix the reserved registers to hold their values. Doing so reduces the occurrences of the costly register synchronization.

### 5.2.3 Instruction Sanitization

Privileged instructions (e.g., `sysret`) are not allowed to appear in the BTC, to avoid privilege escalation by the malicious code that exploits UB. During translation, the translator avoids elevating a fast path to the kernel if it contains any privileged instruction.

Due to register remapping, some instructions have to be rewritten. For stack operation instructions like `PUSH/POP`, the translator substitutes them with multiple instructions. Take `POP` as an example. The translator first adds an instruction to `MOV` the operand to the popped target from the memory addressed by the reserved register (i.e., the acting stack pointer), and then updates the reserved register with the new stack pointer value, i.e., plus 8.

### 5.2.4 Memory Access Sanitization

To prevent unauthorized access to the kernel memory, the translator sanitizes all memory access instructions. For ev-

ery such instruction, the translator inserts address checking instructions before the instruction, such that only userspace addresses are allowed to be accessed, i.e., the addresses start with 0. Similar to address masking of SFI [44], the translator shifts left the address by one bit and then shifts it right by one bit, to fulfill the address requirement. Two extra instructions (i.e., `SHL` and `SHR`) are introduced to this end, but our evaluation suggested the extra overhead is negligible (0.4%). Note that the added checks do not prevent BTC from accessing *unmapped* memory region and triggering page fault, and we handle it with the procedure described below.

**Page fault handling.** We modify the page fault handler to monitor the page fault events. For minor fault and major page fault, the page fault handler behaves the same for kernel mode and userspace mode. Therefore, faults caused by the userspace applications are resolved in the same way as without UB. When invalid page fault (i.e., illegally accessing some memory regions) happens, the execution of BTC code is aborted.

Nacl also isolates the memory space between the extensions and the host browser, with the help of the segmentation provided by x86 CPUs. As such, extensions' instructions can only access memory within a segment and instructions to modify segment states are not allowed. However, although `x86_64` still provides segmentation, it only adds a segment offset to the address but does not check segment boundary, which cannot be directly used for memory isolation.

### 5.3 Security Guarantees

The translated BTC has the following security properties (termed SP), and they jointly make UB fulfill SFI policies [44] on kernel.

**SP1: Kernel control-flow integrity (CFI) for BTC.** This property is guaranteed because when the BTC runtime hands control flow over to the userspace, the execution will only terminate through the exit point. More importantly, when the runtime executes the BTC, the thread cannot jump to a location unknown to the translator. For direct control-flow transfer, the destination can only be a label of a known basic block that has been translated. Indirect control-flow transfers are all translated to direct transfers by replacing the destinations. Therefore, the BTC prevents malicious code from hijacking the kernel control-flow after it is elevated.

We want to point out that UB does not claim to add extra protection against control-flow hijacking, e.g., ROP, JOP, COOP [4, 6, 8, 37, 41], and they can still occur in userspace. Though the attacker can construct gadgets when the destination checks are passed, jumping to the kernel code segment from BTC is never allowed, as it can be detected and aborted by the translator.

**SP2: Kernel data (memory and register) integrity.** For kernel context (or registers), we design BTC runtime to be compatible with the calling conventions, and the caller (kernel)

context is saved on the stack before jumping to the BTC, which is recovered before returning to kernel instructions. The context switching is lightweight, as it does not cause privilege transfer.

For kernel memory, access sanitization ensures that no kernel memory can be accessed by the sanitized instructions, hence the kernel stack will not be tainted. Though runtime local variables must be accessible by the instructions in BTC, they cannot be exploited by malicious programs to touch the kernel stack. Only intentionally inserted instructions can touch the local variables referred by the stack base pointer, which stores runtime information like swapped-out registers (see Section 5.2.2). Because kernel CFI is guaranteed, execution would never jump to these instructions.

**SP3: No privileged instructions in BTC.** It is explained in Section 5.2.3.

**SP4: Dead loop break.** We also consider the attacks and bugs against the *availability* of the system resources. For instance, userspace applications may fall into a dead loop because of bugs or intentionally. As a countermeasure, the translator maintains a counter in BTC runtime to keep track of the number of instructions already executed. Once the counter exceeds a threshold, the execution flow can exit to runtime and in turn return to userspace, which avoids the kernel being blocked by the BTC code.

### 5.4 Thread Safety

Special attention should be paid to multi-thread userspace applications, because UB has no control over other threads except the one elevated to kernel. Memory order and atomicity have to be preserved to avoid data race. Fortunately, thread safety is automatically guaranteed by the translator and we explain it below.

**Memory order.** To preserve memory order, the translator regards all userspace memory as *volatile*, and only inserts instructions between userspace instructions without optimizing the block (e.g., reordering instructions or caching memory modification in registers). Yet CPUs can still reorder memory loads and stores according to their memory model. The original memory fences placed by the userspace applications are all inherited, and the translator does not insert extra fences.

**Atomicity.** The translator takes special measures to guarantee atomicity when using multiple instructions to emulate one userspace instruction. When translating an instruction, the translator prefers to use one instruction that has the same opcode as the original one. Hence, the atomicity of the original instruction is automatically preserved. For example, instructions with a lock prefix are translated to ones still with lock (e.g., `LOCK MOV`). If more than one instruction is needed for emulation, memory load or store must be completed in a single instruction. For example, when translating `PUSH RIP`, the offset address of the next instruction must be moved to the

userspace stack top. From the view of the translator, when BTC runtime reaches the instruction, the value of `RIP` is statically known and becomes an immediate number. However, `x86_64` does not have an instruction to directly move a 64-bit intermediate value to memory. As a result, the translator generates instructions that first move the immediate value to a 64-bit reserved register and then move the 64-bit register to the top of the userspace stack.

## 6 Evaluation

We implement the prototype of UB for Linux kernel 5.4.44. The BTC runtime is implemented as a kernel module with 416 lines of C code, which hooks syscall epilogue to conduct syscall identification and manage BTC runtime. The translator is implemented with 786 lines of Python code at userspace (except the dependant Python disassembler `miasm` and gcc assembler `as`), which communicates with the BTC runtime kernel module via `sys` file. The kernel is modified by adding only 6 lines of codes to the syscall entry to allow the module to hook syscalls.

We evaluated our prototype in an I/O micro-benchmark and two real-world applications (Redis and Nginx) for macro-benchmarks. It is also compared to related technologies including DPDK, `io_uring`, and eBPF. To evaluate these applications, we set up a virtualized environment and a bare-metal environment. The bare-metal environment consists of a client machine and a server machine<sup>3</sup>, which are connected within the 40G Ethernet LAN. The virtualized environment runs on the server, with NIC pass-through being enabled. For the micro-benchmark I/O experiment, we run the tests directly on server, as it does not require network. For other scenarios, we run the client application in the client machine and the server application in the server machine, so the traffic goes through the physical network. To show the effects of virtualization and KPTI, which impact the syscall performance as explained in Section 2.1, we run each server application in four settings: KPTI on/off  $\times$  VM/physical machine. When KPTI is on, Linux turns on PCID to mitigate performance degradation. All the following tests are conducted 10 rounds, and the average IOPS or Requests Per Second (RPS) values are shown. For the results demonstrated in Section 6.1 to Section 6.4, we focus on the setting of VM with KPTI on and briefly describe how the results are changed under other settings. In Table 2, we list the acceleration ratios among different settings.

<sup>3</sup>The server machine has an Intel Xeon 8175 CPU (24 cores), 192GB memory, Samsung 980 pro NVME SSD, and Mellanox Connectx-3 NIC. It runs Ubuntu 20.04 with 5.4.44 kernel. When set up for VM, it uses QEMU-KVM 1:4.2-3, and assigns 24 cores to the VM. The client machine has an Intel Xeon 8260 CPU, 128GB memory and Mellanox Connectx-5 NIC.

Table 2: Ranges of acceleration ratios for different settings. “In-mem” means the in-memory file access benchmark.

### 6.1 I/O Micro-benchmark

We first consider accelerating a thread that purely performs file I/O requests via blocking syscalls as the micro-benchmark, which approximates the best-case scenario for UB. The thread runs a tight loop that sequentially reads files from kernel to userspace buffer via `READ` syscall 8.39 M times. The real-world applications may exhibit different patterns like executing more instructions between consecutive I/O requests, reducing the acceleration ratios by UB. For comparison, we employ `io_uring` (liburing-2.2) for the same task (i.e., tight-loop `READ` syscall) and compare the IOPS.

**In-memory file access.** We create a large file in ramfs to avoid possible disk bottleneck, in order to assess how UB accelerates syscalls more accurately. Admittedly, this setting makes the micro-benchmark less realistic. We gradually increase the size of the buffer for each read and evaluate the acceleration ratios of UB under different buffer sizes.

Figure 5 shows the results. For the virtualized environment with KPTI on, UB accelerates syscall-based I/O by  $88.3\% \pm 0.75\%$ <sup>4</sup>, when the I/O size is small (64B). For larger I/O size, IOPS drops for both UB and baseline, and the acceleration ratio drops to  $30.3\% \pm 0.96\%$  for the 4KiB I/O size, because fewer syscalls are invoked. Turning off KPTI increases the IOPS, but the acceleration ratio of UB drops to  $14.3\% \pm 1.83\%$  –  $41.6\% \pm 1.73\%$ , because the syscall overhead is reduced. The acceleration on physical machine is higher especially when the I/O size is small (e.g.,  $112.9\% \pm 1.78\%$  when the I/O size is 64B when KPTI is on), as the IOPS on physical machine is higher and UB saves more context switching overhead.

For `io_uring`, we first examine the different queue depths (i.e., how many requests can be batched) from 1 to 1024, and found IOPS is stable after the depth reaches 128, as shown in Figure 6. Hence, we set the depth to 128 for its comparison with UB. It turns out `io_uring` yields more IOPS for most buffer sizes, according to Figure 5. When running in physical

<sup>4</sup>We report the acceleration ratio together with the standard deviation.

Figure 5: IOPS of READ syscalls, io\_uring and UB syscalls against different buffer sizes. The percentage number is the acceleration ratio of UB against the baseline. Figure 7, 8, 9 and 10 follow this style.

Figure 6: IOPS of different io\_uring depth.

machine, for the small size (64 Byte), UB yields higher IOPS than io\_uring, though it is expected io\_uring should always outperform UB. We have not found a good explanation, but we notice that IOPS of io\_uring increases by 13% when upgrading the Linux kernel from 5.4.44 (the version used by our testing environment) to 5.15. Hence, it is possible that io\_uring will outperform UB consistently on newer Linux.

**File access on NVMe.** We also test reading a file in NVMe disk by 1KiB block size, and show the comparison in Table 3 (“w/o sum”). We only consider the physical machine setting, because when VM accesses a file in a virtual NVMe disk, the file will be automatically cached into memory a priori, which behaves similarly to in-memory file access. The IOPS can be increased from 779 $\pm$ 5K to 852 $\pm$ 3K, yielding 9.4% $\pm$ 0.3% acceleration (KPTI on). When KPTI is off, the baseline increases to 810 $\pm$ 22K while UB increases slightly to 858 $\pm$ 10K, making the acceleration ratio smaller.

We also consider the situation that an I/O thread conducts

lightweight calculation, like parsing packets. When the computations between consecutive I/O requests have dependency, the requests cannot be batched. Specifically, we set the I/O thread to calculate the sum of the buffer by treating it as a 64-bit integer array, after retrieving the buffer from kernel.

	w/o sum	w/ sum
<b>KPTI on</b>	779 $\pm$ 5 (852 $\pm$ 3)	630 $\pm$ 4 (793 $\pm$ 3)
<b>KPTI off</b>	810 $\pm$ 22 (858 $\pm$ 10)	686 $\pm$ 65 (795 $\pm$ 6)

Table 3: KIOPS of reading file on NVMe disk (1KiB size) on physical machine (w/o sum), and reading together with integer summation (w/ sum). The UB accelerated number is shown in the bracket.

As shown in Table 3 (“w/ sum”), even the lightweight computation could reduce considerable amount of IOPS. The baseline IOPS drops by 149K, while it only drops by 59K when UB is on, as such lightweight calculations in userspace can be entirely ported into kernel for execution, so their IPC is less affected by syscalls.

## 6.2 Redis

We choose a popular key-value store engine Redis as one macro-benchmark to test how UB handles real-world workloads. We evaluate Redis 6.2.6 with the built-in Redis benchmark tool [39] to generate workload. We run the Redis server with its default configuration and launch the Redis benchmark with 2 threads. The connection number is kept at the default value 50. In each round, the client issues 1M requests.

By default, Redis completes most of its work within the main thread, which is responsible for not only I/O but also computation tasks like hashing. For a normal workflow, which is also described in [30], the main thread invokes EPOLL to get a list of readable sockets. For each readable socket, the thread READs the socket and then processes the request. As a result, the userspace paths following READs are long (from 3k to 20k), as the computation tasks happen there. At last, Redis WRITES responses to corresponding sockets one by one, with a small number of instructions in between (around 300).

**Results.** Figure 7 shows RPS with and without UB for GET and SET data of sizes ranging from 1B to 16KiB. When tested in VM with KPTI on, for GET, the acceleration ratio ranges from 4.4% $\pm$ 1.52% to 10.8% $\pm$ 2.69%, when the data size is less or equal than 4KiB. The ratio drops to -3.7% $\pm$ 0.51%, when the size rises to 16KiB. Turning KPTI off drops the acceleration ratio to between -2.0% $\pm$ 1.32% and 4.6% $\pm$ 1.96%. The negative acceleration ratio suggests the overhead brought by UB outweighs the syscall overhead saved by itself. Executing on physical machine observes a different range: -5.4% $\pm$ 1.17% to 6.4% $\pm$ 2.01% for KPTI on and -6.4% $\pm$ 3.02% to 3.9% $\pm$ 1.67% for KPTI off. Noticeably, the RPS of Redis is much smaller

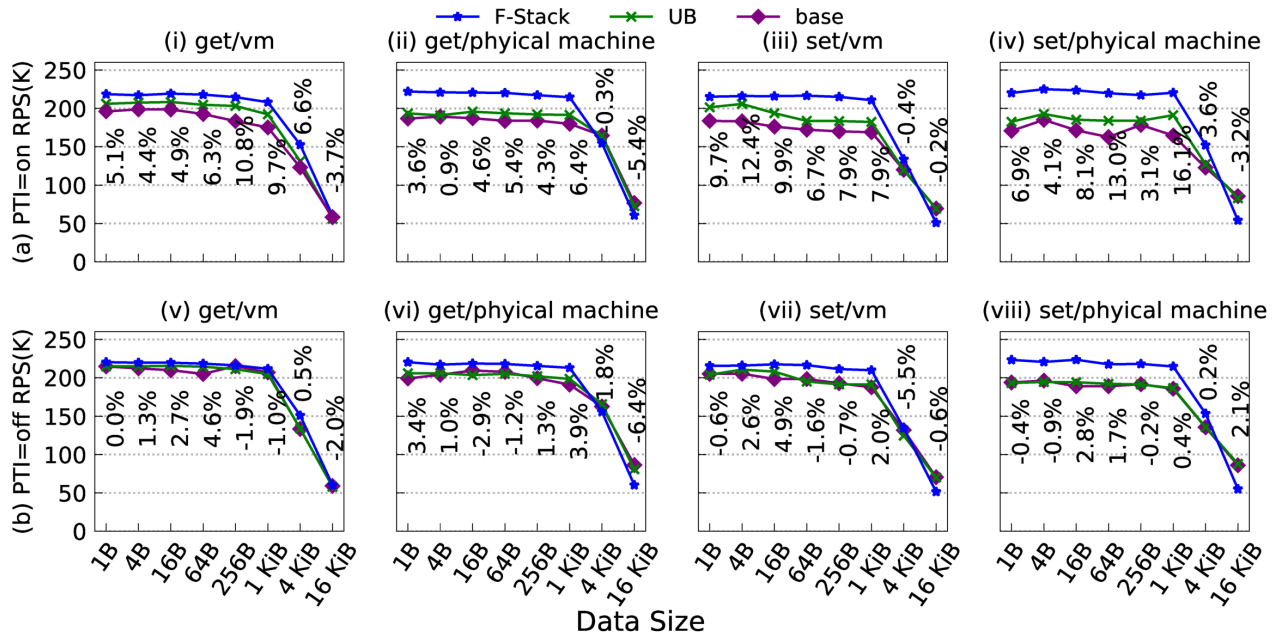

Figure 7: RPS of Redis GET and SET in different data sizes.

than that in our I/O micro-benchmark, so the expense from syscall is not the dominant factor. As a result, the acceleration ratio is much smaller.

Regarding SET, the acceleration ratio ranges from  $-0.4\% \pm 2.19\%$  to  $12.4\% \pm 3.96\%$  in VM with KPTI on. Similar trend is observed when KPTI is turned off and running in physical machine. Noticeably, Redis RPS drops significantly over 1KiB data size for both SET and GET, and similar observation was reported in the official documentation of the Redis benchmark [39].

Surprisingly, we found the RPS on VM is often higher than physical machine, though the virtual setup is supposed to yield lower RPS. We do not have a good explanation for why the opposite happened for Redis.

	Redis Server	BTC	User Space	Do Write
w/o UB	108.57	-	34.29	36.73
w/ UB	102.98	2.42	28.38	36.07

Table 4: Time spent on each part of Redis (VM+KPTI, SET).

**Profiling performance gain.** We let the BTC runtime profile BTC execution and userspace execution using the RDTSCP instruction. We run 20M Redis SET transactions (about 100 seconds) with and without UB. Table 4 shows the results. As we can see, by elevating the fast path to BTC, 5.91s userspace time can be saved, while the BTC only costs 2.42s. The difference (3.49s) can be attributed to the userspace IPC increase (indirect overhead). 5.59s are saved in total (the “Redis Server” column) and 2.1s (i.e., 5.59s - 3.49s) are saved directly by invoking fewer syscalls.

**Overhead of memory checks.** When strong kernel memory safety is unnecessary, e.g., when the binary is formally verified, a user may choose to chase higher performance gain by removing the instructions inserted to check memory boundary (i.e., SHL and SHR). We evaluate how much RPS gain can we get if we ask the translator not to insert such instructions. The results show that only 0.4% more RPS can be gained.

**Comparison with DDPK.** We compare the acceleration ratio of UB on Redis with that on DDPK as there are open-source implementations to empower Redis, like Redis-DDPK [2] and F-Stack Redis [45]. We chose F-Stack as the maintenance of Redis-DDPK has stopped since 2017 and it cannot run on the latest CPUs. F-stack supports the recent Redis 6.2.6 [46] as well as the recent DDPK 20.11. The comparison result is also shown in Figure 7.

It turns out F-Stack provides higher acceleration ratios for small size consistently (no larger than 4KiB). Interestingly, we found for 16KiB, F-Stack performs worse than UB and Redis baseline. One potential explanation is that F-Stack does not benefit from our multi-core setting. When we measure the CPU usage, it is always 100% for F-Stack, but UB and baseline can go up to 124%, which means multiple cores are used. Hence, F-Stack might outperform UB consistently when we restrict the core number to 1.

### 6.3 Nginx

In addition to Redis, we use Nginx (Version 1.20.0), a popular static web server with high RPS, as another macro-benchmark. Table 5 shows the number of instructions in the path followed by each syscall. These followed by less than 1,000 instruc-

syscall	recvfrom	openat	fstat	setsockopt	writew	sendfile	close	setsockopt
#Instructions followed	4,328	38	4,412	43	177	541	477	509

Table 5: Number of instructions following each syscall of Nginx. Those followed by less than 1,000 instructions are hot. The two setsockopt calls are different.

tions can be regarded as hot. Therefore, 6 out of the 8 can be accelerated. We run wrk [50] (Version 4.1.0, with 8 threads and 1024 connections), an HTTP benchmark tool, on the client machine to issue requests to the Nginx server for 12s to examine how much RPS Nginx can handle.

Figure 8: RPS of Nginx against different file sizes (Bytes).

**Results.** We gradually increase the file size requested by wrk and Figure 8 shows the RPS before and after UB acceleration. When being tested in VM with KPTI on, Nginx can be accelerated by  $9.6\%_{\pm 1.81\%}$  to  $10.9\%_{\pm 0.22\%}$  for 1KB to 64KB files, but the ratio drops to  $0.4\%_{\pm 0.86\%}$  for 256KB file. For physical machine, the acceleration ratio ranges from  $6.3\%_{\pm 0.17\%}$  to  $13.4\%_{\pm 3.32\%}$  for 1KB to 64KB files, but also drops to  $-1.4\%_{\pm 0.28\%}$  for 256KB file. These results show the bottleneck shifts from syscall to I/O for large files. When turning off KPTI, UB does not yield noticeable acceleration.

**Multiple worker threads.** We evaluate how multi-threading affects the acceleration ratio. We gradually increase the number of worker threads of Nginx and evaluate the case of 4KB file size. Figure 9 shows the RPS. As we can see, with more worker threads, the acceleration ratio drops noticeably when KPTI is on (from  $8.6\%_{\pm 0.22\%}$  to  $7.1\%_{\pm 0.17\%}$  for VM and  $4.7\%_{\pm 0.15\%}$  to  $2.0\%_{\pm 0.26\%}$  for physical machine), as the worker threads are increased from 2 to 8. When there are more worker threads, more cycles are used for thread synchronization, so fewer requests can be served per thread, reducing the syscall overhead saved by UB.

Figure 9: RPS of Nginx against different # of threads.

## 6.4 Raw Socket vs. eBPF

To avoid the syscall overhead, eBPF is another popular solution as described in Section 2.2. We show that, with the help of UB, developers can simply write the processing logic entirely in userspace with *raw socket*, and compare Packets Per Second (PPS) with eBPF.

We run a program on the client machine to send UDP packets to the server, and the server handles the incoming packets by either raw socket or XDP (eBPF library for packet processing) for 12s in each round. The client runs 15 threads, which can saturate the server. The processing tasks include counting the number of packets and summing packets by treating a packet as an integer array.

**Results.** Figure 10 shows the results by 3 packet sizes (128B, 512B, and 1472B). For VM with KPTI on, eBPF outperforms raw socket for small packets by up to  $368.4\%_{\pm 8.92\%}$ . For packets of MTU size (i.e., 1472B), eBPF still has  $236.7\%_{\pm 4.15\%}$  more PPS. UB accelerates raw socket by  $31.5\%_{\pm 0.25\%}$  –  $34.3\%_{\pm 0.72\%}$ , which are much smaller than eBPF. The PPSs for raw socket are similar across different packet sizes. However, eBPF is very sensitive to packet size, and we believe it is because the bottleneck of raw socket is protocol stack processing, which is bypassed by eBPF whose bottleneck may be the data movement, whose time consumption is related to packet size. When KPTI is off, the acceleration ratio of UB drops to  $14.5\%_{\pm 0.45\%}$  –  $17.8\%_{\pm 0.44\%}$  for various packet sizes. On physical machine, the acceleration ratios of UB

Figure 10: PPS of server handling incoming UDP packets in different packet sizes.

have larger ranges ( $30.9\%_{\pm 0.87\%} - 38.6\%_{\pm 0.56\%}$  for KPTI on and  $9.2\%_{\pm 0.14\%} - 19.8\%_{\pm 0.31\%}$  for KPTI off).

**Computation.** We also consider adding lightweight computation workload, i.e., packet summing, like the experiments for NVMe file access (Section 6.1). In VM, the PPS of raw socket sees greater drop when the packet size increases, but UB can still accelerates raw socket in similar ratios ( $30.1\%_{\pm 0.20\%} - 31.8\%_{\pm 0.50\%}$  for KPTI on and  $10.1\%_{\pm 0.18\%} - 20.1\%_{\pm 0.15\%}$  for KPTI off). eBPF is able to keep the similar PPS without packet summing. On the physical machine, similar trend is observed for raw socket, UB, and eBPF, except that eBPF sees considerable drop of PPS for 512B packet size and KPTI on.

**Profiling execution performance.** We profile the execution time of BTC and eBPF respectively for the case of packet summing with `RDTSCP`, like our experiments on Redis (Section 6.2). In VM with KPTI on, for handling 33.85M incoming packets of 128B, BTC spent 5.86s. In contrast, eBPF costs 9s. As we can see, the execution performance of BTC is better than eBPF VM. However, UB still cannot achieve similar PPS to eBPF based on the previous results. According to our analysis, the reason is that eBPF runs in `softirq`, so the packets can be dispatched into different cores. In contrast, the raw socket protocol stack has in-kernel locks for concurrent access. In particular, we added more threads for socket read, but did not see PPS increase at all. We also tried to assess how eBPF works without multi-threading, by restricting the IRQ of the NIC to a single core and repeating the sum experiment in VM with KPTI on. UB-accelerated socket reaches 1M, 0.96M and

0.93M PPS for the three packet sizes, while eBPF reaches 0.96M, 0.93M and 0.91M PPS respectively. Therefore, we believe the PPS of raw socket can be significantly improved if kernel optimizes its protocol stack for concurrent access. One potential approach is to build a better UB runtime so more deeper kernel trace points can be exposed via syscall, and we leave this as a future work.

## 7 Discussion

### 7.1 UB vs. eBPF

In addition to the comparison on the performance between UB and eBPF, here we compare their restrictions and security guarantees. As eBPF is developed mostly for packet processing and kernel tracing, it has a number of restrictions on the application code. For example, eBPF is not Turing Complete, as infinite loops are not allowed [33]. Due to its extensive restrictions on code, the eBPF verifier is prone to produce false positives, i.e., legal code regarded as illegal [14]. UB does not add any restrictions to developers and translates the userspace code transparently.

Regarding performance, UB only accelerates the paths following syscalls, but eBPF can be attached to many tracing points inside kernel, which makes it more flexible and capable of overcoming kernel bottlenecks. We believe UB could realize similar performance as eBPF, if kernel exposes more tracing points via syscalls.

In terms of security, eBPF relies on the isolation from in-kernel VM, while UB relies on the policies of SFI translator. Attacks targeting eBPF might be effective against UB as well, as described in Section 7.2. Formally verifying the implementation of eBPF and UB could mitigate these issues, but verifying eBPF is likely easier than UB, because eBPF has an official specification and it uses a reduced set of instructions.

## 7.2 Security Risks

Though we follow the SFI principles to design UB, new security risks could be introduced. First, UB might be vulnerable under side-channel attacks, which infer the secrets according to micro-architectural state changes. For instance, the Spectre attack has demonstrated that eBPF can be exploited to steal kernel memory, as eBPF VM compiles userspace code into kernel code [25]. The BTC of UB may also be exploited for similar attacks. To mitigate such risk, defenses against speculation attacks should be considered, e.g., placing speculation blocking instructions by the compiler [25]. Second, our BTC translator might not be able to sanitize privileged undocumented X86 instructions. To mitigate the introduced risk, the translator could allow a whitelist of instructions. When instructions outside the whitelist are encountered, UB should give up elevating their fast path. Third, previous research showed kernel races can lead to time-of-check to time-of-use (TOCTOU) attacks [28]. Since the BTC runtime does not enforce atomicity between the checking point and the use point for the fast path, the malicious userspace code can exploit kernel races. The mitigation can rely on the existing defenses that detect kernel races actively [20].

## 7.3 Other Limitations

Admittedly, kernel-bypass frameworks like DPDK could achieve better performance than UB, when the developers take the right measures to integrate them into the userspace applications. The better performance not only comes from the reduction of context switching overhead, but also the simplified and more efficient userspace drivers. For example, userspace drivers could avoid unnecessary buffer copying, interrupt, etc. In contrast, UB only reduces the context switching overhead. The key advantage of UB is that it does not require any change on the applications by the developers (see Table 1). Therefore, we believe kernel bypass would be favored when the developers are willing to refactor their code or design a new application with kernel bypass in mind.

UB does not aim to replace asynchronous I/O. Admittedly, when an application is both computation-intensive and I/O intensive, asynchronous I/O helps the developers decouple I/O from computation in different threads, making better use of multi-cores. UB does not give synchronous I/O tasks more IOPS than asynchronous tasks, but it can be used jointly with asynchronous I/O. In some cases, the I/O threads of asyn-

chronous tasks still intensively invoke syscalls to submit I/O and UB can accelerate these tasks.

## 8 Related Work

Section 2 has surveyed related works about syscall optimization. Below we describe other related works.

**Dynmaic Binary Translation (DBT).** DBT is a powerful method for debugging and instrumentation [3, 19, 22, 48]. Kedia et al. proposed a fast DBT in kernel to instrument kernel code [22]. Our translator has some similarities with theirs in indirect branch processing, but our translator differs largely in memory protection and register renaming. Besides, some functionalities of their runtime require rollback. In contrast, our runtime never rolls back.

**Software-Based Fault Isolation (SFI).** Enforcing SFI in kernel is not an entirely new idea. XFI was firstly proposed to isolate kernel modules with SFI, and later LXFI added kernel API check to restrict the fault propagated via kernel APIs [13, 32]. UB uses SFI in a different way for the fast path.

**Accelerating Inter-Process Communication (IPC).** Some schemes were proposed recently to exploit hardware assistance to accelerate IPC. Similar to accelerating system calls, they also try to minimize context switching overhead. Gu et al. proposes to accelerate IPC with the help of recent innovation in Intel processors, i.e., MPK [16]. Mi et al. borrows a hardware function designed for virtualization to accelerate IPC [35]. Du et al. proposes to add new features to CPU for context switching without involving kernel [12]. They implemented the prototype on RISC-V FPGA processors.

## 9 Conclusion

The overhead brought by syscalls is prominent to high-IOPS applications, but the existing approaches have not completely addressed this issue, because they require efforts in code refactoring. To preserve binary compatibility, we propose userspace bypass (UB) that executes userspace instructions directly in kernel. UB employs a JIT translator that translates userspace instructions between syscalls into sanitized code blocks. The code blocks are constrained to avoid introducing extra harm, therefore they can be executed directly in kernel. With UB, I/O micro-benchmark can be accelerated by 30.3 – 88.3% and real-world applications like Redis can be accelerated by 4.4 – 10.8% for 1B – 4KiB data sizes under GET, when the applications are executed in VM with KPTI on.

## A Artifact Appendix

### Abstract

Our artifact includes the source code of UB, and the apps we used for evaluation. The readers can follow the instructions to modify the Linux kernel to support UB, compile UB to run on it, and evaluate the apps on it.

### Scope

The IOPS of all the apps we evaluated can be reproduced. Specifically, Figure 5, Figure 7, 8, 9 and 10. Reproducing the I/O benchmark is the most convenient case. Therefore, it is recommended to start from Figure 5.

The whole experiment can be time-consuming, so people may take fewer repeat rounds to save time.

### Content

The artifact includes the implementation of UB, which consists of the three files to be modified over Linux Kernel (zz\_lkm, zz\_daemon, and zz\_disassem). zz\_lkm is the kernel part of UB, which profiles processes and executes the BTC. zz\_daemon sits at userspace to communicate with the kernel module and invoke zz\_disassem to do the actual translation.

### Hosting

The source codes are hosted at <https://github.com/glaerer/UserspaceBypass>, as well as the readme file.

### Requirement

The I/O benchmark experiment requires only a server machine. Because Redis, Nginx, and raw socket experiments involve network, another client machine is required to be connected to the server.

The IOPS is highly related to CPU performance. Therefore, the reproduced IOPS values may be different by different CPUs, but we can always see the performance gain.

The IOPS can also be disturbed by network performance. If the NIC used is not sufficiently powerful, the IOPS may drop for large I/O size, as well as the performance gain.

# Triangulating Python Performance Issues with SCALENE

## Abstract

This paper proposes the SCALENE Python profiler. SCALENE precisely and simultaneously profiles CPU, memory, and GPU usage, all with low overhead. SCALENE’s CPU and memory profilers help Python programmers direct their optimization efforts by distinguishing between inefficient Python and efficient native execution time and memory usage. SCALENE’s memory profiler employs a novel sampling algorithm that lets it operate with low overhead yet high precision. It also incorporates a novel algorithm that automatically pinpoints memory leaks within Python or across the Python/native boundary. SCALENE tracks a new metric called copy volume, which highlights costly copying operations that can occur when Python silently converts between native and Python data representations, or between CPU and GPU. Since its introduction, SCALENE has been widely adopted, with over 675,000 downloads to date. We present experience reports from developers who used SCALENE to achieve significant performance improvements and memory savings.

## 1 Introduction

Python is now firmly established as one of the most popular programming languages, with first place rankings from TIOBE [42] and IEEE Spectrum [6], second place on the Redmonk Rankings [24], and fourth place in the 2022 Stack Overflow Developer Survey [38]. Large-scale industrial users of Python include Dropbox [4], Facebook [18], Instagram [15], Netflix [22], Spotify [47], and YouTube [44].

At the same time, Python is (in)famously slow. The standard Python implementation, known as CPython, is a stack-based bytecode interpreter written in C [48]. Pure Python code typically runs 1–2 orders of magnitude slower than native code. As an extreme example, the Python implementation of matrix-matrix multiplication takes more than 60,000× as long as the native BLAS version.

Python’s performance costs are nearly matched by its high memory overhead. Python data types consume dramatically

more memory than their native counterparts. For example, the integer 1 consumes 4 bytes in C, but 28 bytes in Python; “a” consumes 2 bytes in C, but 50 bytes in Python. This increased space demand is primarily due to metadata that Python maintains for every object, including reference counts and dynamic type information. Python is a garbage collected language; because garbage collection delays memory reclamation, it can further increase the amount of memory consumed compared to native code [14].

Because of these costs, one of the most effective ways for Python programmers to optimize their code is to identify performance-critical and/or memory-intensive code that uses pure Python, and replace it with native libraries. Python’s ecosystem includes numerous high-performance packages with native implementations, which are arguably the key enabler of its adoption and popularity. These libraries include the NumPy numeric library [25], the machine learning libraries SciKit-Learn [29] and TensorFlow [2, 3], among many others. By writing code that makes effective use of these packages, Python programmers sidestep Python’s space and time costs, and at the same time take full advantage of hardware resources like multiple cores, vector instructions, and GPUs.

Unfortunately, past Python profilers—which can be viewed as ports of traditional profilers for native code—fall short. We believe Python programmers need a profiler designed from the ground up to meet the specific challenges of developing high performance Python applications.

This paper proposes SCALENE, a profiler that comprises a suite of profiling innovations designed specifically for Python. Unlike all past Python profilers, SCALENE simultaneously profiles CPU, memory usage, and GPU usage. It provides fine-grained information targeted specifically at the problems of optimizing Python code. In particular, SCALENE teases apart time and memory consumption that stem from Python vs. native code, revealing where programmers can optimize by switching to native code. SCALENE reports a new metric, *copy volume*, that helps identify costly (and often inadvertent) copying across the Python/native divide, or copying between CPU and GPU. Its memory profiler accurately tracks memory

**Figure 1: SCALENE vs. past Python profilers.** SCALENE provides vastly more information than past Python profilers, with more accurate memory profiling (§6.3) and with low overhead (§6.4, §6.5). Most past profilers (§8.5) exclusively profile either CPU time or memory; SCALENE simultaneously profiles CPU, GPU, and (optionally) memory, and comprises a suite of unique features backed by novel algorithms.

consumption over time, and automatically identifies memory leaks, whether within Python or in native code. Its GPU profiler tracks GPU utilization and memory consumption, letting it identify when native libraries are not being used to their best advantage. At the same time, SCALENE imposes low overhead (median: 0% for CPU+GPU, 32% for CPU+GPU+memory). SCALENE’s design addresses the substantial differences between Python and past environments such as JVMs, including the widespread use of native libraries, the resulting reduced usage of garbage collection, and its popularity for machine learning applications that make GPUs a first-class concern.

Since its introduction, SCALENE has become a popular tool among Python developers, with over 600,000 downloads to date. We report on case studies supplied by external users of SCALENE, including professional Python open source developers and industrial users, highlighting how SCALENE helped them diagnose and then remedy their performance problems, leading to improvements ranging from 45% to 125×.

This paper makes the following contributions: it proposes SCALENE, a profiler specifically tailored to Python; it presents several novel algorithms, including its algorithm for attributing time consumption to Python or native code; its sampling-based memory profiling that is both accurate and low overhead; and its automatic memory leak detector, which identifies leaks with low overhead. It also introduces and demonstrates the value of a new metric, *copy volume*, that surfaces hidden costs due to copying.

The next sections explain SCALENE’s implementation and algorithms. We first outline how SCALENE efficiently performs line-level CPU profiling, focusing on its approach to

teasing apart time spent running in the Python interpreter from native code execution and system time (§2). We then describe SCALENE’s memory profiling component (§3), including its *threshold-based* sampling approach that reduces overhead while ensuring accuracy, its memory leak detection algorithm, and how it tracks copy volume. We then explain how SCALENE profiles GPU utilization and memory consumption (§4). Finally, we present technical details underpinning SCALENE’s user interface (§5). We then present our evaluation (§6) and a number of case studies of user experiences with SCALENE (§7); we conclude with a discussion of related work (§8).

## 2 CPU Profiling

SCALENE’s CPU profiler employs sampling, but unlike past profilers, it leverages an apparent limitation of how Python delivers signals to extract more granular information.

Sampling profilers like SCALENE work by periodically interrupting program execution and examining the current program counter. Given a sufficiently large number of samples, the number of samples each program counter receives is proportional to the amount of time that the program was executing. Sampling can be triggered by the passage of real (wall-clock) time, which accounts for CPU time as well as time spent waiting for I/O or other events, or virtual time (the time the application was scheduled for execution), which only accounts for CPU time.

However, in Python, using sampling to drive profiling leads to erroneous profiles. Like other scripting languages such as Perl and Ruby, Python only delivers signals to the main

					5			22 x = self.conv1(x)
								124 dataset1 = datasets.MNIST('./data', tr

**Figure 2: An example profile from SCALENE’s web UI**, sorted in descending order by GPU utilization. The top graphs provide a summary for the entire program, with more detailed data reported for each active line (and, not shown, for each function). CPU time is in blue, with different shades reflecting time taken in Python code, native code, or system/GPU time (§2). Average and peak memory consumption is in green, with different shades distinguishing memory consumed by Python objects vs. native ones (§3); the memory timeline depicts memory consumption over time (§5). Copy volume is in yellow (§3.5), as well as GPU utilization and GPU memory consumption (§4). Hovering over bars provides detailed statistics in hoverslips.

**Figure 3: Overview of SCALENE’s inference of Python vs. native execution.** Sampling profilers depend on regular timer interrupts, but Python defers all signals when running native code, leading to the appearance of no time spent executing that code. SCALENE leverages this apparent limitation to accurately attribute time spent executing Python and native code (§2.1) in the main thread; it uses a different algorithm for code running in threads (§2.2).

thread [31]. Also like those languages, Python defers signal delivery until the virtual machine (i.e., the interpreter loop) regains control, and only checks for pending signals after specific opcodes such as jumps.

The result is that, during the entire time that Python spends executing external library calls, no timer signals are delivered. The effect can be that the profiler will reflect *no time* spent executing native code, no matter how long it actually took. In addition, because only main threads are interrupted, sampling profilers can fail to account for any time spent in child threads.

## 2.1 Accurate Python-Native Code Profiling

SCALENE’s CPU profiler turns these limitations of Python signals to its advantage, inferring whether a line spent its time executing Python or native code (e.g., C). It leverages the following insight: *any delay in signal delivery corresponds to time spent executing outside the interpreter*. That is, if SCALENE’s signal handler received the signal immediately (that is, in the requested timing interval), then all that time must have been spent in the interpreter. If it was delayed, it must be due to running code outside the interpreter, which is the only cause of delays (at least, in virtual time).

Figure 3 depicts how SCALENE handles signals and attributes time to either Python or native code. SCALENE tracks time between interrupts recording the current virtual time whenever it receives a CPU timer interrupt (using `time.process_time()`). When it receives the next interrupt, it computes  $T$ , the elapsed virtual time, and compares it to the timing interval  $q$  (for quantum).

SCALENE uses these values to attribute time spent to Python or native code. Whenever SCALENE receives a signal, SCALENE walks the Python stack until it reaches code being profiled (that is, outside of libraries or the Python interpreter itself), and attributes time to the identified line of code. SCALENE maintains two counters for every line of code being profiled: one for Python, and one for native code. Each time a line is interrupted by a signal, SCALENE increments the Python counter by  $q$ , the timing interval, and it increments the native counter by  $T - q$ , the delay.

## 2.2 Accurate Python-Native Profiling of Threads

The approach described above attributes execution time for Python vs. native code in the main thread, but it does not attribute execution time at all for subthreads, which, as described above, never receive signals. To correctly attribute time for code running in subthreads, SCALENE applies an algorithm leveraging a combination of Python features: *monkey patching*, *thread enumeration*, *stack inspection*, and *bytecode disassembly*.

Monkey patching refers to the redefinition of functions at runtime. SCALENE uses monkey patching to ensure that signals are always received by the main thread, even when the main thread is blocking (e.g., waiting to join with child threads). SCALENE replaces blocking functions like `threading.join` with variants that always use timeouts. It sets these timeouts to Python’s own thread quantum, obtained via `sys.getswitchinterval()`. Replacing these calls forces the main thread to yield regularly and allow signal delivery.

In addition, to attribute execution times correctly, SCALENE maintains a status flag for every thread, all initially *executing*. In each of the calls it intercepts, before SCALENE issues the blocking call, it sets the calling thread’s status as *sleeping*. Once that thread returns (either after successfully acquiring the desired resource or after a timeout), SCALENE resets the status of the calling thread to *executing*. SCALENE only attributes time to currently executing threads.

Now, when the main thread receives a signal, SCALENE invokes `threading.enumerate()` to collect a list of all running threads. It then obtains the Python stack frame from each thread using Python’s `sys._current_frames()` method. As above, SCALENE walks the stack to find the appropriate line of code to attribute execution time.

Finally, SCALENE uses bytecode disassembly (via the `dis` module) to distinguish between time spent in Python vs. native code. Whenever Python invokes an external function, it does so using a bytecode whose textual representation is either `CALL_FUNCTION`, `CALL_METHOD`, or, as of Python 3.11, `CALL`. SCALENE builds a map of all such bytecodes at startup.

SCALENE checks the stack of each running thread to see if the currently executing bytecode is a call instruction. SCALENE uses this information to infer if the thread is currently executing Python or native code.

If a thread is running Python code, it is likely to spend almost no time in a bytecode before executing another Python bytecode. By contrast, if it is running native code, it will be “stuck” on the `CALL` bytecode for the duration of native execution. Leveraging this fact lets SCALENE accurately attribute execution time: if it finds that a stack is executing `CALL`, SCALENE assigns time elapsed to the native counter; otherwise, it assigns time elapsed to the Python counter.

**Figure 4: Threshold-Based vs. Rate-Based Sampling.** SCALENE employs a novel sampling scheme that only triggers when memory use grows or declines beyond a set threshold, letting it capture all significant changes in footprint (beyond a given granularity, here 10MB) with low overhead. (§3.2).

## 3 Memory and Copy Volume Profiling

Almost all past profilers either report CPU time or memory consumption; SCALENE reports both, at a line granularity. It is vital that SCALENE track memory both inside Python and out, as external libraries are often responsible for a considerable fraction of memory consumption.

### 3.1 Intercepting Allocation Calls

SCALENE intercepts all system allocator calls (`malloc`, `free`, etc.) as well as Python internal memory allocator by inserting its own “shim” memory allocator, using Python’s built-in memory hooks. This two-fold approach lets SCALENE distinguish between native memory allocated by libraries and Python memory allocated in the interpreter.

The shim allocator extends and uses code from the Heap Layers memory allocator infrastructure [5]; SCALENE injects it via library interposition before Python begins executing using `LD_PRELOAD` on Linux and `DYLD_INSERT_LIBRARIES` on Mac OS X. To interpose on Python’s internal memory allocator, SCALENE uses Python’s custom allocator API (`PyMem_SetAllocator`).

Each shim allocator function handles calls by sampling for inclusion in the profiling statistics (§3.2) and then passing these to the original (Python or system) allocator. A complication arises from the fact that the Python allocators themselves may handle allocation requests by calling into the system allocator. To avoid counting Python allocations also as native allocations, SCALENE sets a flag, stored in thread-specific data, indicating it is within a memory allocator. When a shim allocator function is called with this flag set, it skips over the profiling, just forwarding to the original allocator. This approach both avoids double counting and simplifies writing profiling code, as it can allocate memory normally without causing infinite recursion.

## 3.2 Threshold-Based Sampling

The standard approach to sampling memory profilers, as exemplified by several non-Python memory profilers in Android, Chrome, Go, and Google's `tcmalloc` [40] and in Java TLAB based sampling [1], use a *rate-based* sampling approach. This sampler triggers samples at a rate proportional to the number of bytes allocated or freed. In effect, each byte allocated or freed corresponds to a Bernoulli trial with a given probability  $p$  of sampling; e.g., if  $p = 1/T$ , then (in expectation) there will be one sample per  $T$  bytes. In practice, for efficiency, these samplers initialize counters to random numbers drawn from a Poisson process or a geometric distribution with the same parameter. Each allocation and free then decrements this counter by the number of bytes allocated and freed, and triggers a sample when the counter drops below 0.

By contrast, the SCALENE sampler introduces *threshold-based* sampling. The allocator maintains a count of all memory allocations and frees, in bytes. Once the absolute difference between allocations and frees crosses a threshold ( $|A - F| \geq T$ ), SCALENE triggers a sample, corresponding to appending an entry to a sampling file and resets the counters. Figure 4 illustrates this operation. The sampling threshold  $T$  is currently set to a prime number slightly above 10MB; SCALENE uses a prime number to reduce the risk of stride behavior interfering with sampling.

Threshold-based sampling has several advantages over rate-based sampling. Unlike rate-based sampling, which is triggered by all allocation activity (even when it has almost no effect on footprint), threshold-based sampling is only triggered by significant memory use growth or decline. Table 2 shows the dramatic reduction in the number of samples, as high as  $676\times$  (median:  $18\times$ ) fewer. This reduced number of samples translates directly to lower runtime overhead.

At the same time, threshold-based sampling deterministically triggers a new sample whenever a significant change in footprint occurs. This approach improves repeatability over rate-based sampling (which is probabilistic) and avoids the risk of missing these changes.

Crucially, threshold-based sampling avoids two sources of bias inherent to rate-based sampling. Rate-based sampling can overstate the importance of allocations that do not contribute to an increased footprint since it does not take memory reclamation or footprint into account. It also biases the attribution of memory consumption to lines of code running Python code that exercises the allocator, rather than code responsible for footprint changes. By contrast, threshold-based sampling filters out the vast number of short-lived objects that are created by the Python interpreter itself, and only triggers based on events that change footprint.

## 3.3 Collecting and Processing Samples

When a memory sample is taken, SCALENE temporarily enables tracing using Python's `PyEval_SetTrace`. Tracing remains active only until it detects execution has moved on from that line. This approach lets SCALENE properly account for average memory consumption per line.

Each entry in SCALENE's sampling file includes information about allocations or frees, the fraction of Python (vs. native) allocations in the total sample, as well as an attribution to a line of Python source code.

SCALENE attributes each sample to Python source code at the time the sample is taken. It does so by obtaining the current thread's call stack from the interpreter and skipping over frames until one within profiled source code is found. This attribution needs to happen whenever a sample is taken, so it is implemented as a C++ extension module, using read-only accesses to Python structures. SCALENE loads this module upon startup, which in turn uses a symbol exported by the shim library to complete the linkage, making itself available to the shim.

A background thread in SCALENE's Python code reads from the sampling file and updates the profiling statistics. SCALENE also tracks the current memory footprint, which it uses both to report maximum memory consumption and memory trends. SCALENE records a timestamp and the current footprint at each threshold crossing, which SCALENE uses to generate memory trend visualizations (§5).

## 3.4 Memory Leak Detection

Like other garbage-collected languages, Python can suffer from memory leaks when references to objects are accidentally retained so that the garbage collector cannot reclaim them. As in other garbage collected languages, identifying leaks in Python programs is generally a slow, manual process.

In Python, the standard approach to identifying leaks is to first activate `tracemalloc`, which records the size, allocation site, and stack frame for each allocated object. The programmer then inserts calls at the appropriate place to produce a series of heap snapshots, and then manually inspects snapshot diffs to identify growing objects. This approach is laborious and depends on a post hoc analysis of the heap. It also can be quite slow. In our tests, just activating `tracemalloc` can slow Python applications down by  $4\times$ .

SCALENE incorporates a novel sampling-based memory leak detection algorithm that is both simple and efficient. The algorithm piggybacks on threshold-based sampling (§3.2). Whenever the sampler triggers because of memory growth, SCALENE checks if this growth has reached a new maximum footprint. If so, SCALENE records the sampled allocation. Every call to free then checks to see whether this object is ever reclaimed. This checking is cheap—a single pointer comparison—and highly predictable (almost always false).

**Leak Score:** At the next crossing of a maximum, SCALENE updates a *leak score* for the sampled object. The leak score tracks the historic likelihood of reclamation of the sampled object, and consists of a pair of (*freed*, *mallocs*). SCALENE first increments the *mallocs* field when it starts tracking an object, and then increments the *freed* field only if it reclaimed the allocated object. It then resumes tracking with a newly sampled object.

Intuitively, leak scores capture the likelihood that an allocation site is leaking. A site with a high number of *mallocs* and no *freed* is a plausible leak. By contrast, a site with a matching number of *mallocs* and *freed* is probably not a leak. The more observations we make, the higher the likelihood that we are observing or ruling out a leak.

SCALENE uses Laplace’s Rule of Succession to compute the likelihood of a success or failure in the next Bernoulli trial, given a history of successes and failures [50]. Here, successes correspond to reclamations (*freed*) and failures are non-reclamations (*mallocs* - *freed*). According to the Rule of Succession, SCALENE computes the leak probability as  $1.0 - (\text{freed} + 1) / (\text{mallocs} - \text{freed} + 2)$ .

**Leak Report Filtering and Prioritization:** To provide maximal assistance to Python developers, SCALENE filters and augments leak information. First, to limit the number of leak reports, SCALENE only reports leaks whose likelihood exceeds a 95% threshold, and only when the slope of overall memory growth is at least 1%. Second, SCALENE lets developers prioritize leaks by associating each leak with an estimated *leak rate*: the average amount of memory allocated at a given line divided by time elapsed.

### 3.5 Copy Volume

SCALENE uses sampling to collect information about *copy volume* (megabytes per second of copying) by line. This metric, which SCALENE introduces, helps identify costly (and often inadvertent) copying across the Python/native divide, or copying between CPU and GPU.

The SCALENE shim library used for memory allocation also interposes on *memcpy*, which is invoked both for general copying (including to and from the GPU, and copying across the Python/native boundary). As with memory allocations, SCALENE writes an entry to a sampling file once a threshold number of bytes has been copied. However, unlike memory sampling, copy volume sampling employs classical rate-based sampling: since copy volume only ever increases, threshold-based sampling and rate-based sampling would effectively be equivalent. The current *memcpy* sampling rate is set at a multiple of the allocation sampling rate.

## 4 GPU Profiling

SCALENE performs both line-granularity GPU utilization and memory profiling on systems equipped with NVIDIA GPUs. This feature helps Python programmers identify whether they are efficiently making use of their GPUs.

SCALENE piggybacks GPU sampling on top of its CPU sampler. Every time SCALENE obtains a CPU sample, it also collects the total currently used GPU memory and utilization, which it associates with the currently executing line of code. Whenever possible, SCALENE employs per-process ID accounting, which increases accuracy in a shared GPU setting.

At startup, SCALENE checks to see if per-process ID accounting has been enabled on the attached NVIDIA GPU. If not, SCALENE offers to enable it, a process that requires that the user invoke SCALENE once with super-user privileges.

## 5 GUI Design and Implementation

SCALENE’s primary user interface is web-based, though it also offers a non-interactive rich text-based CLI. In the UI, SCALENE not only reports net memory consumption per line, but also reports memory usage over time, both for the program as a whole and for each individual line. Figure 2 presents several examples. The x-axis corresponds to execution time, and the y-axis corresponds to the footprint of the program, as seen by that line of code.

Because it can be expensive to visualize graphs with large numbers of points, SCALENE limits the number of points it outputs in its JSON payload and HTML output. Prior to generating the profile output, SCALENE applies the Ramer-Douglas-Peucker (RDP) algorithm [9, 32] to each line’s memory footprint log (if any). The RDP algorithm aims to reduce the total number of points while preserving the overall shape of the curve. The RDP algorithm depends on a parameter  $\epsilon$ , a distance parameter below which RDP merges adjacent points; SCALENE sets  $\epsilon$  to a value that approximately reduces the total number of points to a manageable size (100 points). Sometimes this process fails to reduce the number of points sufficiently. To guarantee that the number of points is always bounded, after applying RDP, SCALENE randomly downsamples all memory logs to exactly 100 points.

To further ensure the scalability of the user interface, SCALENE only reports lines of code that are responsible for at least 1% of execution time (CPU or GPU) or at least 1% of total memory consumption, along with the preceding and following line. This approach guarantees that a SCALENE profile never contains more than 300 lines. In practice, profiles are generally skewed and resulting profilers are often far smaller.

## 6 Evaluation

Our evaluation answers the following questions: How does SCALENE’s CPU profiling accuracy compare to other CPU profilers? (§6.2) How does SCALENE’s memory profiling accuracy compare to other memory profilers? (§6.3) How does SCALENE’s CPU profiling overhead compare to other CPU profilers? (§6.4) How does SCALENE’s memory profiling overhead compare to other memory profilers? (§6.5)

### 6.1 Experimental Setup

Our prototype of SCALENE consists of roughly 3,500 lines of Python 3 code and 1,700 lines of C++-17 code; its user interface comprises 800 lines of JavaScript, excluding white space and comments as measured by `cloc` [8]. This prototype runs on Linux, Microsoft Windows, and Mac OS X, for Python versions 3.8 and higher; we report Linux results here. We use the latest version of SCALENE, released 12/08/2022.

We perform all experiments on an 8-core 4674 MHz AMD Ryzen 7, equipped with 32GB of RAM and an NVIDIA GeForce RTX 2070 GPU, running Linux 5.13.0-35-generic. All C/C++ code is compiled with `g++` version 9, and we use CPython version 3.10.9 (release date 12/06/2022) For overhead numbers, we report the interquartile mean of 10 runs.

### 6.2 CPU Profiling Accuracy

Here, we explore a specific threat to the accuracy of Python CPU profilers. We show that some profilers suffer from a *probe effect* that distorts the time spent by applications. Specifically, we observe that Python profilers that rely on Python’s tracing facility exhibit a bias caused by tracing triggering both on function calls and lines of code, dilating the apparent time spent in function calls. We call this phenomenon *function bias*; we show that sampling-based profilers like SCALENE do not suffer from this bias.

We wrote a microbenchmark to measure this bias. It executes a varying number of iterations of two semantically identical functions: one invokes another function inside its loop, while the other inlines the same logic. We vary the amount of time spent in one function versus the other, and compare the profiler results to the ground truth, as measured with high resolution timers.

Figure 5 presents the results of this experiment. The x-axis is the amount of time measured while running the variant with a function call (the ground truth), while the y-axis is the amount of time reported by each profiler. The ideal is a diagonal running from the origin. The trace-based profilers exhibit a high degree of inaccuracy, showing significant function bias. In the worst case, one such profiler reports a function takes 80% of execution time while in fact it only consumes 25%. We conclude that such profilers may be too potentially misleading to be of practical value for developers.

Accuracy: Time spent vs. time reported

Figure 5: CPU Profiling Accuracy: SCALENE is among the most accurate CPU profilers. This graph measures the accuracy of profile reports vs. the actual time spent in functions; the ideal is shown by the diagonal line (the amount the profiler reports is exactly the time spent). Some profilers are highly inaccurate (§6.2).

### Memory accounting, Scalene vs. RSS-based proxies

Figure 6: Memory Profiling Accuracy: SCALENE produces more accurate memory profiles than resident set size (RSS) based profilers. Varying the amount of memory accessed causes RSS-based profilers to significantly under-report, and sometimes over-report, the true amount of allocated memory. Interposition-based profilers are far more accurate (§6.3).

### 6.3 Memory Profiling Accuracy

We next compare the accuracy of memory profilers with a simple test designed to explore the effect of using resident set size (RSS) instead of direct memory tracking. We expect to see a difference between the two, since RSS corresponds to the use of memory rather than the allocation of objects. Our test first allocates a single 512MB array, and then accesses a varying amount of the array (from 0% to 100%).

Figure 6 presents the result, confirming our hypothesis. Both `memory_profiler` and `Austin` rely on RSS as a proxy

Benchmark	Repetitions	Time
async_tree_io <sub>none</sub>	22	11.9s
async_tree_io <sub>io</sub>	9	12.0s
async_tree_io <sub>cpu_io_mixed</sub>	14	12.3s
async_tree_io <sub>memoization</sub>	16	10.6s
docutils	5	12.5s
fannkuch	3	12.1s
mdp	5	13.4s
pprint	7	12.8s
raytrace	25	11.1s
sympy	25	11.3s

**Table 1: Benchmark suite:** We conduct our evaluation using the top ten most time consuming benchmarks from the standard pyperformance benchmark suite. For each, we extend their running time by running them in a loop enough times to exceed 10 seconds.

for memory consumption. But RSS is a measure of the *physical* memory currently in use, and depends on a number of other factors such as memory access patterns and the memory needs of other processes. The figure clearly shows that this proxy can be wildly inaccurate, leading to under-reporting and even over-reporting the size of the allocated object. The other profilers directly measure allocation, and produce much more accurate results. Both SCALENE and Fil report within 1% of the actual size of the allocated object (512MB), while Memray is within 6%.

**Drawbacks of peak-only profiling:** Both Fil and Memray only report live objects at the point of peak memory allocation by a program. This information can be useful, but it can both exaggerate the potential for reducing memory and obscure other sources of memory consumption. Consider a program that allocates and discards a 4GB object, and then allocates a 4GB + 8 byte object. A report that only contains information at the point of peak allocation will reveal the second object but not the first. That profile will suggest an enormous opportunity to save memory, but eliminating the second object entirely would have almost no effect on peak memory consumption. Unlike peak profilers, SCALENE provides information about *all* significant memory allocation over time, giving programmers a global view of memory consumption.

**Summary:** SCALENE’s memory profiling is highly accurate, while capturing memory consumption over time.

## 6.4 CPU Profiling Overhead

In our evaluation, we use the ten longest-running benchmarks from pyperformance, the standard suite for evaluating Python performance (Figure 1). We modify these benchmarks to run in a loop so that they execute for at least 10 seconds on our experimental platform. We also modify the benchmarks slightly by adding @profile decorators, as these are

Benchmark	Rate	Threshold	Ratio
async_tree_io <sub>none</sub>	556	215	3×
async_tree_io <sub>io</sub>	524	187	3×
async_tree_io <sub>cpu_io_mixed</sub>	719	167	4×
async_tree_io <sub>memoization</sub>	375	167	2×
docutils	20	5	4×
fannkuch	426	5	85×
mdp	316	6	53×
pprint	7976	23	347×
raytrace	215	7	31×
sympy	6757	10	676×
<b>Median:</b>			18×

**Table 2: Threshold vs. Rate-Based Sampling:** SCALENE’s threshold-based sampling tracks footprint with as many as 676× fewer samples than conventional rate-based sampling (median: 18×).

required by some profilers; we also add code to ignore the decorators when they are not used. Finally, we add a call to `system.exit(-1)` to force py-spy to generate output. Figure 7 provides the results of running the profilers across all these benchmarks.

**Summary:** In general, SCALENE imposes low to modest overhead (median: 2% for CPU+GPU, and 30% for full functionality), placing it among the profilers with the lowest overhead.

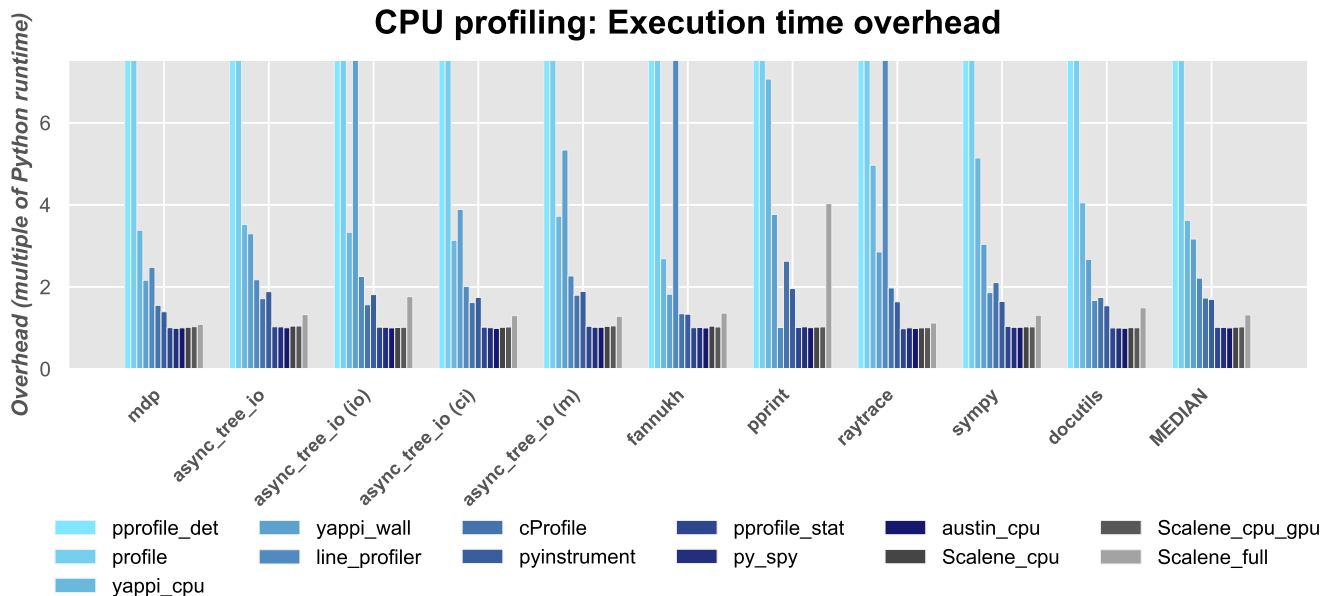

## 6.5 Memory Profiling Overhead

Next, we evaluate the overhead of memory profilers (`memory_profiler`, Fil, Memray and Austin), and compare them to SCALENE. We use the same benchmarks as we used for measuring runtime overhead for CPU profilers.

Figure 8 shows the results. Because it can slow down execution by at least 150×, we omit `memory_profiler` from the graph. SCALENE’s performance is competitive with the other profilers; while Austin is faster, as Section 6.3 shows, it provides inaccurate estimates of memory consumption.

**Log file growth:** Some memory profilers feature a surprising other source of overhead. Two of the memory profilers, Memray and Austin, produce detailed (and copious) logs of memory activity that may limit their usefulness for profiling long-lived applications.

Memray deterministically logs information including all allocations, all updates to the Python stack, and context switches, which it later post-processes for reporting. Austin similarly generates logs meant to be consumed by an external tool. These files can grow rapidly: in our tests, Memray’s output file grows by roughly 3MB/second, while Austin’s grows by 2MB/second.

**Figure 7: CPU profiling: SCALENE has modest overhead.** Despite collecting far more detailed information, SCALENE is competitive with the best-of-breed CPU profilers in terms of overhead (§6.4). The graph truncates the slowest profilers; see Table 3 for full data.

	mdp	a_t_i	(io)	(ci)	(m)	fannkuch	pprint	raytrace	sympy	docutils	Median

Scalene_cpu_gpu	1.03×	1.05×	1.02×	1.02×	1.05×	1.02×	1.03×	1.01×	1.03×	1.01×	1.02×
Scalene_full	1.09×	1.33×	1.76×	1.30×	1.28×	1.36×	4.03×	1.12×	1.31×	1.49×	1.32×

**Table 3: Detailed profiling overhead (CPU and memory).** All numbers are relative to the Python baseline (no profiling); a\_t\_i refers to the async\_tree\_io benchmark.

By contrast, SCALENE only records samples when memory consumption grows or shrinks by a large amount (§3.2), leading to vastly smaller logs. For example, when running the mdp benchmark, Austin’s log file consumes 27MB and Memray’s log file consumes almost 100MB, while SCALENE’s log file consumes just 32K.

**Summary:** Among the accurate memory profilers, SCALENE operates with the lowest overhead (median: 1.32× vs. 3.98× (memray) and 2.71× (Fil)), while capturing memory usage over time and producing small log files.

## 7 Case Studies

This section includes reports on real-world experience by external developers using SCALENE to identify and resolve performance issues. For each, we identify the features of SCALENE that were instrumental in enabling these optimizations.

**Rich:** A user reported severe slowness when printing large tables to the developer of Rich [20], an immensely popular Python library for formatting text in the terminal (downloaded over 130 million times, with 41K stars on GitHub). When Rich’s developer profiled it using SCALENE, he identified two lines occupying a disproportional amount of run-

### Memory profiling: Execution time overhead

**Figure 8: Memory profiling overhead: SCALENE has competitive runtime overhead.** Despite collecting far more detailed information, SCALENE is faster than the accurate memory profilers (§6.5).

time. SCALENE indicated that a call to `isinstance` was taking an unexpectedly large amount of time—though each call takes very little time, the developer reported that it was being called 80,000 times. Rich’s developer replaced these calls with a lower-cost function, `hasattr`. In our benchmarks, `isinstance` (when marked as a runtime protocol via `@typing.runtime_checkable`) can run over  $20\times$  slower than `hasattr`. The developer also indicated that an unnecessary copy was being performed once every cell. Optimizing these calls led to a reported 45% improvement in runtime when rendering a large table. **[Features: Fine-grained CPU profiling, copy volume.]**

**Pandas – Chained Indexing:** A developer was seeing suboptimal performance in their code using Pandas [41]. SCALENE identified that a list comprehension performing nested indexes into a Pandas dataframe was taking an unexpectedly large amount of time and resulting in a significant amount of copy volume. The developer noted that the first level of indexing was repeatedly using a string that was loop invariant; the way this was being done in Pandas caused it to perform copies rather than using views, a problem known as chained indexing ([https://pandas.pydata.org/pandas-docs/stable/user\\_guide/indexing.html#returning-a-view-versus-a-copy](https://pandas.pydata.org/pandas-docs/stable/user_guide/indexing.html#returning-a-view-versus-a-copy)). After manually hoisting this outer indexing operation, the developer obtained an  $18\times$  speedup. **[Features: Copy volume and fine-grained CPU profiling.]**

**Pandas – concat and groupby queries:** An instructor had their students use SCALENE in a tutorial designed to teach higher performance Pandas. The instructor found that SCALENE revealed significant issues in both performance and space consumption when using Pandas. First, SCALENE revealed that calling `concat` on Pandas dataframes was using more memory than anticipated. SCALENE’s copy volume reporting revealed that the problem was that `concat` copies all the data by default (<https://pandas.pydata.org/pandas-docs/stable/reference/api/pandas.concat.html#pandas.concat>), effectively doubling memory usage when managing large dataframes. Second, SCALENE confirmed that excessive RAM usage in some groupby operations is due to copying of the groups; this bug has been reported to the Pandas developers (<https://github.com/pandas-dev/pandas/issues/37139>). Restructuring the groupby operation reduced memory consumption by a further 1.6GB (43%). **[Features: Fine-grained CPU and memory profiling, copy volume.]**

**NumPy vectorization:** A graduate student was using NumPy to implement classification with gradient descent and was seeing extremely low performance. SCALENE showed that 99% of the time was being spent in Python (rather than native code), indicating that his code was not vectorized. In other words, the code was not expressed in a way that allowed NumPy to efficiently compute vector operations (using native code). Guided by SCALENE’s feedback, the graduate student gradually improved the performance from 80 iterations per minute to 10,000 per minute, a  $125\times$  improvement. **[Feature: Fine-grained native vs. Python CPU profiling.]**

**Semantic Scholar:** Semantic Scholar reports that they have been using SCALENE as part of their tool suite for operationalizing their machine learning models. Recently, they found that a model was cost-prohibitive and put an entire product direction in jeopardy. They generated a set of test data and ran their models with SCALENE. SCALENE’s output was able to pinpoint the issues and help them validate that their changes were having an impact. While iteratively using SCALENE while applying optimizations, they were ultimately able to reduce costs by 92%. Additionally, SCALENE allowed Semantic Scholar’s developers to quickly determine what fraction of their runtime would benefit from hardware acceleration and what CPU-bound code they needed to optimize in order to achieve their goals. **[Features: Simultaneous, fine-grained CPU, memory, and GPU profiling.]**

**Summary:** In nearly all of the cases described above, SCALENE was either invaluable or provided additional help that narrowed down performance issues, by leveraging unique or novel features of SCALENE: separation of native from Python

time, copy volume, GPU profiling, and its ability to simultaneously measure memory and CPU usage. Though other tools can separately identify high RAM usage or slow code, past tools would either misattribute the location of usage due to the use of resident set size as a metric (unlike SCALENE’s accurate memory profiling approach) or not be able to simultaneously measure memory usage and CPU usage. The insights generated by SCALENE were actionable, yielding substantial improvements in execution time and space, and reducing cost.

## 8 Related Work

There is an extensive history of profilers; we focus our attention here on profilers that specifically support Python. The Python ecosystem contains many Python profilers, most of which have not been discussed in the academic literature. This section describes the most prominent profilers; Figure 1 provides a tabular overview.

We first survey CPU-only profilers. We divide them into two categories: *deterministic* (tracing-based) (§8.1) and *sampling-based* (§8.2). We then discuss memory profilers (§8.3), ML-specific profilers (§8.4), other Python profilers (§8.5), and general profilers with Python support (§8.6), and touch on more distantly related profilers for other languages (§8.7).

### 8.1 Deterministic CPU profilers

Python provides built-in tracing support (`sys.settrace`) that several profilers build upon. The tracing facility, when activated, triggers a callback in response to a variety of events, including function calls and execution of each line of code. This deterministic, instrumentation-based approach leads to significant inaccuracies due to its probe effect, as Section 6.2 shows. Because of the overhead of tracing, they are also the slowest profilers.

**Function-granularity:** Python includes two built-in function-granularity profilers, `profile` [35] and `cProfile` [34]. The primary difference between these two profilers is that `cProfile`’s callback function is implemented in C, making it much faster (1.7× slowdown vs. 15.1×) and somewhat more accurate than `profile`. Another profiler, `yappi`, operates in two modes, wall clock time (sample-based) and CPU time (deterministic); it is among the most inaccurate of CPU profilers, with slowdowns ranging from 1.8× to 33.3×.

**Line-granularity:** `pprofile` [30] comes in two flavors: a deterministic and a “statistical” (sampling-based) profiler. Both flavors correctly work for multithreaded Python programs, unlike `line_profiler` [17]. All of these report infor-

mation at a line granularity. `pprofile_det` imposes a median overhead of 36.8×, while `line_profiler`’s median overhead is 2.2×.

### 8.2 Sampling-based CPU profilers

Sampling-based profilers are more efficient and often more accurate than the deterministic profilers. These include `pprofile_stat`, `py-spy` [10], and `pyinstrument` [33]. Their overhead is between 1× and 1.7×, comparable to SCALENE. Because it fails to cope with Python’s deferred signal delivery, `pprofile_stat` incorrectly ascribes zero runtime to execution of native code or code in child threads (§2).

Compared to past CPU-only profilers, SCALENE is nearly as fast or faster, more accurate, and provides more detailed CPU-related information, breaking down time spent into Python, native, and system time.

### 8.3 Memory profilers

`memory_profiler` is a deterministic memory profiler that uses Python’s trace facility to trigger it after every line of execution [36]. By default, it measures the RSS after each line executes and records the change from the previous line. `memory_profiler` also does not support Python applications using threads or multiprocessing.

`Fil` measures the peak allocation of the profiled program by interposing on system allocator functions and forcing Python to use the system allocator (instead of Python’s `Pymalloc`) [45]. `Fil` records a full stack trace whenever the current memory footprint exceeds a previous maximum. On exit, it produces a flamegraph [13] of call stacks responsible for memory allocation at the point of maximum memory consumption. The `Fil` website reports that it supports threads (“In general, `Fil` will track allocations in threads correctly.” [46]). However, in our tests, `Fil` (version 2022.6.0) fails to ascribe any memory allocations to threads. `Fil` also does not currently support multiprocessing.

`Memray` is a recently released (April 2022), Linux-only memory profiler that deterministically tracks allocations and other profiler events [37]. `Memray` interposes upon the C allocation functions and optionally on the `pymem` functions, letting it distinguish native from Python allocations.

The only previous CPU+memory profiler we are aware of besides SCALENE is `Austin` [43]. `Austin` reduces performance overhead by profiling with a separate process.

### 8.4 Profilers for Machine Learning Libraries

Two widely used machine learning libraries, TensorFlow and PyTorch [28], include their own profilers [11, 19]. Both profilers are targeted at identifying performance issues specific to deep learning training and inference. For example, the

PyTorch profiler can attribute runtime to individual operators (running inside PyTorch’s native code). NVIDIA’s Deep Learning profiler (DLprof) [23] provides similar functionality for either PyTorch or TensorFlow. Unlike SCALENE, these profilers are specific to machine learning workloads and are not suitable for profiling arbitrary Python code. These profilers are complementary to SCALENE, which aims to be a general-purpose profiler. They also lack many of SCALENE’s features.

## 8.5 Other Python Profilers

PieProf aims to identify and surface specific types of inefficient interactions between Python and native code [39]. PieProf leverages data gathered from on-chip performance monitoring units and debug registers combined with data from libunwind and the Python interpreter to identify redundant loads and stores initiated by user-controlled code. It surfaces pairs of redundant loads and stores for the developer to potentially optimize. PieProf is not publicly available, so it was not possible to empirically compare it to SCALENE.

## 8.6 Profilers with Python Support

Several non-Python specific conventional profilers offer limited support for Python. Intel’s VTune profiler [49] can attribute its metrics to Python lines, with a number of caveats, including “if your application has very low stack depth, which includes called functions and imported modules, the VTune Profiler does not collect Python data.” [16]. VTune does not directly distinguish between time spent in Python code and time spent in native code and does not track Python memory allocations. Google Cloud Profiler [12] only profiles Python execution time, but neither distinguishes between Python and native time nor does it perform memory profiling for Python. Both lack most of SCALENE’s other features.

Python 3.12, the current development version of Python, recently (November 2022) added support for use with the perf profiler on Linux platforms by reporting function names in traces [26]. Using perf in this mode only measures performance counters or execution time. Unlike SCALENE, perf does not measure memory allocation, or attribute runtime (Python or native) to individual lines of Python code.

## 8.7 Non-Python Profilers

AsyncProfiler is a Java profiler that, like SCALENE, profiles both CPU and memory [27]. AsyncProfiler is a sampling profiler that avoids the *safepoint bias problem* [21]. Since Python does not have safepoints (all garbage collection happens while the global interpreter lock is held), Python profilers cannot suffer from this bias. Instead, as we show, they can suffer from function bias (§6.2). Similarly, pprof is a profiler

for the Go language that can report both CPU and memory [7]. Both profilers use rate-based memory sampling (§3.2).

## 9 Conclusion

This paper presents SCALENE, a novel Python profiler. SCALENE delivers more actionable information than past profilers, all with high accuracy and low overhead. Its suite of novel algorithms enables SCALENE’s holistic reporting of Python execution. SCALENE has been released as open source at <https://github.com/plasma-umass/scalene>.

## Acknowledgements

We thank SCALENE’s users for their feature requests, questions, and bug reports, which have helped shape and guide this research. We are most grateful to users who contributed pull requests or worked with us to resolve compatibility issues, including Raphael Cohen, James Garity, Ryan Grout, Friday James, and Marguerite Leang. We thank the users who contributed their experiences, reported here as case studies: Will McGugan, Ian Oszvald, Donald Pinckney, Nicolas van Kempen, and Chris Wilhelm. Finally, we thank our shepherd, Phil Levis, and the reviewers of this paper, whose feedback helped improve not only the paper but also SCALENE itself.

This material is based upon work supported by the National Science Foundation under Grant No. 1954830.

# Relational Debugging

## — Pinpointing Root Causes of Performance Problems

### Abstract

Performance debugging is notoriously elusive—real-world performance problems are rarely clear-cut failures, but manifest through the accumulation of fine-grained symptoms. Oftentimes, it is challenging to determine performance anomalies—*absolute* measures are unreliable, as system performance is inherently *relative* to workloads. Existing techniques focus on identifying absolute predicates that deviate between executions, which limits their application to *performance* problems.

This paper introduces *relational debugging*, a new technique that automatically pinpoints the root causes of performance problems. The core idea is to capture and reason about relations between fine-grained runtime events. We show that relations provide immense utilities to explain performance anomalies and locate root causes. Relational debugging is highly effective with a minimal two executions (a good and a bad run), eliminating the pain point of producing and labeling many different executions required by traditional techniques.

We realize relational debugging by developing a practical tool named *Perspect*. *Perspect* directly operates on x86 binaries to accommodate real-world diagnosis scenarios. We evaluate *Perspect* on twelve challenging performance issues with various symptoms in Go runtime, MongoDB, Redis, and Coreutils. *Perspect* accurately located (or excluded) the root causes of these issues. In particular, we used *Perspect* to diagnose *two open bugs*, where developers failed to find root causes—the root causes reported by *Perspect* were confirmed by developers. A controlled user study shows that *Perspect* can speed up debugging by at least 10.87 times.

## 1 Introduction

Performance makes or breaks a software system: severe performance problems lead to unresponsiveness and even malfunctions; even seemingly-small performance degradations can incur high costs—a half-second search delay reduces Google’s revenue by 20% [33]. Therefore, it is crucial to diagnose performance problems in a timely manner.

Performance debugging is known to be elusive and difficult. Unlike functional failures with clear-cut symptoms, such as

crashes and runtime exceptions, performance problems are typically observed via the cumulative effect of fine-grained symptoms over time, such as latency increases due to regressions of code efficiency and resource overuse due to leaks. While fine-grained symptoms can potentially be identified by profilers [9, 10, 12, 13, 19], profiling alone cannot explain a performance anomaly—not every local symptom is related to the anomaly. Causality analysis [34, 37, 42] captures runtime events that are causally related to the symptoms, but it does not pinpoint the root causes in the code; the causality graph can be complex to navigate and analyze. In fact, it can be even challenging to determine whether or not the observed is performance an anomaly, because *absolute* measures are unreliable—system performance is inherently *relative* to inputs and workloads.

Existing performance diagnosis techniques target specific types of root causes and thus are limited when applied to many challenging performance problems. For example, X-ray [15] diagnoses performance anomalies due to unexpected inputs or configuration values by summarizing performance impact of each input/configuration value; however, as a tool designed for end users, X-ray does not address problems rooted in the source code. Statistical debugging [24, 26, 29, 32, 38] can address certain types of performance problems which result in differences in program predicates (e.g., branches and returns) [39]. However, unlike functional failures, many performance problems do not cause changes in predicates (e.g., due to distribution changes in runtime events). Besides, it can be challenging to design predicates and statistical models in the first place [39].

This paper introduces *relational debugging*, a new technique that automatically pinpoints the root causes of performance problems. The core idea is to capture *relations* between fine-grained runtime events. We show that relations provide immense utilities to explain performance anomalies and locate root causes. Relational debugging analogizes performance problems to *relative motion* in physics—just like the speed of an object is a relative measure depending on the reference frame, so is performance when viewed from different runtime events during program execution. Root causes of performance problems can be revealed by analyzing changes of

relative measures of these events (i.e., their relations) between a good run and a bad run (with performance anomalies).

Consider a real-world performance issue (see §2.1), where the developer observes an abnormal increase in memory consumption by a server application. Potential root causes can be: 1) an influx of more requests (in which consuming more memory is normal), 2) each request allocating more memory (indicating regression of code efficiency), and 3) allocated memory not being reclaimed (indicating memory leaks). Each of these hypotheses can be expressed as a relation (a measure relative to an event): 1) the number of requests *relative to* each time epoch, 2) the amount of memory allocated *relative to* each request, 3) the amount of memory reclaimed *relative to* each request. Relational debugging verifies the hypotheses by comparing the three relations in executions with and without the observed performance anomaly. In this example, 1) and 2) are the same, while 3) decreases significantly, suggesting memory leaks. Relational debugging further pinpoints the root cause of the memory leak by analyzing fine-grained relations. It finds that *relative to* all memory objects not reclaimed by the garbage collector (GC), many more are unreachable by pointers in the abnormal execution than the normal execution—a bug in the GC mistakenly treats constant values as pointers.

Relational debugging is highly effective with a minimal two executions (a good and a bad), eliminating the pain point of producing and labeling many different executions required by traditional statistical techniques [24, 26, 29, 32, 38, 39]. Notably, relational debugging utilizes the repetitiveness of performance symptoms which accumulate during the execution—a single execution offers a large sample of normal or abnormal patterns. Relational debugging is *generic* to performance problems with different types of root causes, including inefficient code, misconfigurations, and workload changes, etc. Moreover, relations can describe different types of symptoms such as slowdowns and memory overuse.

We realize relational debugging by developing a practical tool named Perspect. Perspect is fully *automatic*; it does not require manual instrumentations or annotations. Perspect takes the symptoms (such as a program counter that indicates excessive memory usage or a function with abnormal execution time) as inputs. It outputs the relations that are 1) *causally relevant* to the symptoms and 2) have significant impacts on the performance measures of the symptom; such relations describe the root causes of the performance problems. Perspect directly operates on x86 binaries to accommodate real-world diagnosis scenarios (e.g., when the binary build is nontrivial), and can tolerate small differences in the binaries.

Perspect focuses on capturing a small set of relations that can pinpoint the root cause. Instead of tracking all possible relations of every runtime event, Perspect reduces the search space by identifying runtime events that are causally related to the symptoms through control or data flow. Perspect then filters out relations that are not changed between the good and bad executions. For relations that are changed between

the executions, Perspect automatically differentiates between relation changes that reflect the *effect* (e.g., a decrease of reclaimed memory relative to each request), and changes that reflect the *cause* (e.g., an increase in objects not referred by real pointers). These strategies effectively filter out most of the irrelevant relations, with the remaining relations being root cause candidates. Lastly, Perspect ranks root-cause relations based on their impacts on performance measures of the observed symptom, and outputs them in descending order.

Perspect is carefully implemented so its analysis is both *precise* and *scalable* to real complex systems. It has an efficient algorithm that computes all the relations by traversing the dependency graph only once. In addition, it distributes the precise but expensive data-flow dependency analysis onto different servers. Finally, Perspect is able to handle the difference between two different versions of the binary executables.

We evaluate Perspect on twelve real-world performance issues from complex systems (Go runtime, MongoDB, Redis, and Coreutils), covering different symptoms (slowdown and memory overuse). Perspect effectively locates the root causes of these challenging issues. Notably, we applied Perspect to *two open issues* where developers failed to find the root causes; Perspect successfully located the root causes of both issues which are confirmed by the developers. For an issue where the root cause is located outside the target program (in the OS kernel), which took developers a long time to debug, Perspect correctly excluded the root cause from the application code, since it detects no significant relation changes.

In summary, this paper makes the following contributions:

- We present relational debugging, a new technique that analyzes the relations between causally related events, seizing the essence of performance debugging.
- We build Perspect, a practical tool that realizes relational debugging for large, complex real-world systems. Perspect directly operates on x86 binaries and accommodates real-world diagnosis/debugging scenarios.
- We show that Perspect can effectively locate the root causes of real performance problems, and can help resolve two previously unresolved issues. The source code of Perspect and the dataset are available at <https://gitlab.dsrg.utoronto.ca/dsrg/perspect>.

## 2 Relational Debugging by Examples

We use two real-world examples to show how relational debugging locates the root causes of challenging performance problems in complex software systems. Both problems are among the most challenging performance issues faced by developers, who were unable to locate the root causes with existing tools. Specifically, the Go runtime bug (§2.1) took a year of investigation, and the MongoDB bug (§2.2) is an open issue that developers failed to diagnose. Perspect automatically pinpoints the root causes in the form of relations.

## 2.1 Go-909: A Memory Leak

Go-909 is among the most famous performance bugs in the Go runtime. The developers reported that “*garbage collection is ineffective on 32-bit*” systems, causing workloads to run out of memory [2]. The same bug resulted in 9 other tickets (which turned out to have the same root cause) and at least 2 extensive discussion threads on Golang’s email list. The bug was also discussed in Hacker News with 147 comments [4].

### 2.1.1 Challenges of Debugging Go-909

Debugging Go-909 was very challenging not only for application developers but also for developers of the Go runtime. During the course, many wrong hypotheses, some of which were wildly off, were developed. For example, a developer believed that the bug was caused by the Go runtime forgetting to `munmap` freed memory [1]. There are at least three other bugs, of which developers could not agree on the root cause, that were eventually attributed to Go-909. After more than a year of investigations, the root cause was discovered through a trial-and-error process: the bug can be worked around by commenting out specific packages that contain a lot of static constants.

Existing performance debugging techniques can hardly address Go-909. First, Go-909 does not always cause a clear-cut out-of-memory error; in fact, many developers reported the bug simply after noticing their programs using more memory than expected [1, 3]. Moreover, since the root cause is not in program inputs, isolating faulty inputs using X-ray [15] or delta debugging [48] does not help. The root cause also can hardly be revealed by statistical debugging [32, 39], because it does not manifest in any abnormal predicates such as branch targets, unexpected return values, or scalar-pairs [39]. In fact, the memory leak also occurred in the reference executions (64-bit systems), only affecting many fewer objects.

### 2.1.2 Root Cause

Figure 1 shows the simplified code snippet in the buggy version of the Go runtime. Go programs invoke `runtime.malloc` to allocate memory and the Go runtime uses a mark-and-sweep garbage collector (GC). Once an object is allocated (L2), `runtime.malloc` increments the `heap_size` counter (L3).

The `mark` function looks for objects that are reachable through variables on the stack and in the data segments. Unmarked objects will later be reclaimed by `sweep`. During the stack scan, `mark` takes the pointer to the start of the stack and data segments (`b`), as well as the size of the respective regions (`n`). For every word on the stack and data segments, it initially assumes it to be a pointer and checks whether it points to an address inside the heap’s range (L15). If so, `mark` sets the “marked” bit in the metadata of the object (L18–19). Then, `mark` uses an iterative worklist `w` to further scan the memory based on the marked pointers. Later, `sweep` goes through each span, a memory region containing same-sized blocks. The

```
1 void* runtime.malloc(uintptr size, ...) {
2     void *p = runtime.Alloc(...);
3     heap_size += size;
4     uintptr bits = get_metadata(p);
5     ...
6     set_metadata(p, bits);
7     return p;
8 }
9 // Mark objects reached by pointers
10 static void mark(byte *b, int64 n) {
11     void **w = get_buffer_head();
12     while(b != nil) { ...
13         for(i = 0; i < n; i++) {
14             byte *p = (byte*)b[i];
15             if(p < HEAD_START || p >= HEAD_USED)
16                 continue;
17             uintptr bits = get_metadata(p);
18             bits |= BIT_MARKED; /* set mark bits */
19             set_metadata(p, bits);
20             *w++ = p;
21         }
22         b = *--w;
23         n = get_size(b);
24     }
25 }
26 // Reclaim unreachable objects
27 static void sweep(void) {
28     uintptr size = getsize(span);
29     for(byte *p = span->start; ... p += size) {
30         uintptr bits = get_metadata(p);
31         if((bits & BIT_MARKED) != 0) {
32             bits &= ~BIT_MARKED; /* clear mark bit */
33             continue;
34         }
35         set_metadata(p, bits);
36         runtime.Free(p, size, ...);
37         heap_size -= size;
38     }
39 }
```

GC log heap\_size is logged

GC log heap\_size is logged

```
./Perspect run_64 run_32
run_64: R<(L7|L18) = 0.99 // 64-bit (good run)
run_32: R<(L7|L18) = 0.01 // 32-bit (bad run)
```

Figure 1: Code snippets showing how Perspect locates the root causes of Go-909 by pinpointing the changed relation between L7 and L18 by comparing the two runs.

loop at L29 goes through each block, checks if the marked bit is set, and if so, clears the mark bit (L32) and continue on to the next block. Otherwise, it frees the object and decrements the heap size (L37).

The implementation of `mark` suffers from fake pointers—non-pointer variables that happen to have values within the range of `HEAP_START` and `HEAP_USED` (L15). The objects pointed to by those variables will not be reclaimed.<sup>1</sup> The defect affects both 32- and 64-bit systems; however, fake pointers occur orders of magnitude more frequently in 32-bit systems than 64-bit systems due to data layouts differences.

<sup>1</sup>This is a known side effect of using a conservative garbage collector.

### 2.1.3 Relational Debugging Go-909

Perspect takes as inputs a good run (which uses the 32-bit Go runtime) and a bad run (which uses the 64-bit Go runtime) of the Go program provided by the bug reporter, as well as the symptom. Since the bug manifests in abnormal heap sizes in the GC log, we (users) feed Perspect the `heap_size` variable which records the heap size value printed in the log. Perspect identifies the instructions that modify `heap_size`, i.e., L3 and L37 in the code of Figure 1, and Perspect treats these instructions as symptom instructions. Perspect will not only analyze what causes these symptom instructions to execute, but also what prevents these symptom instructions from executing; To do this, Perspect also identifies “negation” symptoms which are instructions that directly prevent a symptom instruction from executing, for example, L18, because each time L18 executes which marks and object, it directly prevents an instance of L37 which reclaims the object.

Perspect carries out relational debugging starting from instructions that directly determine the `heap_size` (L3, L37, and L18). It builds relations between symptom instructions and their causal predecessors. In this case, Perspect efficiently locates the root cause to a single relation (see Table 1 for notations):

$$R\blacktriangleleft(L7_{\text{malloc.return}} \mid L18_{\text{mark}})$$

On 64-bit systems, the relation is expected to be 1 : 1, indicating that for every marked object on L18, there exists a dependency on a pointer returned by `malloc`. Yet, on 32-bit systems, the relation drops to 1 : 0.01, i.e., only 1% of the marked objects have a pointer returned by `malloc`. The remainings are pointed to by fake pointers (constant values).

Note that the 1 : 1 relation in the reference run on 64-bit systems is *not* an invariant. Precisely, Perspect observed the relation to be 1 : 0.99, i.e., 99% of the marked objects are pointed to by a pointer returned by `malloc`. This is because the defect still exists in 64-bit systems, but only affecting 1% of the objects in the reference run.

$R\blacktriangleleft(L7 \mid L18)$  is not the only relation built by Perspect. Taking L18 as an example, Perspect builds four relations w.r.t L18’s causal predecessors L1 and L10:

- $R\blacktriangleleft(L1 \mid L18)$ : the distribution of the number of marked objects that depend on `malloc`;
- $R\blacktriangleright(L18 \mid L1)$ : the distribution of the number of times an object (still reachable by real pointers) gets marked;
- $R\blacktriangleleft(L10 \mid L18)$ : the distribution of the number of marked objects that depend on `mark`;
- $R\blacktriangleright(L18 \mid L10)$ : the distribution of the number of objects marked per `mark` call;

Perspect filters out  $R\blacktriangleright(L18 \mid L1)$  because the distribution of the lifetimes of objects reachable by real pointers do not change significantly between the good and bad run; and Perspect filters out  $R\blacktriangleleft(L10 \mid L18)$  because each marked object always depend on one invocation of `mark`.  $R\blacktriangleright(L18 \mid L10)$  is

$L_n$	An static instruction at line $n$
$eL_n_i$	The $i$ -th instance of $L_n$ in the execution
$S$	A symptom instruction
$eS_i$	A symptom event
$P$	A static insn. & causal predecessor of $S$
$P^+$	A static insn. & direct causal successor of $P$
$R\blacktriangleright(S \mid P)$	A forward relation between $P$ and $S$
$R\blacktriangleleft(P \mid S)$	A backward relation between $P$ and $S$
$R\blacktriangleleft\blacktriangleright(P, S)$	A pair of forward and backward relations
$R_?(P, S)$	A relation btw. $P$ and $S$ of unspecified direction

Table 1: Notations for relations.

changed across the runs, because fake pointers causes many more objects to be marked during each `mark` call in the bad run, but Perspect also excludes it because relational debugging recognizes that the relation only reflects the *effect* of the root cause, but is not the root cause. Finally, for  $R\blacktriangleleft(L1 \mid L18)$ , Perspect refines it to the most specific variant,  $R\blacktriangleleft(L7 \mid L18)$ . The other relations (e.g., those w.r.t symptom instructions at L3 and L37) are handled in similar ways, and eventually filtered out. We discuss Perspect’s filtering and refinement techniques in §3.3.

## 2.2 MongoDB-57221: A Slowdown

*“[Perspect’s result] ties all the pieces together into a nice explanation. That explanation being, having some unnecessary cursors simply open on failed plans isn’t strictly the problem. It’s that we’re paying the (also unnecessary) cost to reposition them after every delete + restore.”*

—MongoDB developer’s comment on Perspect’s result.

MongoDB-57221 is an open bug which developers were unable to diagnose. It is triggered by executing a query that deletes all the records in the table. The query could slow down by 5x on the buggy version. During the deletion, MongoDB uses a cursor, i.e., a pointer to a record in the table that indicates the current position, to locate each record. It advances the cursor to the next record after deleting the previous one; this process is known as cursor restoration.

This bug is caused by maintaining unnecessary cursors on multiple query plans. Before the query execution, MongoDB generates multiple query plans, performs a sandboxed trial of these plans, and chooses the best-performing plan. Different query plans use different indexes, thereby deleting records in different orders. The actual order of the deletion is determined by the index of the *winning* plan. However, MongoDB still keeps the rejected plans and their cursors. More importantly, it restores the cursor of each rejected plan following the same order as the winning plan. Whereas for the winning plan, restoring the cursor means simply moving to the next position, for the losing plan, restoring the cursor requires traversing through many already deleted records. And if the number of deleted records encountered exceeds a threshold, it flags the page for eviction. The increase in unnecessary evictions leads to the slowdown.

Developers were unable to understand the root cause of this bug, despite them quickly identifying evictions being the bottleneck based on profiling and being aware of the existence of multiple query plans. However, they could not explain *why* excessive evictions occurred, because they could not establish the causal link between evictions and the cursor restoration of the rejected plans. This led to rounds of ping-pongs between the Storage Engine team (responsible for the eviction) and the Query Execution team (responsible for maintaining multiple plans). The storage team suspected that the slowdown was caused by maintaining multiple plans, but the query execution developers believed that it was cheap to keep multiple plans around. And they further suspected that the slowdown was caused by the threshold misconfiguration that triggered the eviction. In the end, seven different developers actively discussed this issue for over a month. The JIRA discussion has over 3,000 words in 18 comments, with multiple rounds of reproduction and profiling with multiple screenshots posted. And the two teams had multiple off-line teleconference discussions. Still, they were unsure why the slowdown occurred.

Perspect pinpoints the root cause and explains the slowdown. It captures that the costly evictions are causally dependent on the restoration of multiple cursors. Figure 2 displays a simplified version of static dependency graph for eviction. Starting from *eviction* as the symptom, Perspect returns the root cause candidate: (1)  $R \blacktriangleright (\text{cursor\_search} \mid \text{restore})$ , where *restore* invokes *cursor\_search* once in the good run to restore one cursor, but twice in the bad run to restore two cursors. Perspect infers that restoring an additional cursor causes a significant increase in evictions in the bad run.

Moreover, Perspect specifically infers that during cursor restoration, additional traversals through dead records increased evictions. It returns (2)  $R \blacktriangleleft \blacktriangleright (\text{eviction} \mid \text{search\_forward})$  as a new pair of relations unique to the bad run: *search\_forward* is invoked by *cursor\_search* to search for the next cursor position by traversing forward in the records. In the good run, *search\_forward* almost always locates the next cursor position immediately, triggering no evictions; whereas in the bad run, *search\_forward* traverses through many dead records and triggers additional evictions. Perspect also returns (3)  $R \blacktriangleright (\text{search\_backward} \mid \text{cursor\_search})$  as a root cause candidate. In the good run, *cursor\_search* invokes *search\_backward* only 1% of the time, because *search\_forward* locates the next cursor position most of the time; however, in the bad run, *cursor\_search* invokes *search\_backward* half of the time. The increased searches lead to additional evictions.

### 3 Perspect

Generally speaking, debugging a performance problem takes three steps: 1) observing symptom(s), 2) capturing runtime events that are causally related to the symptom(s), and 3) locating the root cause. Perspect automates the last two steps, taking the symptoms as its inputs. Perspect supports different

Figure 2: A simplified version of the static dependency graph for eviction. Each edge with a single arrow represents a dependency. An edge with a double arrow represents a backedge in a loop. *restore* loops through every cursor and restores each by invoking *cursor\_search*. *cursor\_search* then invokes *search\_forward* which looks for the next record by iterating forward. If *search\_forward* returns without locating the next record, *cursor\_search* will then invoke *search\_backward*. If *search\_backward* or *search\_forward* encounters too many dead records, it will trigger *eviction*.

Figure 3: An overview of Perspect’s workflow

forms of symptoms, including: program variables that record the symptoms (e.g., *heap\_size* in Go-909), slow functions (such as *eviction* in MongoDB-57221), and basic blocks (captured by profilers like *gprof* [12]). Perspect automatically identifies the instructions related to the input symptoms as the starting points of its analysis (§3.1). Perspect outputs a list of relations that explain the root cause in descending order based on their impacts on the observed symptom.

Figure 3 shows the workflow of Perspect. Perspect uses causality analysis to reduce the search space of relational debugging to a small set of instructions and their runtime instances that are causally related to the symptom (see §3.2). Perspect then performs relational debugging to build relations with regard to the symptom. It filters out relations that are irrelevant to the symptom, refines relations to be specific to the root cause, and ranks relations based on their impacts on the observed symptom (see §3.3).

#### 3.1 Bootstrapping with Symptoms

Perspect bootstraps itself by identifying the instructions that reflect the observed symptoms. If the symptom is a performance counter recorded in a program variable (such as *heap\_size* in Go-909), Perspect identifies the instructions that use the variable as an operand. If the symptom is a function or a basic block (typically captured by profilers), Perspect identifies the first instruction of the function or the first instruction in the basic block. Hence, Perspect converts different types of symptom inputs to unified starting points in the form

of instructions, termed *symptom instructions*, denoted as  $\mathcal{S}$  in Table 1. A dynamic instance of the symptom instruction is a *symptom event*.

Each symptom instruction is assigned a *weight*. The weight can be the value of a variable in an instruction, such as `size` in L3 or L37 in Go-909 (Figure 1), or the estimated time or cycles taken by a code block (e.g., `eviction`).

Perspect also identifies instructions that prevent the occurrence of symptoms (i.e., the negation of a symptom) as a special type of symptom instructions. An example is L18 in Go-909. Perspect searches every conditional branch that dominates a symptom instruction, which could prevent the symptom from occurring (e.g., L31 in Go-909 w.r.t L37). It then identifies the instructions that determine the branch conditions (e.g., L18 in Go-909). In practice, we find it suffices to only include instructions of negation for the initial symptom instructions. Therefore, in our current implementation, Perspect does not recursively search for negation symptoms.

## 3.2 Causality Analysis

Perspect reduces the search space of relational debugging by restricting the subsequent analysis to a small subset of instructions and their runtime instances that are causally related to the symptoms. The high-level idea is to dynamically track instructions that the symptoms are causally dependent on through control- and data-flow (aka information flow) during the execution of the good or bad reproduction runs. Specifically, Perspect generates a *dynamic* program dependency graph that contains instances of instructions that the symptom is causally dependent on.

The causality tracking is done in two phases. Perspect first generates the *static* program dependency graph (SDG) [25] for all the symptom instructions from the program. In the SDG, a node  $v$  is an instruction and an edge  $(u, v)$  represents a causal dependence, either a data dependence (a data value  $v$  depends on) or a control dependence (a control condition on which  $v$  depends on). We call  $u$  a *causal predecessor* of  $v$  and  $v$  a *causal successor* of  $u$ . To generate the SDG, Perspect performs *backward* causality tracking: it starts from each symptom instruction (including negation symptoms) and recursively includes causal predecessor instructions by tracking control or data flow.

Perspect then automatically instruments the instructions in the program binary that belong to the SDG; it later generates *dynamic* program dependency graphs (DDGs) by running the program binary and monitoring the execution of each instrumented instruction. Different from the SDG, which consists of static instructions, in a DDG, a node is a runtime *event*—an instance of an instruction in the execution. Each instruction in the SDG can correspond to multiple events in a DDG. We use  $eLn_i$  to denote an event of the  $i$ -th occurrence of the instruction at line  $n$  (i.e.,  $Ln$ ) in the execution (see Table 1).

Section 4 describes the implementation details.

## 3.3 Relational Debugger

Within the scope of instructions that are causally related to the symptom(s), Perspect computes the relations between the symptom instructions and their causal predecessors in the SDG, based on runtime dependencies derived from the DDGs (§3.3.1). Perspect only considers relations that are changed between the good and the bad executions as potential root causes by filtering out unchanged relations (§3.3.2). Perspect further refines each relation until it finds the specific relation that captures a root cause of the change in the number of symptom events between the good and the bad executions (§3.3.3). The filtering and refinement steps are iterated repeatedly to select a minimal set of relations as the candidates of the root cause (Figure 3). Lastly, Perspect ranks the root-cause candidate relations based on their impact on the symptoms (§3.3.4).

We use Go-909 (Figure 1) as a running example when explaining the above components.

### 3.3.1 Computing Relations

For each symptom (including the negative symptoms), Perspect computes the relation between an instruction  $P$ , which the symptom depends on causally, and the corresponding symptom instruction  $\mathcal{S}$ . Both  $P$  and  $\mathcal{S}$  are nodes in the SDG generated in §3.2. The relation is computed based on the DDG (§3.2) which records runtime events of  $P$  and  $\mathcal{S}$  during the executions. Perspect computes relations for the good run and the bad run, respectively.

Perspect starts by only considering the relation between  $\mathcal{S}$  and the root nodes of the SDG as  $P$ . These root nodes are typically the entry point of a software module and the `main` function. It gradually considers other events on the causal dependency paths between the root node and  $\mathcal{S}$  using a refinement process described in §3.3.3.

Perspect computes both *forward relations* and *backward relations*. A forward relation is defined as  $R \blacktriangleright (\mathcal{S}|P) = \{n_i\}$ , where each element  $n_i$  in the set, which corresponds to an instance of instruction  $P$  (denoted as  $eP_i$ ) in the DDG, is the number of causally dependent  $\mathcal{S}$  instances ( $e\mathcal{S}_j, e\mathcal{S}_k \dots e\mathcal{S}_m$ ) of  $eP_i$ . Therefore, a relation can be viewed as a distribution; We use the mean of the distribution to represent a relation for simplicity. Here,  $P$  can be thought of as serving as a reference point, and  $\mathcal{S}$  as the object under observation.

For example, in Go-909, for the symptom instruction  $L18_{mark}$  (marking one object), Perspect constructs a relation  $R \blacktriangleright (L18_{mark}|L1_{malloc.start})$ , which represents the number of times each allocated object got marked. If the first allocated object gets marked (i.e., it results in an instance of  $L18$ ) but the second one does not, then  $R \blacktriangleright (L18_{mark}|L1_{malloc.start})$  would be  $\{1, 0\}$ . In practice,  $R \blacktriangleright (L18|L1)$  has a much larger sample size, because hundreds of objects are allocated and marked.

A backward relation is defined as  $R \blacktriangleleft (P|\mathcal{S}) = \{m_i\}$ , where each element  $m_i$ , which corresponds to an instance of  $\mathcal{S}$  in the DDG ( $e\mathcal{S}_i$ ), is the number of causally dependent  $P$  instances

( $eP_i, P_j \dots eP_k$ ) of  $eS_i$ . Opposite to a forward relation, for a backward relation, the symptom serves as the reference point, and the predecessor as the object under observation.

Regarding the example,  $R\blacktriangleleft(L1_{malloc.start}|L18_{mark})$ , which contains, for each marked object ( $L18_{mark}$ ), the number of causally connected `malloc` instances ( $L1_{malloc.start}$ ); each object pointed to by real pointers is connected to 1 instance of  $L1_{malloc.start}$  whereas an object pointed to only by fake pointers is connected to 0 instances.

Note that a backward and forward relation,  $R\blacktriangleleft(P|S)$  and  $R\blacktriangleright(S|P)$ , complement each other. A forward relation tells: “given the same unit of input, is the same number of symptom events produced?”, whereas a backward relation tells: “given the same symptom event, is it still produced by the same units of input?” In Go-909, fake pointers introduce additional causal paths through which the symptom at  $L18$  (marking one object) may occur. This is reflected in a change of the backward relation  $R\blacktriangleleft(L1_{malloc.start}|L18_{mark})$ , from 100% to 1% on average; the forward relation  $R\blacktriangleright(L18_{mark}|L1_{malloc.start})$ , reflecting the number of times each object (reachable from real pointers) gets marked, does not change significantly.

### 3.3.2 Filtering Unchanged Relations

Perspect filters out a relation  $R_{\gamma}(P, S)$  if it has not changed between the executions of the good and bad runs. Perspect determines if a relation has changed based on its distribution using the two-sample Kolmogorov-Smirnov test [27], with a confidence interval of 95%. For example, in Go-909, the relation  $R\blacktriangleright(L18_{mark}|L1_{malloc.start})$  does not change, because, for the objects still reachable from real pointers, the distribution of object life-spans (the number of times they get marked) does not change significantly; therefore, Perspect filters out this relation.

Furthermore, if a relation  $R_{\gamma}(P, S)$  is unchanged across two executions, it implies that the relations between any of  $P$ 's causal successors— $Q$ —and  $S$  have not changed. Perspect skips the computation of these relations. In other words, if there exists a causal successor  $Q$  where  $R_{\gamma}(Q, S)$  is changed, then  $R_{\gamma}(P, S)$  would be changed. Intuitively, it means that the same set of runtime events produces the same symptom events (forward relation) or the same set of symptom events is still produced by the same events (backward relation). This optimization allows us to skip many unnecessary relation computations.

In Go-909, Perspect filters out most of the relations at this step, and only keeps three relations (which will be further refined and filtered in §3.3.3):

- $R\blacktriangleleft(L1_{malloc.start}|L18_{mark})$ : the number of marked objects reachable from real pointers decreased;
- $R\blacktriangleright(L18_{mark}|L10_{mark.start})$ : the number of objects marked per `mark` call increased;
- $R\blacktriangleright(L37_{sweep}|L27_{sweep.start})$ : the number of objects reclaimed at  $L37$  per `sweep` call ( $L27$ ) decreased.

### 3.3.3 Relation Refinement

Perspect further refines the relations to replace a more “general” relation with a more “specific” one. Refinement is analogous to moving the reference point closer to the object under observation in relative motion. If a relation  $R_{\gamma}(P, S)$  is deemed *refinable*, Perspect replaces the relation with its child relations:  $R_{\gamma}(P_0^+, S), R_{\gamma}(P_1^+, S) \dots R_{\gamma}(P_n^+, S)$ , where  $\{P_0^+, P_1^+ \dots P_n^+\}$  are the direct causal successors of  $P$  (i.e., children of  $P$ ). Perspect iteratively refines a relation until it is no longer refinable or can be filtered out by §3.3.2.

Refinement aims to pinpoint the root cause(s). Without refinement, Perspect only outputs relations between  $S$  and root nodes  $R$  in the SDG, where  $R$  can be the entry point of a module or the `main` function. But the root cause(s) are often located at events on the causal paths connecting  $R$  and  $S$ . Intuitively, the root cause are events which, if executed, will inevitably cause the performance bug to manifest [50]. The refinement process aims to locate such events.<sup>2</sup>

We design the following two refinement rules:

Rule 1: A relation  $R_{\gamma}(P, S)$  is refinable, if there is no change in any of the relations between  $P$  and its children  $\{P_0^+, P_1^+ \dots P_n^+\}$ :  $R_{\gamma}(P, P_0^+)$ ,  $R_{\gamma}(P, P_1^+)$ , and  $R_{\gamma}(P, P_n^+)$ .

Intuitively, this rule says  $P$  is *not* a root cause; the root cause(s) is located further down the causal paths. Recall that the root cause(s) are events which, once executed, the performance bug will inevitably manifest. But now we have  $P+$  that occurred after  $P$  in *both* the good and bad run, and  $R_{\gamma}(P, P+)$  does not change. This means that after  $P$  executes, the performance bug may still be avoided when  $P+$  executes. So we should move one step forward on the causal chain to consider whether  $P+$  is the root cause.

With this rule, Perspect refines  $R\blacktriangleleft(L1_{malloc.start}|L18_{mark})$  to  $R\blacktriangleleft(L7_{malloc.return}|L18_{mark})$  in Go-909, because  $R\blacktriangleleft(L1|L7)$  is an invariant that does not change across executions. In the actual code, the program logic between  $L1$  and  $L7$  is complex; ruling out  $L1$  and narrowing it down to  $L7$  significantly helps the developer to understand the root cause.

Figure 4 further shows the sequence of refinements performed on  $R\blacktriangleright(L37_{sweep}|L27_{sweep.start})$ . Based on rule 1 we can refine it twice to  $R\blacktriangleright(L37|L31)$ , because neither  $R\blacktriangleright(L29|L27)$  nor  $R\blacktriangleright(L31|L29)$  changes.

Even if a relation is not deemed refinable by rule 1, we do not give up—it can still be refined based on rule 2:

Rule 2: Even if there is a change in  $R_{\gamma}(P, P_i^+)$ ,  $R_{\gamma}(P, S)$  is still refinable if the change in  $R_{\gamma}(P, P_i^+)$  is caused by the change of  $R_{\gamma}(P', P)$ , where  $P'$  is a predecessor of  $P+$  and  $P' \neq P$ .

Rule 2 differentiates whether a changed relation is a true root cause, or merely the *effect* (i.e., manifestation) of the root

<sup>2</sup>Zhang *et al.* defines the root cause as the *inflection point*: if we model the execution as a sequence of instructions, the inflection point in a failure execution  $F$  is the point of divergence with a non-failure execution  $N$  where  $N$  is the non-failure execution that has the longest common prefix with  $F$  [50]. Perspect’s refinement essentially locates such inflection points.

Figure 4: An example to illustrate the refinement rules on Go-909. On the right is (part of) the SDG; a solid edge indicates a control-flow dependency, whereas dotted edges represent dataflow dependencies.

cause. In the former case, we should not be able to find such a  $P'$ , whereas in the latter case, we can.

Specifically, we consider two cases in our implementation. The first is when  $P$  is a branch instruction,  $P^+$  is an instruction in the branch target, and  $P'$  is the dataflow direct predecessor of  $P$  that defines the branch condition variable. In this case, the change in  $R\blacktriangleright(P^+|P)$  is the effect of the change of  $R\blacktriangleleft(P'|P)$ , which affects the branch direction.

Consider  $R\blacktriangleright(L37_{sweep}|L31_{sweep.test})$ . Here,  $P$  and  $P^+$  are  $L31$  and  $L37$ , respectively. This relation decreased in the bad run since fewer objects are deemed reclaimable by  $L31$ , and is therefore no longer refinable according to Rule 1, as illustrated by Figure 4. However,  $L31$ 's direct dataflow predecessors include  $L18$ , which sets the mark bit ( $L18$  is the  $P'$  in this case). The decrease in  $R\blacktriangleright(L37|L31)$  is merely caused by the increase in  $R\blacktriangleleft(L18|L31)$ , i.e., more objects are being marked at  $L18$  before  $L31$  checks the marked bit. Therefore, according to Rule 2,  $R\blacktriangleright(L37|L31)$  is still refinable, and we refine it to  $R\blacktriangleright(L37|L37)$  (because  $L37$  is  $L31$ 's direct successor). It can be subsequently filtered based on §3.3.2 since a relation between two identical events doesn't change between runs. This is shown in Figure 4.

Note that we do not need to compute relations on this newly discovered  $P'$  separately, because our algorithm guarantees that this relation is computed through other causal paths from the root. For example, after Perspect found  $L18$  is the  $P'$  in the above example, it does not go on to compute relations between  $L18$  and its predecessors, because these relations are already computed through the causal path starting from `mark`.

The second case involves loops, when  $P^+$  is a loop head and  $P'$  is the loop tail. Consider  $R\blacktriangleright(L12_{mark.loop}|L10_{mark.start})$ . In this case,  $P$  is  $L10$  and  $P^+$  is  $L12$  (which is a loop head). This relation increased in the bad run because more objects are getting marked. However, this is caused by  $L12$ 's backedge from  $L24$  (loop tail, which is  $P'$ ) executing more often, i.e.,  $R\blacktriangleright(L24|L10)$  also increased by the same amount.

As a result, even though  $R\blacktriangleright(L12_{mark.loop}|L10_{mark.start})$  has changed,  $R\blacktriangleright(L18_{mark}|L10)$  can be further refined to  $R\blacktriangleright(L18|L12)$ . Eventually,  $R\blacktriangleright(L18|L12)$  will be filtered out because by further analyzing the dataflow predecessor of  $L12$  under Rule 2, Perspect finds that the number of times  $L12$  executes is controlled by the size of `w`, which in turn is dataflow-dependent on  $L18$  itself (i.e., each time an object is marked, it is pushed onto the queue `w` and popped from the queue later into `b` so `mark` can further scan the content of the object for more pointers). So the relation is refined to  $R\blacktriangleright(L18|L18)$  eventually.

By applying the two refinement rules iteratively, Perspect filters both  $R\blacktriangleright(L37_{sweep}|L27_{sweep.start})$  and  $R\blacktriangleright(L18_{mark}|L10_{mark.start})$ . Therefore, Perspect only reports one relation at the end of the filter-refine iterations:  $R\blacktriangleleft(L7_{malloc.return}|L18_{mark})$ .

### 3.3.4 Ranking Root-Cause Candidates

After the iterative compute-filter-refine process, the remaining relations are the ones that have not been filtered and are not refinable anymore. We call them root cause candidates.

Perspect ranks the root-cause candidates based on their estimated contributions to performance, in terms of the difference in performance relative to the predecessor  $P$ . Specifically, for a forward relation  $R\blacktriangleright(S|P) = \{n_i\}$ , where each  $n_i$  is the number of symptom instances that causally depend on  $eP_i$  (the  $i$ -th instance of  $P$ ), Perspect computes a weighted sum:  $\sum w_i \times n_i$ , where  $w_i$  is the average weight of the  $n_i$  symptom events;  $\sum w'_i \times n'_i$  is the weighted sum for the good run. Then the contribution to performance is estimated by  $\sum w_i \times n_i - (\sum w'_i \times n'_i) \times \frac{c_P}{c'_P}$ , where  $c_P$  and  $c'_P$  are the number of times  $P$  occurred in the bad and good run, respectively. Note that Perspect normalizes  $\sum w'_i \times n'_i$  with  $c_P/c'_P$  to obtain the performance relative to  $P$  in scenarios where the number of times  $P$  occurred has changed between the executions. (Say the change in  $P$ 's occurrences is caused by relation  $R\blacktriangleright(S|P')$ , where  $P'$  is a predecessor of  $P$ , the normalization helps correctly attribute performance impact between  $R\blacktriangleright(S|P)$  and  $R\blacktriangleright(S|P')$ .)

In a backward relation  $R\blacktriangleleft(P|S) = \{m_i\}$ , Perspect computes weighted sums:  $\sum w_i$ ,  $\sum w_j$  where  $w_i$  is the weight of the  $i$ -th instance of the symptom, and  $w_j$  is the weight of the  $j$ -th instance of  $P$  that can reach a symptom event; And  $\sum w'_i$ ,  $\sum w'_j$  are the weighted sums for the good run. Then the contribution to performance is estimated by  $\sum w_i - \sum w_j / (\sum w'_i / \sum w'_j)$ , where  $\sum w_j / (\sum w'_i / \sum w'_j)$  estimates the total number of symptom events, had the same number of symptom events been reachable from  $P$  instances in the good run; This formula also handles when the total number of reachable  $P$  instances from the symptom differs in the two executions. If the symptom has a negative polarity, as in the case of  $L37_{sweep}$ , which reduces the heap size as opposed to increasing it, Perspect multiplies its performance impact with  $-1$ .

## 4 Implementation

Perspect is implemented in 10,199 lines of C++ and 14,006 lines of Python. It is built on top of three tools, Dyninst [8] (a binary-level static analysis tool), RR [7] (a deterministic record-and-replay tool), and PIN [11] (a binary instrumentation tool). Perspect operates on application binaries directly.

A key challenge in our implementation is to scale Perspect to the real, complex systems software. This section describes a number of techniques we use for scalability.

### 4.1 Building Static Dependency Graph (SDG)

Perspect generates the SDG by recursively identifying instructions that are causal predecessors of the symptom instructions via control and data flow. (Figure 4 shows a snippet of the SDG on Go-909.) This is done by three components: 1) a *static analysis* (SA) process running Dyninst, 2) 64 *dynamic dataflow analysis* (DDA) processes running RR (across 4 servers), and 3) a controller. These components form a distributed system that parallelizes computation to scale to real-world systems.

The SA process iteratively infers the instructions on which the symptom instruction  $\mathcal{S}$  is control-flow dependent. It analyzes the control-flow graph provided by Dyninst, and only keeps those instructions that  $\mathcal{S}$  actually depends on. This analysis is first performed in the function ( $f$ ) that contains  $\mathcal{S}$ ; it is then repeated iteratively in the caller functions by tracing the call-sites starting from  $f$ .

To obtain dataflow dependencies, Perspect uses a combination of static and dynamic analysis. Perspect only uses Dyninst to obtain the dataflow dependencies of local variables stored in registers or on the stack with static offsets. On the other hand, when a variable is read from other memory locations, *i.e.* the heap or stack locations with non-static offsets, Perspect does not analyze them statically through pointer analysis, because precise pointer analysis can be hard to scale [31]. Instead, Perspect uses the DDA processes to dynamically identify such data dependencies in parallel.

For example, say  $\mathcal{S}$  is dominated by an if statement: `if (*p || *q)`; at this point, Perspect needs to infer the dataflow of both `*p` and `*q`, and Dyninst cannot infer the source of the dataflow precisely. Therefore, the SA process sends this request to the controller, which forwards it to a (pre-forked) DDA process to run the RR-guided reproduction. The DDA process first sets breakpoints at the `if` statement to determine the addresses of `*p` and `*q`. It then sets watchpoints at these two addresses and re-run the RR-guided reproduction.<sup>3</sup> (Since execution through RR is deterministic, addresses stay the same across multiple runs.) And via the watchpoints, Perspect locates the store instructions that defined `*p` and `*q`. The DDA process then sends these newly located store in-

<sup>3</sup> If a breakpoint or watchpoint is not hit in the RR-guided reproduction, Perspect will deem them causally irrelevant to the symptom events and ignore them.

Figure 5: A simplified version of the Dynamic Dependency Graph (DDG) for the symptom instruction at L18 from Go-909. The *red* colour represents the `malloc` function, and the *grey* colour represents the `mark` function. Solid and dotted edges represent control and data flow. The set next to each event is the  $\mathcal{S}$ -set.

structions back to the SA process (via the controller). This causes the SA process to restart the analysis with these two instructions as the new starting points.

In practice, the SA is orders of magnitude faster than the DDA. Yet, the DDA can be parallelized: for example, the analysis of the dataflow source of `*p` and `*q` can be done in parallel. We create 64 DDA processes, each of which can set at most 4 watchpoints in each run (limited by the number of hardware watchpoints).

### 4.2 Building Relations

Once the SDG is obtained, Perspect instruments the program at each instruction in the SDG using PIN, and runs the instrumented program to obtain a trace of the good and the bad run, respectively. Perspect builds one DDG for each unique symptom instruction. Each vertex in the DDG is an event, and an edge is a control- or data-flow dependency. Figure 5 shows a simplified version of the DDG for the symptom instruction at L18 from Go-909. There are two objects in the DDG: The first one is reachable from a real-pointer, which means it's dependent on `malloc` (`eL10`, `eL70`), and the object gets marked (`eL100`, `eL120`, `eL150`, `eL180`). The second object is from a fake pointer; it also gets marked once in the same loop iteration as the first object (`eL100`, `eL120`, `eL151`, `eL181`), but has no dependencies on `malloc`.

Instead of traversing the DDG each time it needs to compute a relation, Perspect only carries out a one-pass traversal of the DDG to compute all the forward and backward relations. To compute forward relations, each node in the DDG keeps an  $\mathcal{S}$ -set, which is the set of all unique reachable symptom events. We initialize the  $\mathcal{S}$ -set of the symptom nodes to the symptom event itself. In Figure 5, `eL180` and `eL181`'s  $\mathcal{S}$ -sets are initialized with themselves. Perspect then traverses the DDG in *post-order* to iteratively compute the  $\mathcal{S}$ -sets. For each node  $N$ , its  $\mathcal{S}$ -set is the union of the  $\mathcal{S}$ -sets of all its children nodes. (Post-order traversal guarantees that  $N$ 's children are visited before  $N$ .) But keeping the  $\mathcal{S}$ -set of each node consumes too much memory. As an optimization, we replace

node  $N$ 's  $\mathcal{S}$ -set with its cardinality (i.e., number of elements or  $|\mathcal{S}\text{-set}|$ ) as soon as its  $\mathcal{S}$ -set is propagated to all of  $N$ 's parent nodes. For a forward relation  $R \blacktriangleright (\mathcal{S}|P) = \{n_i\}$ , each  $n_i$  is simply the  $|\mathcal{S}\text{-set}|$  of each event of  $P$ . For example, in Figure 5,  $R \blacktriangleright (L18|L10) = \{2\}$ , where 2 is the  $|\mathcal{S}\text{-set}|$  of  $eL10_0$ ; and  $R \blacktriangleright (L18|L15) = \{1, 1\}$ , where the two 1s come from the  $|\mathcal{S}\text{-set}|$  of  $eL18_0$  and  $eL18_1$ .

To compute backward relations, Perspect keeps a hashmap  $H$  for each symptom event. Each  $H$  keeps the number of reachable predecessor events for every corresponding predecessor instruction. For example, in Figure 5, Perspect keeps two  $H$ s, one for  $eL18_0$  and one for  $eL18_1$ . The  $H$  for  $eL18_0$  contains 5 entries:  $\{L15, L12, L10, L7, L1\}$ , and the count for each key is 1.  $H$  for  $eL18_1$  only contains 3 entries:  $\{L15, L12, L10\}$ , where the count for each key is also 1. A backward relation  $R \blacktriangleleft (L1|L18)$  is simply the set containing the count kept for  $L1$  in each  $H$ , which is  $\{1, 0\}$ .

**Optimization: two-phase analysis.** As an optimization, we perform our analysis in two phases. The first phase, or the “sketch” phase, only performs the analysis on the call graph. Specifically, each node in the SDG in this phase is a function, and each edge is a function invocation. The exceptions are functions that contain the symptom instructions: we directly connect the symptom instructions to the entry of these functions. We do not perform the expensive data-flow analysis in the sketch phase. Given this SDG, we build relations using the same algorithm: first obtain the DDG from the sketch SDG, and perform the relation analysis on this DDG. So, the  $P$  in the relations  $R_{\blacktriangleright}(P, \mathcal{S})$  we obtained is a function. For  $P$  whose relation changes, we zoom into  $P$  and perform the full data- and control-flow analysis described in §4.1. This optimization allows us to avoid the expensive dependency computations on functions that are not relevant to the root cause; it is particularly effective in large code bases like MongoDB where the symptom often has a deep call stack. In practice, this optimization reduces Perspect’s static analysis time by 10 times.

### 4.3 Handling Binary Difference

Perspect is able to compare relations generated from different binaries by matching each binary instruction to its corresponding one in the other binary, or between different binaries generated from the same source code (i.e., compiled for the 64- and 32-bit machines). Perspect first performs the source-level `diff` to establish the file and line number mapping between two versions. However, a line in the source code often compiles to multiple binary instructions, sometimes even multiple basic blocks of binary instructions. So we cannot only rely on source-level line number mapping to map binary instructions. Instead, for two binary instructions to be considered as the same between two version, they have to have 1) the mapping source-level line number, and 2) the same binary basic block number, assigned according to the postorder traversal of all the basic blocks of the same source code line, and 3) the same

offset within the basic block. If the instruction is not found at the same offset, Perspect also searches for nearby instructions.

## 5 Experimental Evaluation

Perspect’s premise is that relational debugging can automatically and effectively locate the root causes of real-world performance problems that are hard to diagnose by existing tools. We validate these hypotheses with three evaluation questions: 1) Can Perspect effectively locate the root cause of challenging performance problems? 2) Can Perspect’s output, in the form of relations, help users understand root causes? 3) What is the analysis time of Perspect?

- §5.1: Perspect effectively locates root causes of evaluated performance problems in Go runtime, MongoDB, Redis, and Coreutils. Perspect also correctly excludes a root cause from application code when it is in the OS kernel.
- §5.2: The output of Perspect, in the form of relations, can speed up debugging time by at least 10.87 times.
- §5.3: Perspect diagnoses 10/12 of the issues in 8 minutes on average, and diagnoses the other two in a few hours.

**Target applications and performance problems.** We evaluate Perspect on twelve real-world performance issues of four applications: the Go runtime, MongoDB, Redis, and Coreutils. All three are complex software systems, consisting of more than 220K, 6,955K, 37K, and 456K lines of code, respectively. The performance problems are collected from the issue trackers of the target applications, based on keywords like “performance”, “slow”, “degrade”, etc. Where possible, we focus on high-priority issues that cannot be simply answered by using a profiler but take significant human time and effort, as those are the problems that need advanced tools like Perspect.

We then try to reproduce these issues based on the steps described in the issue reports. Reproducing performance problems is nontrivial and time-consuming—many of the issues are imprecisely described (e.g., no version information or reproduction steps) and are hard to reproduce. In total, it took several person-months for us to prepare the dataset. We realize that our dataset has several “famous” bugs (e.g., Go-909 in §2) because they have more detailed information for reproduction.

As shown in Table 2, the twelve issues cover different symptoms and use cases. In terms of symptoms, nine caused slowdown; three caused memory overuse, including bloated heap size and resident set size (the amount of memory used by the process). There are three different types of performance baselines: five are from a different version, one from different hardware architecture, and the other five are from different inputs. Notably, we evaluated *two open issues* where developers were unable to diagnose them (MongoDB-56274 and -57221).

**Inputs.** Perspect takes as inputs of the reproduction of the performance problems. We directly used reproduction programs

	Issue	Description	Metric	Succ?	Rank	Abs. pred.?	Cand. relns.	SDG size	DDG size
Go runtime	909	Fake pointers stops GC from freeing dead objects	heap	Yes	1st	No	1	16054	516k
	7330	Performance of operator += is worse than single +	time	Yes	1st	Yes	1	26	200k
	8832	Hugepage promotion causes memory bloat	RSS	Partial	-	-	-	3140	6851
	11068	Printing is very slow for large Floats	time	Yes	1st	Yes	1	10650	1409k
	12228	More aggressive GC degrades performance	time	Partial	-	Yes	-	9886	39745
	13552	Not recycling large stack spans leaks memory	RSS	Yes	1st	No	1	18060	55580
Mongo	44991	Erroneous cache clear for common prefixed keys	time	Yes	1st	Yes	1	2109	461k
	<b>56274</b>	Slow when deleting opposite to search order	time	Yes	1st	No	3	56	6132
	<b>57221</b>	Slow due to moving cursor of obsolete query plan	time	Yes	1st	No	3	5100	268k
Redis	7595	performance downgrade after enabling TLS	time	Yes	1st	Yes	1	35	801
Core	930965	seq 84x slower with -equal-width	time	Yes	1st	Yes	1	668	20002
	1014738	du -exclude 4x slower when given a trivial string	time	Yes	1st	Yes	1	7563	20784

Table 2: **Perspect’s result on 12 real-world performance issues across 4 systems: Go runtime, MongoDB (“Mongo”), Redis, and Coreutils (“Core”).** Mongo-56274 and -57221 are two *open bugs*. “Metric” shows the type of performance metric that describes the symptoms. “Succ?” shows whether Perspect *successfully* locates the root cause. “Rank” shows the ranking of root-cause relations. “Abs. pred?” tells whether the root-cause relations break any absolute predicates. “Cand. relns.” shows the number of root-cause candidate relations. Where Perspect returns a pair of forward and backward relations, it is counted as one root cause candidate. “SDG size” and “DDG size” show the average SDG and DDG size from the good and bad runs, in terms of the number of instructions and their runtime instances, respectively.

attached in the reports, or created reproductions by closely following the descriptions in the reports. We find that except for Go-909, which provided three similar reproductions, all issues describe at most one good and one bad execution. Perspect is able to exploit high repetitiveness of runtime events within one execution, and works with two executions as is.

## 5.1 Effectiveness

Table 2 shows the effectiveness of Perspect in diagnosing the twelve performance bugs. The overall results are very positive. Perspect successfully locates the root causes for ten performance problems, and ranks the root-cause relation as the highest (or the only) suspect. Eight of them are closed issues and we use the criteria that the reported root cause has to be captured by the output relations of Perspect. For the two open bugs, the relations output by Perspect provided explanations of the root causes that were confirmed by the developers.

Perspect partially locates the root causes of the other two issues (Go-8832 and Go-12228). For Go-8832, Perspect correctly excludes the root cause (which lies in Linux) from the Go runtime. For Go-12228, the source codes changed significantly; Perspect is unable to map the relations across the executions. In this case, Perspect outputs the relations between the symptoms and causal predecessors so that a human developer can complete the rest of the debugging process.

As shown in Table 2, Perspect is able to effectively nail down a very small set of root-cause candidate relations. This is attributed to its iterative filtering (§3.3.2) and refinement (§3.3.3); Our experiments confirm that the relations between most events and their direct successors do not change across

executions. Perspect also filters out most causally related events with low contributions to the symptoms.

Note that 10/12 of the evaluated issues have no clear-cut failures—they are reported because the programs ran slower or consumed more memory than their respective baselines; the remaining two only *occasionally* result in out-of-memory errors (Go-909 and Go-13552). Hence, those issues can hardly be diagnosed by tools for functional failures. In at least four issues, the root causes do not manifest in any absolute predicate changes—the relations captured by Perspect show that the root causes exist in both executions, only their distributions differ. Lastly, as shown by the sizes of SDGs and DDGs, there are too many causally related instructions and runtime events—causality analysis alone can hardly pinpoint the root cause in code.

We discussed how Perspect locates the root causes of Go-909 and MongoDB-57221 in §2. We briefly present a few more.

**Mongodb-44991.** Mongodb-44991 is major performance regression introduced in v4.2.1 and took developers several days to diagnose. Figure 6 shows the simplified code containing the root cause. As a memory optimization, Mongodb stores key prefixes only once per page [5]; hence, it needs to decompress a key before evicting it back to disk. If the same key has been decompressed before, Mongodb copies the cached data directly (L4) to avoid building the key from scratch (L6). In v4.2.1, L11 was erroneously added, which clears the `size` variable, effectively invalidating cached data (L4).

Perspect takes the inputs of two executions from the good version (v4.0.13) and the buggy version (v4.2.1) as reported

```

1 void convert(void *key) {...
2   get_key_info(key, &data, &size);
3   if (... && size > 0)
4     memcpy(key, data, size); // fast path
5   else
6     build_key(entry, key); // slow path
7 }
8 void get_key_info(void *key, void *data, int *size) {
9   data = get_data(key);
10  ...
11  size = 0; — Invalidated the condition of using cached data (fast path);
12 } — Erroneously introduced in v4.2.1.

```

Figure 6: The root cause of MongoDB-44991 (used in §5.2).

in the issue. Perspect locates a pair of relations in the bad run:  $R \blacktriangleleft (L6, L11)$  and reports it as the highest-ranked root cause.

**Go-13552.** Developers noticed that the RSS slowly crept over to 1GB, even though the actual heap usage stayed below 4MB [6]. Diagnosing this bug took 5 days, and the developers eliminated several wrong guesses before nailing down the root cause. First, they had a hard time deciding whether the problem came from the heap or the stack. Once they focused on the stack, they further thought that the memory bloat was due to normal stack spans not being recycled fast enough. Finally, they found the root cause to be a special type of large stack spans which were not recycled at all.

Perspect ranks a relation  $R \blacktriangleright (\text{sysMmap}|\text{allocLarge})$  the highest, indicating that the increased mmap allocations are for large-sized stack spans. This connects the two essential pieces of information together to pinpoint the bug.

**MongoDB-56274 (open issue).** MongoDB-56274 is another open issue we diagnosed using Perspect, and the root cause has been confirmed by developers. The developers noticed that deleting records in descending order was twice as slow as in ascending order. MongoDB deletes records iteratively: after it deletes the record, it searches for the next record to delete. The `search` function has a hard-coded order: it always looks for the next record in ascending order first (`search_forward`); if no record is found, it searches backwards in descending order (`search_backward`). Hence, when the deletion order is the same as the search order, the next record is always found immediately; but, when the deletion order is the opposite, MongoDB traverses through many deleted records, then searches in the opposite direction, causing the slowdown.

Perspect locates the root cause to the hard-coded search order logic; In particular, it identifies three relations that increased significantly in the bad run: 1)  $R \blacktriangleright (\text{search_backward}|\text{search})$ : in the good run, `search_backward` is rarely invoked, as the next record is always immediately located by `search_forward`; 2)  $R \blacktriangleright (\text{prev\_record}|\text{search\_backward})$  and 3)  $R \blacktriangleright (\text{next\_record}|\text{search\_forward})$  indicates increased number of records traversed in both directions of search.

**Go-8832.** Developers observed unexpected memory bloat and mistakenly thought it was caused by bugs from Go’s GC code. In fact, the root cause was Linux’s promotion of huge pages in the background, which bloated the resident set size (RSS) since the distribution of the base 4KB pages was sparse. The developers spent a lot of time examining incorrect hypotheses about bugs in the GC logic, making it one of the most discussed Go performance issues.

While the current implementation of Perspect cannot analyze the OS kernel, it can help rule out wrongly suspected buggy behaviors of the Go runtime. Specifically, after comparing relations associated with the symptoms `mmap` and `munmap`, Perspect outputs no root cause candidate relations.

## 5.2 Usability

We evaluated the usability of Perspect with a controlled user study. We tested on 20 programmers (who are not co-author of this paper) who indicated extensive experience in debugging and GDB.

We used Go-909 and MongoDB-44991 in the study to represent resource issues and slowdowns. Each participant was asked to debug one case without any help and a different case with Perspect; so each bug has two controlled groups for comparison. For each participant, we first described the bugs and helped reproduce them. We chose one of the two cases randomly and asked the participant to diagnose it without Perspect; then for the second case, we introduced relational debugging and allowed them to use Perspect. We limited the debugging session to two hours for each bug (not including setup or reproduction time). If the time was exceeded, we considered the bug unsolved.

For Go-909, we considered a participant to have caught the root cause if they concluded that unreachable objects got marked and prevented reclamations. For MongoDB-44991, we used the criteria that the participant had to locate the instruction that clears the `size` variable erroneously (L11 in Figure 6).

Our results show that when using Perspect, participants concluded the root cause *at least 10.87 times faster* than when not using Perspect. With the help of Perspect, all participants successfully located the root causes of both issues, with an average of 10 minutes; much of the time was spent on navigating code and understanding instructions pointed to by the relations. Without Perspect, only 5/10 of the participants concluded the root causes within two hours, with an average of one hour and 47 minutes.

Interestingly, we observed that without Perspect many participants had *manual practices* like relational debugging: they printed out counters to compare occurrences of functions or instructions in the good and bad runs, and ruled out ones that did not change. However, we observed that such manual effort was neither rigorous nor systematic. For example, for Go-909, many participants examined if GC happened less often, but did not realize objects reclaimed per GC cycle changed.

We interviewed participants after the debugging session. The most overwhelming feedback is that the relation semantic is intuitive and easy to understand. One suggestion is to visualize SDGs and DDGs alongside the changed relations, which we consider implementing via GUI support.

### 5.3 Analysis Time

For the twelve performance issues, Perspect takes an average of under one hour to output the results. For 10/12 issues, Perspect finishes under 20 minutes, with an average of 8 minutes. The other two take an average of 5.3 hours. Most of the analysis time was spent on static and dynamic causality analysis (§3.2); the relational debugger (§3.3) takes a small fraction of the total analysis time.

Static causality analysis takes 24 minutes on average. It is bottlenecked by repeatedly invoking RR to build non-local dataflow dependencies (§4). The worst-case complexity of static causality analysis is  $O(n * m)$ , where  $n$  is the number of dynamic instructions executed during each RR run, and  $m$  is the number of static instructions that are causally related to the symptom instructions. The two-phase optimization described in §4.2 reduces  $m$  significantly. We can further speed up static analysis by adding more servers to parallelize the invocation of RR runs (§4.1).

Dynamic causality analysis is bottlenecked by running the instrumented program in PIN. It takes on average 35 minutes across the 12 issues (<20 minutes for 10/12 issues). Perspect effectively reduces the DDGs's sizes by sampling one symptom event out of  $N$ , while keeping a large number of symptom events to maintain statistical significance.

In comparison, the relational debugger only takes a small fraction of the total dynamic analysis time, typically a few minutes. Reducing the size of the DDG also effectively reduces the average complexity of the relational debugger, which has a worst-case complexity of  $O(p^2)$ , where  $p$  is the number of instructions executed that are causally relevant to the symptom events.

## 6 Discussion and Limitations

Relational debugging provides a new way of understanding performance problems. We find it generally applicable to many challenging performance problems that do not manifest via clear-cut predicates. Relational debugging assumes that the relations in the executions are statistically significant. It is possible that an execution is too short. On the other hand, our evaluation shows that the executions based on the reproduction steps documented in real-world issue reports are mostly sufficient—there are enough repetitive patterns for Perspect to be effective. It is straightforward to apply Perspect to multiple runs if one is too short.

Our current implementation of Perspect shares some limitations of its building blocks. Specifically, Perspect cannot debug performance problems that are non-deterministic (e.g., they depend on the scheduling and timing of events), because

Perspect uses deterministic replay (RR [7]) and its dynamic instrumentation could change the timing. Please note: this does *not* mean that Perspect cannot debug multi-threaded systems—all the evaluated systems (except Coreutils) are multi-threaded. In fact, it is reported that the vast majority (>90%) of real-world performance problems are deterministic [28].

Perspect currently only supports native code. We plan to implement relational debugging for applications in managed languages like Java. We believe the implementation can be built on the JVM Tool Interface. Perspect can be easily extended to handle additional language constructs like exception handling etc.<sup>4</sup> We will also explore how to apply relational debugging to performance problems of distributed systems by analyzing relations of distributed events. Perspect can be extended to support metrics such as P95 latency etc.<sup>5</sup>

## 7 Related Work

Performance debugging with Perspect takes three steps: 1) identifying symptoms, 2) causality analysis, and 3) relational debugging for automatically pinpointing root causes. We discuss related work based on the three components.

**Automatic performance debugging/diagnosis.** The closest related work (in terms of locating root causes in code) is [39], which applies statistical debugging [32] to performance problems. The essential idea of statistical debugging is to identify predicates that have strong correlations with the failure. However, as we have shown in this paper, it is fundamentally limited to performance problems that manifest via absolute predicates. Moreover, since statistical debugging in [39] does not take causality into consideration, many of the observed predicates could be irrelevant to the symptom; To compensate, it requires a large number of highly variable good and bad executions. Another related work is X-ray [15] which summarizes performance costs of runtime events and attributes them to input and configuration values w.r.t the symptom. Different from Perspect, X-ray is designed for end users (e.g., sysadmins) and does not target root causes in the code. X-ray uses differential performance summarization which identifies branches where execution paths diverge and reasons about the performance difference between the two branch outcomes. In this sense, it also focuses on divergence of predicates between executions.

There are tools for debugging special types of performance problems with predefined patterns, such as loops [35, 40, 44],

<sup>4</sup> When Perspect detects a symptom instruction is causally related to an exception handler, it can perform the analysis at instructions that can potentially throw an exception that is caught by this handler, treating these instructions as symptom instructions.

<sup>5</sup> Instead of calculating weighted sums, Perspect can perform the z-test on the weight of each symptom event against the distribution of weights of all symptom events (symptom events with a z-test score of 1.645 corresponds to the 95th percentile). The rank of each relation can be the number of causally related outlier symptom events.

memory leaks [41], and data locality [30]. Differently, Perspect is designed to be a general debugging/diagnosis tool.

**Automatic functional failure debugging/diagnosis.** Prior studies developed techniques to pinpoint the root causes of functional failures in code, based on invariant analysis [24, 26, 38], log analysis [50] and statistical debugging [32]. Perspect focuses primarily on performance problems which have very different characteristics from function failures.

**Causality analysis.** Perspect applies relational debugging to instructions and their runtime events that are causally related to the symptoms. Many advanced techniques have been developed for causality analysis [16, 22, 29, 34, 37, 42, 45–47, 49, 53]. Perspect can potentially use them to enhance its causality analysis (§3.2). For example, we can further accelerate the causality analysis, learning from failure sketching [29], REPT [22] and ER [53] that use Intel PT to efficiently trace causally dependent instructions and augment the trace with symbolic execution [18, 21]. Argus [42] developed a way to annotate causality graphs with strong and weak edges, which can prioritize relational analysis of Perspect. SherLog [45], lprof [52], and Pensieve [49] show that runtime logs can be used with static analysis to guide the reconstruction of causal paths.

Our work is complementary to causality analysis for distributed systems (many targeting performance problems [14, 17, 20, 34, 43, 51]). Relational debugging for distributed systems based on distributed causality is our future work (§6).

**Profilers.** Profilers [9, 10, 12, 13, 19, 23, 36] are important utilities for performance debugging. Advanced profilers like [23, 36] can effectively identify true bottlenecks. They provide effective inputs for Perspect to locate root causes.

## 8 Conclusion

Debugging performance problems is (still) among the most challenging, time-consuming tasks. We presented relational debugging as a new way of understanding performance problems and locating their root causes in the code. Our key insight is that the root causes of performance bugs can be generalized to changes in relations between fine-grained runtime events, and by using relations, we capture root causes of performance bug existing semantics (such as invariants or predicates etc.) fail to capture. We developed Perspect to automate relational debugging. Perspect takes a minimal of just two executions (a good and bad run), and pinpoints the root causes of complex real-world bugs to a small number of root cause relations using an effective “filter-and-refine” algorithm. We further demonstrate Perspect’s effectiveness by diagnosing two open issues which developers were unable to diagnose using existing tools. Finally, we deploy a number of carefully designed optimizations to scale Perspect to large-scale code-bases. We open-sourced Perspect and will continue improving it towards a common toolkit for performance debugging.

## Acknowledgement

We thank our shepherd, Jason Flinn, and the anonymous reviewers for their feedback and comments on our work. We also thank Serguei Makarov for the suggestion to output binary instead of plain-text PIN logs for optimized performance. This work was supported by the Canada Research Chair fund, an NSERC Discovery grant, an NSERC Alliance Mission grant, and an NSF grant CNS-2130560.

**Abstract.** Credential compromise is hard to detect and hard to mitigate. To address this problem, we present larch, an accountable authentication framework with strong security and privacy properties. Larch protects user privacy while ensuring that the larch log server correctly records every authentication. Specifically, an attacker who compromises a user’s device cannot authenticate without creating evidence in the log, and the log cannot learn which web service (relying party) the user is authenticating to. To enable fast adoption, larch is backwards-compatible with relying parties that support FIDO2, TOTP, and password-based login. Furthermore, larch does not degrade the security and privacy a user already expects: the log server cannot authenticate on behalf of a user, and larch does not allow relying parties to link a user across accounts. We implement larch for FIDO2, TOTP, and password-based login. Given a client with four cores and a log server with eight cores, an authentication with larch takes 150ms for FIDO2, 91ms for TOTP, and 74ms for passwords (excluding preprocessing, which takes 1.23s for TOTP).

## 1 Introduction

Account security is a perennial weak link in computer systems. Even well-engineered systems with few bugs become vulnerable once human users are involved. With poorly engineered or configured systems, account compromise is often the first of several cascading failures. In general, 82% of data breaches involve a human element, with the most common methods including use of stolen credentials (40%) and phishing (20%) [79].

When users and administrators identify stolen credentials, it is challenging to determine the extent of the damage. Not knowing what an attacker accessed can lead to either inadequate or overly extensive recovery. LastPass suffered a breach in November 2022 because they didn’t fully recover from a compromise the previous August [72]. Conversely, Okta feared 366 organizations might have been accessed when an attacker gained remote desktop access at one of their vendors. It took a three-month investigation to determine that, in fact, only two organizations, not 366, had really been victims of the breach [32].

Single sign-on schemes, such as OpenID [74] and “Sign in with Google,” can keep an authentication log and thereby determine the extent of a credential compromise. However, these centralized systems represent a security and privacy risk: they give a third party access to all of a user’s accounts and to a trace of their authentication activity.

An ideal solution would give the benefits of universal authentication logging without the security and privacy drawbacks of single-sign-on systems. For security, the logging service shouldn’t be able to authenticate on behalf of a user. For privacy, the logging service should learn no information about a user’s authentication history: the log service should not even learn if the user is authenticating to the same web service twice or to two separate web services.

In this paper, we propose larch (“login archive”), an accountable authentication framework with strong security and privacy properties. Authentication takes place between a user and a service, which we call the *relying party*. In larch, we add a third party: a user-chosen larch log service. The larch log service provides the user with a complete, comprehensive history of her authentication activity, which helps users detect and recover from compromises. Once an account is registered with larch, even an attacker who controls the user’s client cannot authenticate to the account without the larch log service storing a record that allows the user to recover the time and relying-party name.

The key challenge in larch is allowing the log service to maintain a complete authentication history *without becoming a single point of security or privacy failure*. A malicious larch log service cannot access users’ accounts and learns no information about users’ authentication histories. Only users can decrypt their own log records.

Larch works with any relying party that supports one of three standard user authentication schemes: FIDO2 [36] (popularized by Yubikeys and Passkeys [3]), TOTP [68] (popularized by Google Authenticator), and password-based login. FIDO2 is the most secure but least widely deployed of the three options.

A larch deployment consists of two components: a browser add-on, which manages the user’s authentication secrets, and one or more larch log services, which store authentication logs on behalf of a set of users. At a high level, larch provides four operations. (1) Upon deciding to use larch, a user performs a one-time *enrollment* with a log service. (2) For each account to use with larch, the user runs *registration*. To relying parties, registration looks like adding a FIDO2 security key, adding an authenticator app, or setting a password. (3) The user then performs *authentication* with larch as necessary to access registered accounts. Finally, (4) at any point the user can *audit* login activity by downloading and decrypting the complete history of authentication events to all accounts. The client can use auditing for intrusion detection or to evaluate the extent of the damage after a client has been compromised.

All authentication mechanisms require generating an authentication credential based on some secret. In FIDO2, the secret is a signature key and the credential is a digital signature; the signed payload depends on the name of the relying party and a fresh challenge, preventing both phishing and credential reuse. With TOTP, the secret is an HMAC key and the credential an HMAC of the current time, which prevents credential reuse in the future. With passwords, the credential is simply the password, which has the disadvantage that it can be reused once a malicious client obtains it.

Larch splits the authentication secret between the client and log service so that both parties must participate in authentication. We introduce split-secret authentication protocols for FIDO2, TOTP, and password-based login. At the end of each protocol, the log service holds an encrypted authentication log record and the client holds a credential. Larch ensures that if the client obtains a valid credential, the log service also obtains a well-formed log record, even if the client is compromised and behaves maliciously. At the same time, the log service learns no information about the relying parties that the user authenticates to.

We design larch to achieve the following (informal) security and privacy goals:

- *Log enforcement against a malicious client:* An attacker that compromises a client cannot authenticate to an account that the client created before compromise without the log obtaining a well-formed, encrypted log record.
- *Client privacy and security against a malicious log:* A malicious log service cannot authenticate to the user's accounts or learn any information about the relying parties to which the user has authenticated, including whether two authentications are for the same account or different accounts.
- *Client privacy against a malicious relying party:* Colluding malicious relying parties cannot link a user across accounts.

Larch's FIDO2 protocol uses zero-knowledge proofs [43] to convince the log that an encrypted authentication log record generated by the client is well-formed relative to the digest of a FIDO2 payload. If it is, the client and log service sign the digest with a new, lightweight two-party ECDSA signing protocol tailored to our setting. For TOTP, larch executes an authentication circuit using an existing garbled-circuit-based multiparty computation protocol [87, 84]. For password-based login, the client privately swaps a ciphertext encrypting the relying party's identity for the log's share of the corresponding password using a discrete-log-based protocol [46].

In the event that a user's device is compromised, a user can revoke access to all accounts—even accounts she may have forgotten about—by interacting only with the log service. At the same time, involving the log service in every authentication could pose a reliability risk (just as relying on OpenID does). We show how to split trust across multiple

log service providers to strengthen availability guarantees, making larch strictly better than OpenID for all three of security, privacy, and availability.

We expect users to perform many password-based authentications, some FIDO2 authentications, and a comparatively small number of TOTP authentications. Given a client with four cores and a log server with eight cores, an authentication with larch takes 150ms for FIDO2, 91ms for TOTP, and 74ms for passwords (excluding preprocessing, which takes 1.23s for TOTP). One authentication requires 1.73MiB of communication for FIDO2, 65.2MiB for TOTP, and 3.25KiB for passwords. TOTP communication costs are comparatively high because we use garbled circuits [84]; however, all but 202KiB of the communication can be moved into a preprocessing step.

Larch shows that it is possible to achieve privacy-preserving authentication logging that is backwards compatible with existing standards. Moreover, larch provides new paths for FIDO2 adoption, as larch users can authenticate using FIDO2 without dedicated hardware tokens, which could motivate more relying parties to deploy FIDO2. Users who do own hardware tokens can use them to authenticate to the larch log service, providing strong security guarantees for relying parties that do not yet support FIDO2 (albeit without the anti-phishing protection). We also suggest small changes to the FIDO standard that would substantially reduce the overheads of larch while providing the same security and privacy properties.

## 2 Design overview

We now give an overview of larch.

### 2.1 Entities

A larch deployment involves the following entities:

**Users.** We envision a deployment with millions of users, each of which has hundreds of accounts at different online services—shopping websites, financial institutions, news sites, and so on. Each user has an account at a larch log service, secured by a strong, unique password and optionally (but ideally) strong second-factor authentication such as a FIDO2 hardware security key. (In Section 6, we describe how a user can create accounts with multiple log services in order to protect against faulty logs.) A user also has a set of devices (e.g. laptop, phone, tablet) running larch client software and storing larch secrets, including cryptographic keys and passwords.

**Relying parties.** A relying party is any website that a user authenticates to (e.g., a shopping website or bank). Larch is compatible with any relying party that supports authentication via FIDO2 (U2F) [36, 80], time-based one-time passwords (TOTP) [68], or standard passwords. The strength of larch's security guarantees depends on the strength of the underlying authentication method.

**Log service.** Whenever the user authenticates to a relying party, the client must communicate with the log service. We envision a major service provider (e.g. Google or Apple) deploying this service on behalf of their customers. The log service:

- keeps an encrypted record of the user’s authentication history, but
- learns no information about which relying party the user authenticates to.

At any time, a client can fetch this authentication record from the log service and decrypt it to see the user’s authentication history. That is, if an attacker compromises one of Alice’s devices and authenticates to `github.com` as Alice, the attacker will leave an indelible trace of this authentication in the larch log. At the same time, to protect Alice’s privacy, the log service learns no information about which relying parties Alice has authenticated to. A production log service should consist of multiple, georeplicated servers to ensure high availability.

## 2.2 Protocol flow

**Background.** We use two-out-of-two *additive secret sharing* [75]: to secret-share a value  $x \in \{0, \dots, p-1\}$ , choose random values  $x_1, x_2 \in \{0, \dots, p-1\}$  such that  $x_1 + x_2 = x \pmod p$ . Neither  $x_1$  nor  $x_2$  individually reveals any information about  $x$ . We also use a cryptographic *commitment scheme*: to commit to a value  $x \in \{0, 1\}^*$ , choose a random value  $r \in \{0, 1\}^{256}$  (the commitment *opening*) and output the hash of  $(x||r)$  using a cryptographic hash function such as SHA-256. For computationally bounded parties, the commitment reveals no information about  $x$ , but makes it impractical to convince another party that the commitment opens to a value  $x' \neq x$ .

The client’s interaction with the log service consists of four operations.

**Step 1: Enrollment with a log service.** To use larch, a user must first *enroll* with a larch log service by creating an account. In addition to configuring traditional account authentication (i.e., setting a password and optionally registering FIDO2 keys), the user’s client generates a secret *archive key* for each authentication method supported. For FIDO2 and TOTP, the archive key is a symmetric encryption key, and the client sends the log service a commitment to this key. For passwords, the archive key is an ElGamal private encryption key, so the client sends the log service the corresponding public key. The client subsequently encrypts log records using these archive keys, while the log service verifies these log records are well-formed using the corresponding commitment or public key.

**Step 2: Registration with relying parties.** After the user has enrolled with a log service, she can create accounts at relying parties (e.g., `github.com`) using larch-protected credentials. We call this process *registration*. Registration works differently depending on which authentication mechanism the relying party uses: FIDO2 public-key authentication, TOTP

codes, or standard passwords. All generally follow the same pattern where at the conclusion of the registration protocol:

- the log service holds an encryption of the relying party’s identity under a key that only the client knows,
- the log service and client jointly hold the account’s authentication secret using two-out-of-two *secret sharing* [75],
- the relying party is unaware of larch and holds the usual information necessary to verify account access: an ECDSA public key (for FIDO2), an HMAC secret key (for TOTP), or a password hash (for password-based login), and
- the log service learns nothing about the identity of the relying party.

By splitting the user’s authentication secret between the client and the log, we ensure that the log service participates in all of the user’s authentication attempts, which allows the log service to guarantee that every authentication attempt is correctly logged.

The underlying authentication mechanisms (FIDO2, TOTP, and password-based login) only provide security for a given relying party if the user’s device was uncompromised at the time of registration; larch provides the same guarantees.

**Step 3: Authentication to a relying party.** Registering with a relying party lets the user later authenticate to that relying party (Figure 1). At the conclusion of an authentication operation, larch must ensure that:

- authentication succeeds at the relying party,
- the log service holds a record of the authentication attempt that *includes the name of the relying party*, encrypted under the archive key known only to the client, and
- the log service learns *no information* about the identity of the relying party involved.

The technical challenge here is guaranteeing that a compromised client cannot successfully authenticate to a relying party without creating a valid log record. In particular, the log service must verify that the log record contains a valid encryption of the relying party’s name under the archive key *without* learning anything about the relying party’s identity.

To achieve these goals, we design *split-secret authentication protocols* that allow the client and log to use their split authentication secrets to jointly produce an authentication credential. Our split-secret authentication protocols are essentially special-purpose two-party computation protocols [88]. In a two-party computation, each party holds a secret input, and the protocol allows the parties to jointly compute a function on their inputs while keeping each party’s input secret from the other. Our split-secret authentication protocols follow a general pattern, although the specifics depend on the underlying authentication mechanism in use (FIDO2, TOTP, or password-based login):

- The client algorithm takes as input the identity of the relying party, the client’s share of the corresponding authentication secret, the archive key, and the opening for the log service’s commitment to the archive key.

Figure 1: The client and log service run split-secret authentication where the client obtains the credential for `amazon.com` and the log service obtains an encryption of `amazon.com` under the client’s key. The client’s inputs are its share  $x$  of the authentication secret, the archive key  $k$ , a random nonce  $r$ , and the string `amazon.com`. The log’s inputs are its shares  $y_{amazon}, \dots, y_{google}$  of all the client’s authentication secrets and the commitment  $cm$  to the archive key generated at enrollment. The `MakeCred` function takes extra inputs for FIDO2 and TOTP.

- The log algorithm takes as input its shares of authentication secrets and the client’s commitment to the archive key (which it received at enrollment).
- The client algorithm outputs an authentication credential: a signature (for FIDO2), an HMAC code (for TOTP), or a password (for password-based login).
- The log algorithm outputs an encryption of the relying party identifier under the archive key.

In this way, the client and log service jointly generate authentication credentials while guaranteeing that every successful authentication is correctly logged. The client and log do not learn any information beyond the outputs of the computation. We use this general pattern to construct split-secret authentication protocols for FIDO2 (Section 3), TOTP (Section 4), and password-based login (Section 5).

**Step 4: Auditing with the log.** Finally, at any time, the user can ask the log service for its collection of log entries encrypted under the archive key. A user could do this when she suspects that an attacker has compromised her credentials. The user’s client could also perform this auditing in the background and notify the user if it ever detects anomalous behavior. The client uses the encryption key it generated during enrollment to decrypt log entries.

### 2.3 System goals

We now describe the security goals of larch (Figure 2).

**Goal 1: Log enforcement against a malicious client.** Say that an honest client enrolls with an honest log service and then registers with a set of relying parties. Later on, an attacker compromises the client’s secrets (e.g., by compromising one of the user’s devices and causing it to behave maliciously). Every

successful authentication attempt that the attacker makes using credentials managed by larch will appear in the client’s authentication log stored at the larch log service. Furthermore, the honest client can decrypt these log entries using its secret key.

**Goal 2: Client privacy and security against a malicious log.** Even if the log service deviates arbitrarily from the prescribed protocol, it learns no information about (a) the client’s authentication secrets (meaning that the log service cannot authenticate on behalf of the client) or (b) which relying parties a client has interacted with.

**Goal 3: Client privacy against a malicious relying party.** A set of colluding malicious relying parties learn no information about which registered accounts belong to the same client. That is, relying parties cannot link a client across multiple relying parties using information they learn during registration or authentication.

To be usable in practice, larch should additionally achieve the following functionality goal:

**Goal 4: No changes to the relying party.** Relying parties that support FIDO2 (U2F), TOTP, or password authentication do not need to be aware of larch. Clients can unilaterally register authentication credentials such that all future authentications are logged in larch.

### 2.4 Non-goals and extensions

*Availability against a compromised log service.* Larch does not provide availability if the log service refuses to provide service. We discuss defenses against availability attacks in Section 6.

*Privacy against colluding log and relying party.* If the log service colludes with a relying party, they can always use timing information to map log entries to authentication requests. Therefore, larch makes no effort to obscure the relationship between private messages seen by the two parties and only guarantees privacy when the relying party and log service do not collude.

*Limitations of underlying authentication schemes.* Larch provides security guarantees that match the security of the underlying authentication schemes. FIDO2 provides the strongest security, followed by TOTP, and then followed by passwords. For TOTP and password-based login, larch provides no protection against *credential breaches*: if an attacker steals users’ authentication secrets (MAC keys or passwords) from the relying party, the attacker can use those secrets to authenticate without those authentications appearing in the log. FIDO2 defends against credential breaches because the relying party only ever sees the client’s public key.

Larch does protect against *device compromise* for all three authentication mechanisms: even if an attacker gains control of a user’s device, generating any of the user’s larch-protected credentials requires communicating with the log service and results in an archived log record. If the user discovers the device break-in later on, she can recover from the log a list

Figure 2: Larch security goals.

of authentications and take steps to remediate the effects of compromise (contacting the affected relying parties, etc.).

An attacker who compromises an account can often disable two-factor authentication or add its own credentials to a compromised account. Therefore, only an attacker’s first successful access to a given relying party is guaranteed to be archived in larch. That said, many relying parties send out notifications, require step-up authentication, or revoke access to logged in clients on credential updates, all of which could complicate an attack or alert legitimate users to a problem. Hence, it is valuable to ensure that all accesses with the original account credentials are logged. Larch can make this guarantee for FIDO2, where every authentication requires a unique two-party signature. It does not provide this guarantee with passwords, as the attacker learns the password as part of the authentication process: only the attacker’s first authentication to a given relying party will be logged. With TOTP, each generated code produces a larch log record. Some relying parties implement a TOTP replay cache, in which case one code allows one login. Other relying parties allow a single TOTP code to be used for arbitrarily many authentications in a short time period (generally about a minute).

Fortunately, when recovering from compromise, a user is most interested in learning whether an attacker has accessed an account zero times or more than zero times. For larch-generated credentials, users will always be able to learn this information from the larch log. However, if users import passwords that are not unique into larch, this guarantee does not hold. By default, the larch client software generates a unique random password for every relying party, but it also allows user to import existing legacy passwords, which might not be unique. In the event of password reuse, the attacker can generate a single log record to obtain the password and then use it to authenticate to all affected relying parties.

### 3 Logging for FIDO2

#### 3.1 Background

**FIDO2 protocol.** The FIDO2 protocol [36, 80] allows a client to authenticate using cryptographic keys stored on a device (e.g., a Yubikey hardware token or a Google passkey). To register with a relying party (e.g., `github.com`), the client generates an ECDSA keypair, stores the secret key, and sends the public

key to the relying party. When the client subsequently wants to authenticate to relying party `github.com`, Github’s server sends the client a random challenge. The client then signs the hash of the string `github.com` and the Github-chosen challenge using the secret key the client generated for `github.com` at registration. If the signature is valid, the Github server authorizes the client. Because the message signed by the client is bound to the name `github.com`, FIDO2 provides a strong defense against phishing attacks. The FIDO2 protocol supports passwordless, second-factor, and multi-factor authentication.

**Zero-knowledge arguments.** Informally, zero-knowledge arguments allow a prover to convince a verifier that a statement is true without revealing *why* the statement is true [43]. More precisely, we consider non-interactive zero-knowledge argument systems [13, 35] in the random-oracle model [10]. Both the prover and verifier hold the description of a computation  $C$  and a public input  $x$ . The prover’s goal is to produce a proof  $\pi$  that convinces the verifier that there exists a witness  $w$  that causes  $C(x, w) = 1$ , without revealing the witness  $w$  to the verifier. We require the standard notions of completeness, soundness, and zero knowledge [13, 43]. Throughout the paper, we will refer to this type of argument system as a “zero-knowledge proof.”

We use the ZKBoo protocol [54, 42, 20] for proving statements about computations expressed as Boolean circuits. Our system could also be instantiated with succinct non-interactive arguments of knowledge, which would decrease proof size and verification time, but at the cost of increasing proving time and requiring large parameters generated via a separate setup algorithm [12, 39, 45, 71].

**Threshold signatures.** A two-party threshold signature scheme [28, 29] is a set of protocols that allow two parties to jointly generate a single public key along with two shares of the corresponding secret key and then jointly sign messages using their secret key shares such that the signature verifies under the joint public key. Informally, no malicious party should be able to subvert the protocols to extract another party’s share of the secret key or forge a signature on a message other than the honest party’s message. We would ideally instantiate our system using BLS multisignatures [14]. Unfortunately, the FIDO2 standard limits the choice of signing algorithms to ECDSA and RSASSA [67]. For backwards-compatibility, we present a construction for two-party ECDSA signing with preprocessing tailored to our setting in Section 3.3.

### 3.2 Split-secret authentication

We now describe our split-secret authentication protocol for FIDO2 where the authentication secret is split between the larch client software and the log service. The key challenge is achieving log enforcement and log privacy simultaneously: every successful authentication should result in a valid log entry encrypting the identity of the relying party, but the log should not learn the identity of the relying party.

We use threshold signing to ensure that both the client and log participate in every successful authentication. A natural way to use threshold signing would be to have the client and log each generate a new threshold signing keypair at every registration. Unfortunately, if the log service used a different key share for each relying party, it would know which authentication requests correspond to the same relying party, violating Goal 2 (privacy against a malicious log). Instead, we have the log use the *same signing-key share for all relying parties*. The client still uses a different signing-key share per party, ensuring the public keys are unlinkable across relying parties. To authenticate to a relying party with identifier  $id$  and challenge  $chal$ , the client computes a digest  $dgst = \text{Hash}(id, chal)$  that hides  $id$ . The client and log then jointly sign  $dgst$ .

We also need to ensure that the log service obtains a correct record of every authentication. In particular, the log should only participate in threshold signing if it obtains a valid encryption  $ct$  of the relying-party identifier  $id$  [77].

To be valid, a ciphertext  $ct$  must (1) decrypt to  $id$  under the archive key  $k$  established for that client, and (2) be correctly related to the digest  $dgst$  that the log will sign (i.e.,  $\text{Dec}(k, ct) = id$  and  $dgst = \text{Hash}(id, chal)$ ). To allow the log service to check that the client is using the right archive key without learning the key, we use a commitment scheme. During enrollment, the client generates a commitment  $cm$  to the archive key  $k$  using random nonce  $r$  and sends  $cm$  to the log service. During authentication, the client uses a zero-knowledge proof to prove to the log that it knows a key  $k$ , randomness  $r$ , relying-party identifier  $id$ , and authentication challenge  $chal$  such that ciphertext  $ct$ , digest  $dgst$ , and commitment  $cm$  from enrollment meet the following conditions:

- (a)  $cm = \text{Commit}(k, r)$ ,
- (b)  $id = \text{Dec}(k, ct)$ , and
- (c)  $dgst = \text{Hash}(id, chal)$ .

The public inputs are the ciphertext  $ct$ , digest  $dgst$ , and commitment  $cm$  (known to the client and log); the witness is the archive key  $k$  (known only to the client), commitment opening  $r$ , relying-party identifier  $id$ , and challenge  $chal$ .

**Final protocol.** We now outline our final protocol.

*Enrollment.* During enrollment, the client samples a symmetric encryption key  $k$  as the archive key and commits to it with some random nonce  $r$ . The client sends the commitment  $cm$  to the log, and the log generates a signing-key share for the user. The log sends the client the public key corresponding

to its signing-key share to allow the client to derive future keypairs for relying parties.

*Registration.* At registration, the client generates a new signing-key share for that relying party. The client then aggregates the log's public key with its new signing-key share and sends the resulting public key to the relying party. No interaction with the log service is required.

*Authentication.* To authenticate to  $id$  with challenge  $chal$ , the client computes  $dgst \leftarrow \text{Hash}(id, chal)$  and  $ct \leftarrow \text{Enc}(k, id)$ . The client then generates a zero-knowledge proof  $\pi$  that it knows an archive key  $k$ , commitment nonce  $r$ , relying-party identifier  $id$ , and authentication challenge  $chal$  such that  $dgst$  and  $ct$  are correctly related relative to the commitment  $cm$  that the client generated at enrollment. The client sends  $dgst$ ,  $ct$ , and  $\pi$  to the log service. The log service checks the proof and, if it verifies, runs its part of the threshold signing protocol. The log service stores  $ct$  and returns its signature share to the client. The log service also stores the current time and client IP address with  $ct$ , allowing the user to obtain additional metadata by auditing. Finally, the client completes the threshold signature and sends it to the relying party.

*Auditing.* To audit the log, the client requests the list of ciphertexts and metadata from the log service and decrypts all of the relying-party identifiers.

### 3.3 Two-party ECDSA with preprocessing

Section 3.2 shows how to implement larch for any two-of-two threshold signing scheme that cryptographically hashes input messages. However, FIDO2 compatibility forces us to use ECDSA, which is more cumbersome than BLS to threshold. We present a concretely efficient protocol for ECDSA signing between the client and log.

There is a large body of prior work on multi-party ECDSA signing [31, 61, 22, 4, 23, 18, 48, 41, 40, 19]. However, existing protocols are orders of magnitude more costly than the one we present here [61, 41, 40, 18, 19]. The efficiency gain for us comes from the fact that we may assume that the client is *honest at enrollment time and only later compromised*. In contrast, standard schemes for two-party ECDSA signing must protect against the compromise of either party at any time. Prior protocols provide this stronger security property at a computational and communication cost. In our setting, we need only ensure that an honest client can run an enrollment procedure with the log service such that if the client is later compromised, the attacker cannot subvert the signing protocol.

We leverage the client to split signing into two phases:

1. During an *offline phase*, which takes place during enrollment, the client performs some preprocessing to produce a “presignature.” Security only holds if the client is honest during the offline phase.
2. During an *online phase*, which takes place during authentication, the client and log service use the presignature to

perform a lightweight, message-dependent computation to produce an ECDSA signature. Security holds if either the client or log service is compromised during the online phase.

Prior work also splits two-party signing into an offline and online phase. However, prior work performs this partitioning to reduce the online time at the expense of a more costly offline phase [22, 85, 23, 18]. (The offline phase in these schemes is expensive since the protocols do not assume that both parties are honest during the offline phase.) We split the signing scheme into an offline and online phase to take advantage of the fact that we may assume that the client is honest in the offline phase and so can reduce the total computation time this way.

An additional requirement in our setting is that the log should *not* learn the public key that the signature is generated under. Because the public key is specific to a relying party, hiding the public key is necessary for ensuring that the log cannot distinguish between relying parties. The signing algorithm can take as input a relying-party-specific key share from the client and a relying-party-independent key share from the log.

**Background: ECDSA.** For a group  $\mathbb{G}$  of prime order  $q$  with generator  $g$ , fixed in the ECDSA standard, an ECDSA secret key is of the form  $sk \in \mathbb{Z}_q$ , where  $\mathbb{Z}_q$  denotes the ring of integers modulo  $q$ . The corresponding ECDSA public key is  $pk = g^{sk} \in \mathbb{G}$ . ECDSA uses a hash function  $\text{Hash}: \{0, 1\}^* \rightarrow \mathbb{Z}_q$  and a “conversion” function  $f: \mathbb{G} \rightarrow \mathbb{Z}_q$ . To generate an ECDSA signature on a message  $m \in \{0, 1\}^*$  with secret key  $sk \in \mathbb{Z}_q$ , the signer samples a signing nonce  $r \xleftarrow{\mathbb{R}} \mathbb{Z}_q$  and computes

$$r^{-1} \cdot (\text{Hash}(m) + f(g^r) \cdot sk) \in \mathbb{Z}_q.$$

**Our construction.** We now describe our construction for a two-party ECDSA signing protocol with presignatures. (See the full version [26] for technical details.) To generate the log keypair, the log samples  $x \xleftarrow{\mathbb{R}} \mathbb{Z}_q$ , sets its secret key to  $x \in \mathbb{Z}_q$ , and sets its public key to  $X = g^x \in \mathbb{G}$ . Then to generate a keypair from the log public key, the client samples  $y \xleftarrow{\mathbb{R}} \mathbb{Z}_q$  and sets the relying-party-specific public key to  $pk = X \cdot g^y \in \mathbb{G}$ . For each public key of the form  $g^{x+y} \in \mathbb{G}$ , the log has one share  $x \in \mathbb{Z}_q$  of the secret key that is the same for all public keys and the client has the other share  $y \in \mathbb{Z}_q$  of the secret key that is different for each public key.

We split the signature-generation process into two parts:

1. *Offline phase:* a message-independent, key-independent “presignature” algorithm that the client runs, and
2. *Online phase:* a message-dependent, key-dependent signing protocol that the log and client run jointly.

To generate the presignature in the offline phase, the client samples a signing nonce  $r \xleftarrow{\mathbb{R}} \mathbb{Z}_q$ , computes  $R \leftarrow g^r \in \mathbb{G}$ , and splits  $r^{-1}$  into additive secret shares:  $r^{-1} = r_0 + r_1 \in \mathbb{Z}_q$ . The log’s portion of the presignature is  $(f(R), r_0) \in \mathbb{Z}_q^2$ , and the client’s portion is  $(f(R), r_1) \in \mathbb{Z}_q^2$ . Then, to produce a signature on a message in the online phase, the client and

log simply perform a single secure multiplication to compute

$$r^{-1} \cdot (\text{Hash}(m) + f(R) \cdot sk) \in \mathbb{Z}_q$$

where  $r^{-1} \in \mathbb{Z}_q$  (signing nonce) and  $sk \in \mathbb{Z}_q$  (signing key) are secret-shared between the client and log.

To perform this multiplication over secret-shared values, we use Beaver triples [9]. A Beaver triple is a set of one-time-use shares of values that the log and client can use to efficiently perform a two-party multiplication on secret-shared values. Traditionally, generating Beaver triples is one of the expensive portions of multiparty computation protocols (e.g., in prior work on threshold ECDSA [22]). In our setting, the client at enrollment time can generate a Beaver triple as part of the presignature. Note that the client and log can use each signing nonce and Beaver triple exactly once. That is, the client and log must use a fresh presignature to generate each signature.

**Malicious security.** By deviating from the protocol, neither the client nor the log should be able to learn secret information (i.e., the other party’s share of the secret key or signing nonce) or produce a signature for any message apart from the one that the protocol fixes. We describe how to accomplish this using traditional tools for malicious security (e.g. information-theoretic MACs [24]) in the full version [26].

**Formalizing and proving security.** We define and prove security in the full version [26].

**Implications for system design.** Our preprocessing approach increases the client’s work at enrollment: the client generates some number of presignatures (e.g., 10K) and sends the log’s presignature shares to the log. To reduce storage burden on the log, the client can store encryptions of the log’s presignature shares.

When the client is close to running out of presignatures, it can authenticate with the log, generate more presignatures, and send the log’s presignature shares to the log service. If the log service does not receive an objection after some period of time, it will start using the new presignatures. An honest client periodically checks the log to see whether any unexpected presignatures (created by an attacker) appear in its log. If the client learns that a new batch of presignatures was generated that the client did not authorize, the client authenticates to the log service and objects.

If the client runs out of presignatures and the log service rejects the client’s presignatures, the client and the log can temporarily use a more expensive signing protocol that does not require presignatures [41, 61, 31, 85]. The client could run out of presignatures and be forced to use the slow multisignature protocol in the following cases:

1. The attacker compromised the user’s credentials with the log service, allowing the attacker to object to the new presignatures. In this case, the attacker could change the user’s credentials and permanently lock the user out of her account.

2. The honest client was close to running out of presignatures, generated new presignatures, and then ran out of presignatures while waiting for a possible objection. This scenario only occurs when the honest client makes an unexpectedly large number of authentications in a short period of time. The client only needs to pay the cost of the slow multisignature protocol for a short period of time.

An attacker that has compromised the log service can also deny service, as we discussed in Section 2.4.

## 4 Logging for time-based one-time passwords

We now show how larch can support time-based one-time passwords (TOTP).

### 4.1 Background: TOTP

TOTP is a popular form of second-factor authentication that authenticator apps (Authy, Google Authenticator, and others [68]) implement. When a client registers for TOTP with a relying party, the relying party sends the client a secret cryptographic key. Then, to authenticate, the client and the relying party both compute a MAC on the current time using the secret key from registration. The client sends the resulting MAC tag to the server. If the client’s submitted tag matches the one that the server computes, the relying party authorizes the client. TOTP uses a hash-based MAC (HMAC).

### 4.2 Split-secret authentication for TOTP

At a high level, in our split-secret authentication protocol for TOTP, both the client and log service have as private input additive secret shares of the TOTP secret key. At the conclusion of the split-secret authentication, the client holds a TOTP code and the log service holds a ciphertext. We now give the details of our protocol.

*Enrollment.* At enrollment, just as with FIDO2, the client generates and stores a long-term symmetric-encryption archive key  $k$  and random nonce  $r$ . Then, the client sends the commitment  $cm = \text{Commit}(k, r)$  to the log service.

*Registration.* To register a client, a relying party generates and sends the client a secret MAC key  $k_{id}$  for TOTP. The client samples a random identifier  $id$  for the relying party and then splits the TOTP secret key  $k_{id}$  into additive secret shares  $klog_{id}$  and  $kclient_{id}$ . The client sends  $(id, klog_{id})$  to the log service and locally stores  $(id, kclient_{id})$  alongside a name identifying the relying party (e.g., `user@amazon.com`).

*Authentication.* In order to authenticate to the relying party  $id$  at time  $t$ , the client needs to compute  $\text{HMAC}(k_{id}, t)$  with the help of the log service. Let  $n$  be the number of relying parties with which the client has registered. To authenticate, the client and log service run a secure two-party computation where:

- The client’s input is its long-term symmetric archive key  $k$  and commitment opening  $r$  from enrollment, the relying-party identifier  $id$ , and the client’s share of the TOTP key  $kclient_{id}$ .
- The log service’s input is the commitment  $cm$  from enrollment, the list of relying-party identifiers that the client has registered with  $(id_1, \dots, id_n)$ , and the log service’s TOTP key shares  $(klog_{id_1}, \dots, klog_{id_n})$ —one per relying party.
- The client outputs the TOTP code  $\text{HMAC}(k_{id}, t)$ .
- The log outputs an encrypted log record: an encryption of the relying-party identifier  $id$  under the archive key  $k$ .

We execute this two-party computation using an off-the-shelf garbled-circuit-based multiparty computation protocol. Garbled circuits allow two parties to jointly execute any Boolean circuit on private inputs, where neither party learns information about the other’s input beyond what they can infer from the circuit’s output [87]. We use the protocol from Wang et al. [84], which provides malicious security, meaning that the protocol remains secure even if one corrupted party deviates arbitrarily from the protocol. As long as either the client or the log service is honest, the log service does not learn any information about the client’s authentication secrets, and the client learn no information about the TOTP secret, apart from the single TOTP code that the protocol outputs. Because we use an off-the-shelf garbled-circuit protocol, the communication overhead is much higher than in the special-purpose protocols we design for FIDO2 and passwords (Section 8). TOTP is challenging to design a special-purpose protocol for because the authentication credential must be generated via the SHA hash function which, unlike the authentication credentials for FIDO2 and passwords, does not have structure we can exploit. Clients can ask the log service to delete registrations for unused accounts to speed up the two-party computation.

*Auditing.* To audit the log, the client simply requests the list of ciphertexts from the log service. The client decrypts each ciphertext with its archive key  $k$  and then, using its mapping of  $id$  values to relying party names, outputs the resulting list of relying party names.

## 5 Logging for passwords

We now describe how larch can support passwords.

### 5.1 Protocol overview

We construct a split-secret authentication protocol that takes place between the client and the log service. In particular, we show how the client can compute the password to authenticate to a relying party in such a way that (a) the log service does not learn the relying party’s identity and (b) the client’s authentication attempt is logged. At the start of the authentication protocol run:

- the client holds a secret key, the log service’s public key, and the identity  $\text{id}^*$  of the relying party it wants to authenticate to, and
- the log service holds its own secret key, the client’s public key, and a list of relying-party identities  $(\text{id}_1, \dots, \text{id}_n)$  at which the client has registered.

At the end of the authentication protocol run:

- the client holds a password derived as a pseudorandom function of the client’s secret, the log’s secret, and the relying party identity  $\text{id}^*$ , and
- the log service holds a ciphertext encrypting the relying party’s identity  $\text{id}^*$  under the client’s public key.

**Limitations inherent to passwords.** As we discussed in Section 2.4, larch for passwords does not protect against credential breaches, but does defend against device compromise.

## 5.2 Split-secret authentication for passwords

The larch scheme for password-based authentication uses a cyclic group  $\mathbb{G}$  of prime order  $q$  with a fixed generator  $g \in \mathbb{G}$ . Our implementation uses the NIST P-256 elliptic-curve group.

When using password-based authentication in larch, the client and log service after registration each hold a secret share of the password for each relying party. In particular, the password for a relying party with identity  $\text{id} \in \{0, 1\}^*$  is the string  $\text{pw}_{\text{id}} = k_{\text{id}} \cdot \text{Hash}(\text{id})^k \in \mathbb{G}$ , where:

- $k_{\text{id}} \in \mathbb{Z}_q$  is a per-relying-party secret share held by the client,
- $\text{Hash}: \{0, 1\}^* \rightarrow \mathbb{G}$  is a hash function, and
- $k \in \mathbb{Z}_q$  is a per-client secret key held by the log service.

Thus, computing  $\text{pw}_{\text{id}}$  requires both the client’s per-site key  $k_{\text{id}}$  and the log’s secret key  $k$ .

The technical challenge is to construct a protocol that allows the client to compute the password  $\text{pw}_{\text{id}}$  while (a) hiding  $\text{id}$  from the log service and (b) ensuring that the log service completes the interaction holding an encryption of  $\text{id}$  under the client’s public key.

**Protocol.** We describe the protocol steps:

*Enrollment.* The client samples an ElGamal secret key  $x \in \mathbb{Z}_q$  as the archive key and sends the corresponding public key  $X = g^x \in \mathbb{G}$  to the log service. The log service samples a Diffie-Hellman secret key  $k \in \mathbb{Z}_q$  and sends its public key  $K = g^k \in \mathbb{G}$  to the client.

*Registration.* The client samples a per-relying-party random identifier  $\text{id} \leftarrow \{0, 1\}^{128}$ , saves  $\text{id}$  locally alongside the name of the relying party (e.g., `user@amazon.com`), and sends  $\text{id}$  to the log service. The log service saves the string  $\text{Hash}(\text{id})$  and replies with  $\text{Hash}(\text{id})^k \in \mathbb{G}$ . To generate a new strong password  $\text{pw}_{\text{id}}$  (the recommended use), the client samples and saves a random key share  $k_{\text{id}} \leftarrow \mathbb{G}$  and sets  $\text{pw}_{\text{id}} \leftarrow k_{\text{id}} \cdot \text{Hash}(\text{id})^k \in \mathbb{G}$ . To import a legacy password  $\text{pw}_{\text{id}}$  (less secure), the client

computes and stores  $k_{\text{id}} \leftarrow \text{pw}_{\text{id}} \cdot (\text{Hash}(\text{id})^k)^{-1} \in \mathbb{G}$ . The client then deletes  $\text{Hash}(\text{id})^k$  and  $\text{pw}_{\text{id}}$ . Note that the log server can discard  $\text{id}$ , which it only uses to avoid providing  $h^k$  for arbitrary  $h$ . When the client samples  $\text{id}$  and  $k_{\text{id}}$  randomly in the recommended usage, the password  $\text{pw}_{\text{id}}$  for each relying party is random and distinct.

*Authentication.* During authentication, the client must recompute the password  $\text{pw}_{\text{id}}$ . To do so, the client first sends the log service an encryption of  $\text{Hash}(\text{id})$  under the public ElGamal archive key  $g^x$ : the client samples  $r \leftarrow \mathbb{Z}_q^*$  and computes the ciphertext  $(c_1, c_2) = (g^r, \text{Hash}(\text{id}) \cdot g^{xr}) \in \mathbb{G}^2$ . In addition, the client sends a zero-knowledge proof to the log service attesting to the fact that  $(c_1, c_2)$  is an encryption under the client’s public key  $X$  of  $\text{Hash}(\text{id})$  for  $\text{id} \in \{\text{id}_1, \text{id}_2, \dots, \text{id}_n\}$ —the set of relying-party identifiers that the client sent to the log service during each of its registrations so far. The client executes this proof using the technique from Groth and Kohlweiss [46]. The proof size is  $O(\log n)$  and the prover and verifier time are both  $O(n)$ . (See the full version [26] for implementation details.)

The log service saves the ciphertext as a log entry, checks the zero-knowledge proof, and returns the value  $h = c_2^k = \text{Hash}(\text{id})^k \cdot g^{xrk} \in \mathbb{G}$  to the client. The client can then compute

$$\text{pw}_{\text{id}} = k_{\text{id}} \cdot h \cdot K^{-xr} = k_{\text{id}} \cdot \text{Hash}(\text{id})^k \in \mathbb{G}.$$

Crucially, the client deletes  $\text{pw}_{\text{id}}$  after authentication to ensure that future authentications must again interact with the log service.

*Auditing.* To audit the log, the client downloads the ElGamal ciphertexts and can decrypt each ciphertext to recover a list of hashed identities:  $(\text{Hash}(\text{id}_1), \text{Hash}(\text{id}_2), \dots)$ . The client uses its stored mapping of ids to relying-party identifiers to recover the plaintext names of the relying parties in the log.

## 6 Protecting against log misbehavior

The larch log service must participate in each of the user’s authentication attempts. If the log service goes offline, the user will not be able to authenticate to any of her larch-enabled relying parties. In a real-world deployment, the log service could consist of multiple servers replicated using standard state-machine replication techniques to tolerate benign failures [58, 70]. However, users might also worry about intentional denial-of-service attacks on the part of the log.

To defend against availability attacks, a user can split trust across multiple logs. At enrollment time, the user can enroll with  $n$  logs. Then at registration, the user can set a threshold  $t$  of logs that must participate in authentication. Thus, the user can authenticate to her accounts so long as  $t$  logs are online, and she can audit activity so long as  $n - t + 1$  logs are available. We need  $n - t + 1$  logs to be available for auditing in order to guarantee that at least one of the  $t$  logs that participated in authentication is online. To ensure that colluding logs cannot authenticate on behalf of a client, the user’s client

can run  $n + 1$  logical parties, and  $n + t + 1$  parties can generate an authentication credential. In the setting with multiple log services, we need to adapt our two-party protocols to threshold multi-party protocols. Although we present our techniques for two parties (the client and a single log), our techniques generalize to multiple parties in a straightforward way.

For FIDO2 and passwords, the client now sends a zero-knowledge proof to each of the  $n$  logs. In the password case, the client can then retrieve  $(t, n)$  Shamir shares of the password [75], and in the FIDO2 case, the client can run any existing multi-party threshold signing protocol that does not take the public key as input [76, 22]. For TOTP, the client and the  $n$  logs can execute the same circuit using any malicious-secure threshold multi-party computation protocol [11].

Note that for relying parties that support FIDO2, users can optionally register a backup hardware FIDO2 device to allow them to bypass the log. In this case, the user can authenticate either via larch or via her backup FIDO2 key. While registering a backup hardware device protects against availability attacks, if an attacker obtains this hardware device, they can authenticate as the user without interacting with the log.

## 7 Implementation

We implemented larch for FIDO2, TOTP, and passwords with a single log service. We use C/C++ with gRPC and OpenSSL with the P256 curve (required by the FIDO2 standard). We wrote approximately 5,700 lines of C/C++ and 50 lines of Javascript (excluding tests and benchmarks). Our implementation is available at <https://github.com/edauterman/larch>.

For our FIDO2 implementation, we implemented a ZK-Boo [42] library for arbitrary Boolean circuits. Our ZKBoo implementation (with optimizations from ZKB++ [20]) uses emp-toolkit to support arbitrary Boolean circuits in Bristol Fashion [83]. To support the parallel repetitions required for soundness error  $< 2^{-80}$ , we use SIMD instructions with a bitwidth of 32 and run 5 threads in parallel. For the proof circuit, we use AES in counter mode for encryption and SHA-256 for commitments (SHA-256 is necessary for backwards compatibility with FIDO2). We built a log service and client that invoke the ZKBoo library, as well as a Chrome browser extension that interfaces with our client application and is compatible with existing FIDO2 relying parties. We built our browser extension on top of an existing extension [56].

Our TOTP implementation uses a maliciously secure garbled-circuit construction [84] implemented in emp-toolkit [83]. We generated our circuit using the CBMC-GC compiler [37] with ChaCha20 for encryption and SHA-256 for commitments.

For our passwords implementation, we implemented Groth and Kohlweiss’s proof system [46].

Our implementation uses a single log server for the log service, does not encrypt communication between the client and the log service, and does not require the client to

authenticate with the log service. A real-world deployment would use multiple servers for replication, use TLS between the client and the log service, and authenticate the client before performing any operations.

**Optimizations.** We use pseudorandom generators (PRGs) to compress presignatures: the log stores 6 elements in  $\mathbb{Z}_q$  and the client stores 1 element. Also, instead of running an authenticated encryption scheme (e.g. AES-GCM) inside the circuit for FIDO2 or TOTP, we run an encryption scheme without authentication (e.g. AES in counter mode) inside the circuit and then sign the ciphertext (client has the signing key, log has the verification key). The log can check the integrity of the ciphertext by verifying the signature, which is must faster than checking in a zero-knowledge proof or computing the ciphertext tag jointly in a two-party computation.

## 8 Evaluation

In this section, we evaluate the cost of larch to end users and the cost of running a larch log service.

**Experiment setup.** We run our benchmarks on Amazon AWS EC2 instances. Unless otherwise specified, we run the log service on a c5.4xlarge instance with 8 cores (2 hyperthreads per core) and 32GB of memory and, for latency benchmarks, the client on a c5.2xlarge instance with 4 cores and 16GB of memory, comparable to a commodity laptop. We configure the network connection between the client and log service to have a 20ms RTT and a bandwidth of 100 Mbps.

### 8.1 End-user cost

We show larch authentication latency and communication costs for FIDO2, TOTP, and passwords.

#### 8.1.1 FIDO2

**Latency.** The client for our FIDO2 scheme can complete authentication in 303ms with a single CPU core, or 117ms when using eight cores (Figure 3). Loading a webpage often takes a few seconds because of network latency, so the client cost of larch authentication is minor by comparison. The client’s running time during authentication is independent of the number of relying parties. The heaviest part of the client’s computation is proving to the log service that its encrypted log entry is well formed.

At enrollment, the client must generate many “presignatures,” which it later uses to run our authentication protocol with the log. Generating 10,000 presignatures for 10,000 future FIDO2 authentications takes 885ms. When the client runs out of presignatures, it generates new presignatures it can use after a waiting period (see Section 3.3).

**Communication.** During enrollment, the client must send the log 1.8MiB worth of presignatures. Thereafter, each authenti-

ation attempt requires 1.73MiB worth of communication: the bulk of this consists of the client’s zero-knowledge proof of correctness, and 352B of it comes from the signature protocol. By using a different zero-knowledge proof system, we could reduce communication cost at the expense of increasing client computation cost.

**Comparison to existing two-party ECDSA.** For comparison, a state-of-the-art two-party ECDSA protocol [85] that does not require presignatures from the client and uses Paillier requires 226ms of computation at signing time (the authors’ measurements exclude network latency, which we estimate would add 80ms) and 6.3KiB of per-signature communication. In contrast, our signing protocol only requires 0.5KiB per-signature communication (including the log presignature and the signing messages) and takes 61ms time at signing, almost all of which is due to network latency and can be run in parallel with proving and verifying as the computational overhead is minimal (1ms).

### 8.1.2 TOTP

**Latency.** In Figure 3 (right), we show how TOTP authentication latency increases with the number of relying parties the user registered with. Because we implement TOTP authentication using garbled circuits [84], we can split authentication into two phases: an “offline”, input-independent phase and an “online”, input-dependent phase (the log service and client communicate in both phases). Both phases are performed once per authentication. However, the offline phase can be performed in advance of when the user needs to authenticate to their account, and so it does not affect the latency that the user experiences. For 20 relying parties, the online time is 91ms and the offline time is 1.23s. For 100 relying parties, the online time is 120ms and the offline time is 1.39s.

**Communication.** Communication costs for our TOTP authentication scheme are large: for 20 relying parties, the total communication cost is 65MiB, and for 100 relying parties, the total communication is 93MiB. The online communication costs are much smaller: for 20 relying parties, the online communication is 202KiB and for 100 relying parties, the online communication is 908KiB. We envision clients running the offline phase in the background while they have good connectivity. While these communication costs are much higher than those associated with FIDO2 or passwords, we expect users to authenticate with TOTP less frequently because TOTP is only used for second-factor authentication.

### 8.1.3 Passwords

**Latency.** In Figure 3 (center), we show how password authentication latency increases with the number of registered relying parties. With 16 relying parties, authentication takes 28ms, and with 512 relying parties, it takes 245ms: the authentication time grows linearly with the number of relying parties. The proof system we use requires padding the number of relying parties to

the nearest power of two, meaning that registering at additional relying parties does not affect the latency or communication until the number of relying parties reaches the next power of two.

**Communication.** In Figure 5, we show how communication increases logarithmically with the number of relying parties. This behavior is due to the fact that proof size is logarithmic in the number of relying parties. With 16 relying parties, the communication is 1.47KiB, and with 512 relying parties, it is 4.14KiB.

## 8.2 Cost to deploy a larch service

If successful, larch can become much simpler and more efficient with a little support from future FIDO specifications (see Section 9). Nonetheless, we show larch is already practical by analyzing the cost of deploying a larch service today (Table 6). We expect a larch log service to perform many password-based authentications, some FIDO2 authentications, and a comparatively small number of TOTP authentications. This is because the majority of relying parties only support passwords, and relying parties typically require second-factor authentication only from time to time.

Throughout this section, we consider password-based authentication with 128 relying parties (based on the fact that the average user has roughly 100 passwords [73]) and TOTP-based authentication with 20 relying parties (based on the fact that Yubikey’s maximum number of TOTP registrations is 32 [2]). The authentication overhead of FIDO2 in larch is independent of the number of relying parties the user has registered with.

**Storage.** For each of the three protocols, the log service must store authentication records (timestamp, ciphertext, and signature). FIDO2 and TOTP have 88B authentication records, and passwords have 138B records (due to the size of ElGamal ciphertexts). The FIDO2 protocol additionally requires the client to generate presignatures for the log, each of which is 192B. For 10K presignatures, the log service must store 1.83MiB. In Figure 4 (left), we show how per-client log storage actually decreases as presignatures are consumed and replaced by authentication records. To minimize storage costs, the log service can encrypt its presignatures and store them at the client. The log service then simply needs to keep a counter to prevent presignature re-use.

**Throughput.** In Table 6, we show the number of auths/s a single log service core can support assuming 128 passwords and 20 TOTP accounts. We achieve the highest throughput for passwords (47.62 auths/cores/s), which are the most common authentication mechanism. For FIDO2, which can be used as either a first or second authentication factor and is supported by fewer relying parties than passwords, we achieve 6.18 auths/core/s. Finally, for TOTP, which is only used as a second factor, we achieve 0.73 auths/core/s.

Our FIDO2 protocol can be instantiated with any NIZK proof system to achieve a different tradeoff between authentication latency and log service throughput. For example, we instan-

Figure 3: On the left, larch FIDO2 latency decreases as the number of client cores increases (latency is independent of the number of relying parties). In the center, larch password latency grows with the number of relying parties, with the majority of the time spent on client proof generation. On the right, larch TOTP latency grows with the number of relying parties, with the majority of the time spent in an input-independent “offline” phase as opposed to the input-dependent “online” phase (both phases require network communication).

tiate our system with ZKBoo, but could also use Groth16 [45] to reduce communication and verifier time (increasing log throughput). We measure the performance of Groth16 on our larch FIDO2 circuit on the BN-128 curve using ZoKrates [91] with libsnark [57] with a single core (we only measure the overhead of SHA-256, which dominates circuit cost, to provide a performance lower bound). While the verifier time is much lower (8ms) and the proof is much smaller (4.26KiB), (1) the trusted setup requires the client to store 19.86MiB and the log service to store 9.2MiB per client, and (2) the proving time is 4.07s, meaning that authentication latency is much higher.

**Cost.** We now quantify the cost of running a larch log service. The cost of one core on a c5 instance is \$0.0425-\$0.085/hour depending on instance size [1]. Data transfer to AWS instances is free, and data transfer from AWS instances costs \$0.05-\$0.09/GB depending on the amount of data transferred per month [1]. In Table 6, we show the cost of supporting 10M authentications for each authentication method with larch.

Supporting 10M authentications requires 450 log core hours for FIDO2, 3,832 log core hours for TOTP, and 59 log core hours for passwords. Compute for 10M authentications costs \$19.13-\$38.25 for FIDO2, \$162.86-\$325.72 for TOTP, and \$2.51-\$5.02 for passwords. Communication for 10M authentications costs \$0.10-\$0.19 for FIDO2, \$17,923-\$32,262 for TOTP, and \$0.015-\$0.027 for passwords. The high cost for TOTP is due to the large amount of communication required at authentication: the log service must send the client 36.8MiB for every authentication. In both the FIDO2 and password protocols, the vast majority of the communication overhead is due to the proof sent from the client to the log service, which incurs no monetary cost. We show how cost increases with the number of authentications for each of the the authentication methods in Figure 4 (right).

TOTP is substantially more expensive than FIDO2 or passwords. However, we expect a relatively small fraction of authentication requests to be for TOTP.

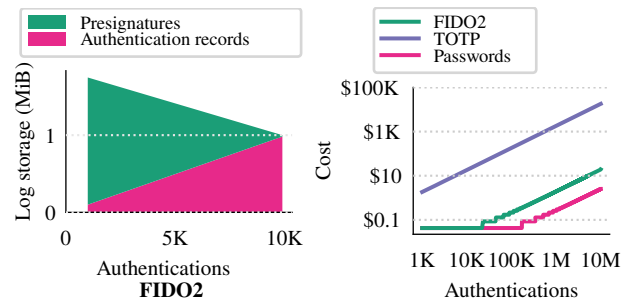

Figure 4: On the left, per-client storage overhead at the log decreases as presignatures are replaced with authentication records (client enrolls with 10K presignatures). On the right, minimum cost of supporting more authentications with passwords, (128 relying parties), FIDO2, and TOTP (20 relying parties). Both axes use a logarithmic scale.

Figure 5: Communication for larch with passwords increases logarithmically with the number of relying parties (both axes use a logarithmic scale).

## 9 Discussion

**Deployment strategy.** Because larch supports passwords, TOTP, and FIDO2, people can use it with the vast majority of web services. In addition, larch offers users many of the benefits of FIDO2 without a dedicated hardware security token, particularly FIDO2’s protection against phishing. The flexibility for users to choose log services can foster an ecosystem of new security products, such as log services that request login confirmation via a mobile phone app, apps that monitor the log to notify users of anomalous behavior, or enterprise security products that monitor access to arbitrary

	FIDO2	TOTP	Password
Online auth time	150 ms	91 ms	74 ms
Total auth time	150 ms	1.32 s	74 ms
Online auth comm.	1.73 MiB	201 KiB	3.25 KiB
Total auth comm.	1.73 MiB	65 MiB	3.25 KiB
Auth record	88 B	88 B	138 B
Log presignature	192 B	∅	∅
Log auths/core/s	6.18	0.73	47.62
10M auths min cost	\$19.19	\$18,086	\$2.48
10M auths max cost	\$38.37	\$32,588	\$4.96

Table 6: Costs for larch with FIDO2, TOTP (20 relying parties), and passwords (128 relying parties). We take the cost of one core on a c5 instance to be \$0.0425-\$0.085/hour (depending on instance size) and data transfer out of AWS to cost \$0.05-\$0.09/GB (depending on amount of data transferred) [1]. For comparison, the Argon2 password hash function should take 0.5s using 2 cores.

third-party services that a company could contract with.

**FIDO improvements.** Larch can benefit from enhancements we hope to see considered for future versions of the FIDO specification. One simple improvement would be to support BLS signatures, which are easier to threshold and so eliminate larch’s need for presignatures [14].

Future versions of FIDO could also directly support secure client-side logging by allowing the relying party to compute the encrypted log record itself. The relying party could then ensure that the log service receives the correct encrypted log record by checking for the log record in the signing payload. Specifically, the signature payload could have the form:

Hash(log-record-ciphertext, Hash(remaining-FIDO-data)) .

The log server can then take the outer hash preimage as input without needing to verify anything else about the log record.

We want to allow the relying party to generate the encrypted log record without making it possible to link users across relying parties. Instead of giving the relying party the user’s public key directly at registration, which would link a user’s identity across relying parties, we instead give the relying party a key-private, re-randomizable encryption of the relying party’s identifier (we can achieve this using ElGamal encryption). At authentication, the relying party can re-randomize the ciphertext to generate the encrypted log record.

We also hope that future FIDO revisions standardize and promote authentication metadata as part of the challenge and hypothetical log record field. For users with multiple accounts at one relying party, it would be useful to include account names as well as relying party names in signed payloads. It would furthermore improve security to allow distinct types of authentication log records for different security-sensitive operations such as authorizing payments and changing or

removing 2FA on an account. An app monitoring a user’s log can then immediately notify the user of such operations.

**Multiple devices.** Clients need to authenticate to their accounts across multiple devices, which requires synchronizing a small amount of dynamic, secret state across devices. Cross-device state could be stored encrypted at the log, or could be disseminated through existing profile synchronization mechanisms in browsers. There is a danger of the synchronization mechanism maliciously convincing two devices to use the same presignature. Therefore, presignatures should be partitioned between devices in advance, and devices should employ techniques such as fork consistency [65] to detect and deter any rollback attacks. Existing tools can help a user recover if she loses all of her devices [25, 55, 81, 62].

**Enforcing client-specific policies.** We can extend larch in a straightforward way to allow the log to enforce more complex policies on authentications. The client could submit a policy at enrollment time, and the log service could then enforce this policy for subsequent authentications. If the policy decision is based on public information, the log service can apply the policy directly (e.g., rate-limiting, sending push notifications to a client’s mobile device). Other policies could be based on private information. For example, if we used larch for cryptocurrency wallets, the log could enforce a policy such as “deny transactions sending more than \$10K to addresses that are not on the allowlist.” For policies based on private information, the client could send the log service a commitment to the policy at enrollment, and the log service could then enforce the policy by running a two-party computation or checking a zero-knowledge proof.

**Revocation and migration.** If a client loses her device or wants to migrate her authentication secrets from an old device to a new device, she needs a way to easily and remotely invalidate the secrets on the old device. Larch allows her to do this easily. To migrate credentials to a new device, the client and log simply re-share the authentication secrets. To invalidate the secrets on the old device, the client asks the log to delete the old secret shares (client must authenticate with the log first).

**Account recovery.** In the event that a client loses all of her devices, she needs some way to recover her larch account. To ensure that she can later recover her account, the client can encrypt her larch client state under a key derived from her password and store the ciphertext with the larch service. The security of the backup is only as good as the security of the client’s password. Alternatively, the client could choose a random key to encrypt her client state and then back up this key using her password and secure hardware in order to defend against password-guessing attacks [25].

**Limitations.** If an attacker compromises the client’s account with the log, the attacker can access the client’s entire authentication history. To mitigate this damage, the log could delete old authentication records (e.g., records older than one week) or re-encrypt them under a key that the user keeps offline.

## 10 Related work

**Privacy-preserving single sign-on.** Like larch, existing privacy-preserving single sign-on systems hide the relying party from the identity provider. Unlike larch, these systems do not protect users' accounts from a malicious attacker that compromises the identity provider, and they do not privately log the identity of the relying party. BrowserID [33] (implemented in Mozilla Persona and Firefox Accounts) and SPRESSO [34] are single sign-on services that ensure that the identity provider does not learn the identity of the relying parties. However, neither prevents colluding relying parties from linking a user's accounts across relying parties. EL PASSO [90], UnlimitID [53], UPRESSO [50], PseudoID [30] and Hammann et al. [51] show how to build single sign-on services that protect clients from curious identity providers while ensuring that relying parties cannot link users' accounts.

Separately, Privacy Pass allows a user to obtain anonymous tokens for completing CAPTCHAs, which she can then spend at different relying parties without allowing them to link her across sites [27]. Like larch, Privacy Pass does not link users across accounts, but unlike larch, Privacy Pass does not provide a mechanism for logging authentications.

**Threshold signing.** Our two-party ECDSA with preprocessing protocol builds on prior work on threshold ECDSA. MacKenzie and Reiter proposed the first threshold ECDSA protocol for a dishonest majority specific to the two-party setting [64]. Genarro et al. [41] and Lindell [61] subsequently improved on this protocol. Doerner et al. show how to achieve two-party threshold ECDSA without additional assumptions [31]. Another line of work supports threshold ECDSA using generic multi-party computation over finite fields [76, 22]. A number of works show how to split ECDSA signature generation into online and offline phases [23, 18, 48, 47, 38, 19, 85, 4]; in many, the offline phase is signing-key-specific, allowing for a non-interactive online signing phase, whereas we need an offline phase that is signing-key-independent. Abram et al. show how to reduce the bandwidth of the offline phase via pseudorandom correlation generators [4]. Aumasson et al. provide a survey of prior work on threshold ECDSA [8]. Arora et al. show how to split trust across a group of FIDO authenticators to enable account recovery using a new group signature scheme [6].

**Proving properties of encrypted data.** Larch's split-secret authentication protocol for FIDO2 and passwords relies on proving properties of encrypted data, which is also explored in prior work. Verifiable encryption was first proposed by Stadler [77], and Camenisch and Damgard introduced it as a well-defined primitive [15]. Subsequent work has designed verifiable encryption schemes for limited classes of relations (e.g. discrete logarithms) [16, 7, 86, 63, 69]. Takahashi and Zaverucha introduced a generic compiler for MPC-in-the-head-based verifiable encryption [78]. Lee et al. [60] contribute a SNARK-based verifiable encryption scheme that decouples the encryption function from the circuit

by using a commit-and-prove SNARK [17]. This approach does not work for us for FIDO2 authentication because the ciphertext must be connected to a SHA-256 digest.

Grubbs et al. introduce zero-knowledge middleboxes, which enforce properties on encrypted data using SNARKs [49]. Wang et al. show how to build blind certificate authorities, enabling a certificate authority to validate an identity and generate a certificate for it without learning the identity [82]. DECO allows users to prove that a piece of data accessed via TLS came from a particular website and, optionally, prove statements about the data in zero-knowledge [89].

**Transparency logs.** Like larch, transparency logs detect attacks rather than prevent them, and they achieve this by maintaining a log recording sensitive actions [66, 44, 52, 21, 59, 5, 25]. However, transparency logs traditionally maintain public, global state. For example, the certificate transparency log records what certificates were issued and by whom in order to track when certificates were issued incorrectly [59]. In contrast, the larch log service maintains encrypted, per-user state about individual users' authentication history.

## 11 Conclusion

Larch is an authentication manager that logs every successful authentication to any of a user's accounts on a third-party log service. It guarantees log integrity without trusting clients. It furthermore guarantees account security and privacy without trusting the log service. Larch works with any existing service supporting FIDO2, TOTP, or password-based login. Our evaluation shows the implementation is practical and cost-effective.

## Abstract

Data privacy laws like the EU’s GDPR grant users new rights, such as the right to request access to and deletion of their data. Manual compliance with these requests is error-prone and imposes costly burdens especially on smaller organizations, as non-compliance risks steep fines.

K9db is a new, MySQL-compatible database that complies with privacy laws by construction. The key idea is to make the data ownership and sharing semantics explicit in the storage system. This requires K9db to capture and enforce applications’ complex data ownership and sharing semantics, but in exchange simplifies privacy compliance. Using a small set of schema annotations, K9db infers storage organization, generates procedures for data retrieval and deletion, and reports compliance errors if an application risks violating the GDPR.

Our K9db prototype successfully expresses the data sharing semantics of real web applications, and guides developers to getting privacy compliance right. K9db also matches or exceeds the performance of existing storage systems, at the cost of a modest increase in state size.

## 1 Introduction

New privacy laws including the European Union’s General Data Protection Regulation (GDPR) [44], the California Consumer Privacy Act (CCPA) [10], and others [7, 17, 20, 56] seek to protect users’ rights to their data in web services. Many of these laws provide users with rights to issue subject access requests (SARs), including a *right to access*, which lets users request a copy of their data, and a *right to erasure*, which requires its deletion on request [51, 52]. Many also impose a mandate to store data securely. Compliance with these laws is important, as violations risk severe fines [9, 39–41].

Achieving compliance can be onerous and expensive, however, particularly for small and medium-size organizations. These organizations must write custom queries and track metadata to identify and extract data related to a user, and continuously maintain this infrastructure as services evolve. Even well-intentioned developers sometimes get it wrong: for example, the ownCloud collaboration platform [43], though it

claims GDPR compliance [42], retains a user’s activity log after account deletion. Retrofitting compliance onto existing systems is tricky, as it still requires manual work [2, 28] and may harm performance [51].

This paper explores an alternative system design that achieves privacy compliance *by construction*. Our key idea is to make data ownership a first-class citizen in the database system itself. K9db, our new database system, tracks sufficient information to know, for each row in the database, what user (or users) have rights to it. This allows K9db to infer correct procedures for data retrieval and deletion, so that the database itself can handle requests under the rights to access or erasure, freeing the application developer from having to write or maintain custom scripts to handle these requests. The ownership information also allows K9db to encrypt data with per-user keys, which helps meet, e.g., the GDPR’s “Protection by Design and Default” requirement, which can be satisfied by encrypting at-rest data [36, 44]. Finally, K9db uses ownership information to generate errors if the database schema or operations on database contents risk violating the GDPR.

To realize K9db, we had to address three challenges. First, K9db must understand and model the complex data ownership and sharing semantics of real applications. A user’s data may span many tables with transitive relationships, may be shared in complex and data-dependent ways, and may require partial redaction when returned or removed. Second, K9db must maintain and enforce compliance invariants matching these ownership semantics throughout application execution, and correctly respond to user access and deletion requests. Third, K9db should match the performance of today’s databases that lack infrastructure for data ownership tracking, and must be both compatible with existing applications and easy for application developers to adopt.

K9db’s design addresses these challenges as follows. First, K9db derives a *data ownership graph (DOG)* from a set of coarse-grained, declarative annotations on the database schema. Using a small number of primitives, the DOG models a wide range of complex data sharing relationships found in real-world applications. The DOG is central to K9db’s

storage organization, to its handling of users' access and erasure requests, and to K9db's ability to enforce privacy compliance. Second, K9db organizes data storage around data ownership to ensure that applications remain in compliance and handle access and deletion requests correctly by construction, without disrupting regular application operations. Third, K9db is a MySQL-compatible drop-in-replacement for existing databases, and requires few application changes beyond declarative schema annotations for normalized schemas. To accelerate complex queries, K9db provides an integrated, privacy-compliant in-memory cache based on materialized views. By integrating and managing materialized views, K9db provides the benefits of caching to applications, while relieving developers from ensuring compliance of cached data.

K9db structures the actual data storage as a set of user-specific logical "micro-databases" ( $\mu$ DBs), realized over a single physical RocksDB [33] store. Each user's  $\mu$ DB contains the data they own, and is encrypted with a user-specific key. K9db also helps developers use the system correctly by providing compliance-specific functionality not found in other databases. A new EXPLAIN COMPLIANCE SQL command gives the developer insight into the DOG and highlights possible schema annotation errors; and K9db supports *compliance transactions* that guard against dynamic compliance problems, such as data without an owner being left behind in the database. K9db provides ACID guarantees similar to those in default MySQL.

K9db provides out-of-the-box compliance for well-intentioned developers who want to comply with privacy laws, and helps developers avoid mistakes. We expect that fines for privacy violations (e.g., the greater than 4% of annual turnover or €25M for GDPR violations) discourage intentional misuse.

In summary, this paper makes the following contributions:

1. The data ownership graph (DOG) for modeling ownership in a database, specified with schema annotations.
2. K9db, a new database that enforces compliance-by-construction based on the DOG and a compliant, ownership-aware storage organization.
3. Mechanisms that, based on the DOG, warn developers if schema annotations are insufficient or if the database becomes non-compliant at runtime.
4. An evaluation of K9db, demonstrating that a database centered around first-class data ownership and compliance-by-construction is practical.

We evaluate K9db with scenarios based on the Lobsters web application [27], the ownCloud document sharing platform [43], and the Shuup e-commerce platform [53]. Our experiments show that K9db can express a wide variety of nuanced data sharing and ownership patterns found in these applications, and that K9db performs on-par with or better than MariaDB and the widely-used MariaDB/memcached stack when serving typical web application workloads.

K9db is open-source at <https://github.com/brownsys/K9db>.

## 2 Background and Related Work

### 2.1 Privacy Laws

Web services must comply with new privacy and data protection laws [7, 10, 17, 20, 44, 56]. Many of these laws have a comprehensive scope: e.g., the EU's GDPR applies to anyone who offers services to users physically in the EU and touches many aspects of web services [52]. In particular, most laws grant users rights over their data that require services to identify all data related to a user. The GDPR, for example, provides *Subject Access Requests* (SARs) that allow a "data subject" (i.e., an end user) to request a copy of their data (Right to Access, Art. 15), to request the deletion of their data (Right to Erasure, Art. 17), and to receive the data in a portable and machine-readable format (Right to Data Portability, Art. 20). Complying with SARs requires the service provider ("data controller" in GDPR terms) to identify the information related to a data subject. As the GDPR has become a model for other privacy laws, many have adopted similar SAR-like requirements. The California Consumer Privacy Act (CCPA), for example, gives consumers a right to request the "specific pieces of personal information [a business] has collected about the consumer" [10, §1789.110] and its deletion [10, §1789.105].

The GDPR and other laws also impose mandates for secure data handling, particularly encryption at rest [44, Arts. 25, 32, 10, §1798.150(a)(1)]. These mandates avoid prescribing particular technologies: e.g., the GDPR only requires that organizations take "appropriate technical measures" to secure personal data [44, Art. 32], giving freedom to meet the requirement in different ways. In practice, encrypting data at rest and deleting encryption keys (referred to as "crypto-shredding"), e.g., to make backups inaccessible, is widely considered a compliant approach [45].

This paper primarily focuses on technical infrastructure to ease compliance with SARs and the requirement for secure storage. Privacy laws also include other provisions that e.g., mandate user consent for processing and regulate data sharing with third parties. Our design is compatible with these requirements, but they are not the focus of this paper.

### 2.2 Complexity of Data Ownership

Compliance with SARs is difficult, both manually and in automated systems, because web services often have complex ownership and data sharing semantics. Identifying data associated with a particular user ("data subject") is challenging. In relational databases, these associations are expressed as foreign keys; but data in many tables link to data subjects transitively via one or more intermediate tables, rather than directly. Multiple data subjects can be associated with the same data (e.g., private messages), and sometimes this association is asymmetric and implies different rights for different data subjects (e.g., a teacher and a student). Finally, many-to-many relationships introduce dynamically changing associations

between data and a variable number of data subjects.

GDPR-like laws afford companies with some flexibility in handling SARs. Applications may keep data associated with the data subject (possibly in some anonymized form) after a deletion request due to legal or contractual obligations (e.g., tax laws) or public interest [44, Art. 17.3]. Data may also be retained depending on the purpose of its processing, including the interests of other users [44, Art 6.1, Art. 17.1(b)]. For example, Facebook’s privacy policy specifies that Facebook deletes the comments that a withdrawing data subject made, but not the private messages they sent to a friend, unless that friend also deletes them [16]. Thus, the compliance policy and exact handling of SARs are application and data dependent.

### 2.3 Existing Approaches to Privacy Compliance

Privacy compliance today requires application developers to write custom queries and maintain metadata to identify and track information related to each data subject [51]. The queries are tricky to get right and maintain as the application evolves. To address part of this burden, some large companies built bespoke GDPR metadata stores [13, §1] and dedicated frameworks for data deletion [14]. However, these frameworks only solve part of the problem, and most organizations lack the resources to build such systems themselves. Our work provides compliance within an off-the-shelf database.

Adaptations of existing database systems can go some way towards providing privacy compliance, but can come at a steep performance cost. For example, Shastri et al. found that secondary indexes and strict metadata tracking impose overheads up to  $5\times$  [51], leading to proposals to accelerate these operations in hardware [21]. SchengenDB [23] outlines a design that provides GDPR compliance, but relies on extensive metadata and conservative, coarse-grained enforcement, e.g., destroying entire VM clusters when a data subject deletes their account. Our work redesigns the database to make correct privacy compliance a first-class property [49], without sacrificing performance and with moderate overheads.

Other proposals have advocated restructuring web services to enforce users’ privacy rights, but face barriers to adoption. W5 [24], Oort [11], Blockstack [3], and Solid [29] decouple data storage from the web application and put data storage under user control. This approach allows for strong guarantees, but requires rewriting web applications, comes with restrictions (e.g., all application logic must run in JavaScript in the browser), and is incompatible with today’s advertising-based business model for web services. Data Capsules [58], Riverbed [57], and Zeph [8] let users specify individual privacy policies for their data in web services. Though powerful, custom policies do not solve the problem of identifying all information related to a user; and may limit possible operations (e.g., to those expressible as homomorphic additions). Our work provides by-construction compliance with subject access requests, but with a storage model and database interface that works for existing web applications.

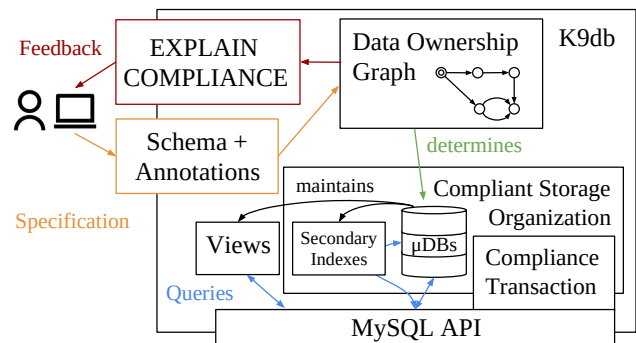

Figure 1: K9db provides privacy-compliant storage based on its data ownership graph, micro-databases ( $\mu$ DBs), and compliance helper mechanisms behind a MySQL interface.

## 3 K9db Overview

K9db is a relational database that makes data ownership an explicit first-class citizen. K9db targets typical web application workloads, which are dominated by reads and point lookup queries [18]. Its design goals are (i) to require few changes to application code, (ii) to capture and enforce the complex data ownership and sharing semantics of real-world applications, and (iii) to provide feedback that helps developers get privacy compliance right.

Figure 1 shows an overview of K9db’s components. K9db requires developers to extend their relational schema (i.e., `CREATE TABLE` statements) with a small set of annotations that encode data ownership and sharing semantics. The annotated schema acts as an application-specific compliance policy that specifies how K9db handles SARs. From these annotations, K9db builds its key abstraction, the *data ownership graph (DOG)* (§4). The DOG lets K9db determine, for every row in the database, who owns it and who has rights to it. K9db uses the DOG to satisfy data subjects’ SARs, to check that the database remains compliant after the application makes changes, and to warn the developer if their annotated schema and the compliance policy it encodes seem incomplete or contradictory.

Using information from the DOG, K9db organizes its storage in a user-centric way, storing each data subject’s data in their own logical “micro-database” ( $\mu$ DB), a shard of the actual database. This design ensures that K9db enforces the developer-provided compliance policy by construction, lets K9db encrypt each data subject’s data with a separate cryptographic key, and speeds up compliance-related enforcement and operations (§5). K9db maintains some additional secondary indices compared to a traditional SQL database, which help K9db efficiently resolve which  $\mu$ DBs store particular data. It also maintains materialized views that help simplify and accelerate execution of complex queries, while also providing an integrated, privacy-compliant in-memory cache (§6).

For normalized schemas, K9db requires little to no applica-

Figure 2: K9db’s annotations on foreign keys (FKs; orange) indicate the direction of data ownership (black edge) between two tables. Circles are tables.

Annotation	Example
DATA_SUBJECT	CREATE DATA_SUBJECT TABLE users (...)
$T_A(x)$ OWNED_BY $T_B(y)$	stories(author_id) OWNED_BY users(id)
$T_A(x)$ OWNS $T_B(y)$	member(gid) OWNS group(id)
$T_A(x)$ ACCESSED_BY $T_B(y)$	share(share_with) ACCESSED_BY user(id)
$T_A(x)$ ACCESSES $T_B(y)$	taggings(tag_id) ACCESSES tags(id)
ON DEL $T_A(x)$ {ANON (...)   DELETE_ROW}	ON DEL chat(receiver) ANON (receiver)
ON GET $T_A(x)$ {ANON (...)   DELETE_ROW}	ON GET review(paper_id) ANON (reviewer_id)

Figure 3: K9db’s table and column-level annotations. All annotations except DATA\_SUBJECT and ANON imply a foreign key from column  $x$  in table  $T_A$  to column  $y$  in  $T_B$ .

tion code changes, except that developers may need to wrap certain operations in a compliance transaction (§5.5). Developers can use K9db as a drop-in replacement for MySQL.

## 4 Modeling Data Ownership and Sharing

K9db aims to provide correct-by construction compliance with privacy laws, which requires K9db to respond to SARs correctly and enforce several invariants over the data and its storage. Correct compliance has two prongs: (i) a compliance policy that is consistent with the privacy law in question, and (ii) correct enforcement of this policy when handling both regular application operations and SARs.

The compliance policy is application-specific and depends on the relationships in the underlying data. For a single application, multiple policies may achieve compliance, and laws afford developers some flexibility in choosing a policy that matches their application’s semantics (§2.2).

In K9db, developers express their compliance policy using schema annotations, which K9db represents using the *data ownership graph* (DOG): a directed, acyclic multigraph whose vertices represent database tables, and whose edges represent ownership relationships between rows in the tables.

### 4.1 K9db’s Annotations

Developers use schema annotations on foreign keys to communicate their application’s data ownership and sharing se-

manantics to K9db. To communicate how the database represents human persons who have rights over data (“data subjects” in GDPR terms), the developer annotates one or more tables with the table-granularity DATA\_SUBJECT annotation.

Foreign keys (FKs) relate rows in tables to each other, and often imply ownership—consider e.g., a story pointing to its author. This is the simplest case: a story is owned by the row its FK value points to. K9db provides the OWNED\_BY keyword for developers to annotate such FKs (Figure 2a; §4.3 discusses transitive cases). But foreign keys may also point in the *opposite* direction of ownership, as is the case e.g., if a user table has a foreign key to their primary address. For such cases, K9db provides the OWNS annotation (Figure 2b).

In addition to ownership, an application may also have data that is owned by one data subject (who has the right to delete it when removing their account), but share it with others. For example, in the file sharing platform ownCloud [43], users want to share files with others, but when they remove their account have the file be removed for everyone. K9db lets developers express this with the ACCESSED\_BY annotation, and its dual for opposite-direction FKs, ACCESSES.

These annotations extend the semantics of foreign keys with compliance semantics, and while every annotation is applied to a foreign key, not every foreign key impacts ownership or needs to be annotated. For example, the foreign key connecting students in a university database with their declared majors carries no ownership information—the students do not own the majors—and should not be annotated.

K9db also provides table-level annotations that allow developers to specify that columns in a table need anonymizing in the context of SARs. This is important because a row may need redacting before returning the row as part of a right-to-access request (ON GET), or because a row may need to be retained in anonymized form (e.g., for tax compliance) after a data subject requests deletion of their data (ON DEL). Each anonymization annotation is associated with an ownership or access foreign key (i.e., an outgoing edge from the table in the DOG). This allows for different anonymization behavior depending on how the data subject who issued a SAR is connected to the data. For example, in the HotCRP conference review system [22], if a data subject who is both a reviewer and an author makes an access request, they should receive an unredacted copy of the reviews they wrote, but redacted, anonymized reviews for the papers they authored.

Figure 3 shows K9db’s complete set of schema annotations.

### 4.2 Expressing Developers’ Compliance Policies

We demonstrate how developers annotate their schema to express their desired compliance policy using two examples extracted from real applications: stories and messages in Lobsters (Figure 4), and file sharing in ownCloud (Figure 5).

In Lobsters, developers begin by annotating the users table, which records the application’s end-users, with DATA\_SUBJECT. A user may post several stories, and retains

```

1 CREATE DATA_SUBJECT TABLE users (id INT PRIMARY KEY, ...);
2 CREATE TABLE stories (
3   id INT PRIMARY KEY, title TEXT, ...
4   author INT NOT NULL OWNED_BY user(id)
5 );
6 CREATE TABLE tags (id INT PRIMARY KEY, tag TEXT, ...);
7 CREATE TABLE taggings (
8   id INT PRIMARY KEY,
9   story_id INT NOT NULL OWNED_BY stories(id),
10  tag_id INT NOT NULL ACCESSES tag(id)
11 );
12 CREATE TABLE messages (
13   id INT PRIMARY KEY, body text, ...
14   sender INT NOT NULL OWNED_BY user(id),
15   receiver INT NOT NULL OWNED_BY user(id),
16   ON DEL sender ANON (sender),
17   ON DEL receiver ANON (receiver)
18 );

```

Figure 4: Partial schema for Lobsters. Users own the stories they authored and their associations with tags. Messages are jointly owned by both sender and receiver.

```

1 CREATE DATA_SUBJECT TABLE user (id INT PRIMARY KEY, ...);
2 CREATE TABLE group (id INT PRIMARY KEY, title TEXT, ...);
3 CREATE TABLE member (
4   id INT PRIMARY KEY,
5   uid INT NOT NULL OWNED_BY user(id),
6   gid INT NOT NULL OWNS group(id)
7 );
8 CREATE TABLE share (
9   id INT PRIMARY KEY, ...
10  uid_owner INT NOT NULL OWNED_BY user(id),
11  share_with INT ACCESSED_BY user(id),
12  share_with_group INT ACCESSED_BY group(id)
13 );

```

Figure 5: Partial schema for ownCloud file sharing: users own their group membership, which owns the group; files have an owner and are shared with users who have access to them.

sole ownership of them: these stories must be retrieved or deleted when the user issues an SAR. Developers express this by annotating the author FK in `stories` with `OWNED_BY`. Lobsters also has a set of tags that represent discussion topics, e.g., `games` and `programming`. Users can assign tags to stories they posted, and have complete ownership of these associations. Developers express this by annotating the `story_id` column in `taggings` with `OWNED_BY`. This makes the story the owner of its taggings, transitively making the data subject who owns the story (i.e., its author) the owner of the associated taggings. But the tags themselves are not related to any data subject. Thus, developers annotate `tag_id` with `ACCESSES` (and not `OWNS`). As a result, a data subject receives a copy of their stories and associated tags when they request access, while disassociating tags from their stories and removing the stories themselves when requesting deletion.

Figure 6: Tables can have transitive ownership relationships (\*: zero or more steps of indirection); if an edge follows a one-to-many or many-to-many relationship, it expresses variable ownership. Double circles indicate data subject tables.

Figure 7: The DOG for stories and messages in Lobsters. Red indicates access-typed edges; 1 and  $n$  are cardinalities.

Similar to private messages in Facebook [16], messages in Lobsters are only deleted when both sender and receiver request deletion. Thus, developers annotate both sender and receiver with `OWNED_BY` (i.e., joint-ownership), along with anonymization annotations that instruct K9db to hide the identity of the associated withdrawing user in surviving messages. An alternative policy could require deleting a message as soon as one of the associated users is deleted. Developers can express this via an `ON DEL ... DELETE_ROW` annotation.

ownCloud’s data subjects are users in the user table, who can be members of a group (in the group table), as defined by the member association table. Users own their group memberships, so the developer annotates the `uid` column of member with `OWNED_BY`. The group and its associated resources are jointly owned by its members (ownCloud has no notion of group admins). Hence, the developer applies the `OWNS` annotation to the `gid` foreign key from member to group.

ownCloud’s share table contains records of users sharing files with others. This table specifies the file’s owner (i.e., its original creator) via the `uid_owner` column, which is a direct FK to the user table. The developer thus annotates this column with `OWNED_BY`. The `share_with` and `share_with_group` columns are also FKs that eventually lead to the user table, but indicate that the file is shared with (rather than owned by) these users. The developer therefore annotates them with `ACCESSED_BY`.

### 4.3 Data Ownership Graph

K9db builds the DOG from developers’ annotations by inserting DOG edges in the underlying FK direction for `OWNED_BY` and `ACCESSED_BY`, and against the FK direction for `OWNS` and `ACCESSES`. Thus, DOG edges always point towards a data subject table, unlike foreign keys.

When tables have a chain of annotated foreign keys, K9db

Figure 8: The DOG for ownCloud file sharing. Red edges are access-typed. Note the variable ownership (Fig. 6b) between member and group, as member rows are the group’s owners.

adds an edge to the DOG that establishes a *transitive* ownership relationship (Figure 6a). For example, in Lobsters (Figure 7), a story’s taggings have no direct references to the story’s author. Instead, they refer to their story ②, which in turn refers to the author ①. Therefore, edges in the DOG always represent a single step towards a data subject.

The DOG is a multi-graph because two tables can have multiple foreign keys between them. For example, in Lobsters the messages table has two foreign keys, one to the sender ④ and one to the receiver of a message ⑤. Since sender and receiver jointly own a private message—i.e., the message only disappears if both users delete their account—there are two annotated edges between messages and users.

Access annotations on foreign keys also add edges to the DOG, but these edges are access-typed and distinct from owner-typed edges. For example, in ownCloud (Figure 8) a file is accessible but not owned by users it is shared with, either directly ⑥ or via a group ⑦. Differentiating ownership and access edges is important for K9db to correctly handle access and deletion requests.

If the destination of a DOG edge can contain multiple rows corresponding to a single row in the source table, then that row can have multiple owners or accessors. The DOG edge ⑧ from ownCloud’s group to member is a one-to-many relationship, so a group may have many owners. This is an example of *variable ownership* (Figure 6b), as the number of owners varies depending on the data (i.e., depending on the rows in member). Similarly, DOG edges may also express *variable access*, e.g., a single tag in Lobsters may be accessed through many stories ③. This contrasts with the typical situation where the destination of a DOG edge is a primary key or unique column, making it a one-to-one or many-to-one relationship, both specifying a single owner (e.g., ⑨ and ⑩). K9db’s DOG metadata stores arity of relationships and K9db handles variable ownership and access appropriately.

#### 4.4 Helping Developers Get Annotations Right

EXPLAIN COMPLIANCE gives the developer information about the DOG, including heuristic warnings and suggestions about how it may be improved. K9db runs a simple heuristic over the schema to discover column names which indicate user data such as variations on “name”, “email” and “pass-

word”. If a table with such column names is not connected to a data subject in the DOG, K9db suggests to make it owned. This heuristic is most useful to discover missing data subjects, as their tables often contain columns with such names.

EXPLAIN COMPLIANCE also reports information that K9db derives from the DOG. For every table, it reports which data subject tables own it, and the paths through the DOG by which they own the table. This essentially shows the developer the closure over the DOG that K9db uses to handle SARs. EXPLAIN COMPLIANCE warns developers if a table is owned by many data subjects, e.g., if a DOG path contains multiple variable ownership edges, which can result in multiplicatively many owners. Such liberal sharing is rare in practice and likely the result of a schema or annotation mistake.

#### 4.5 Data Ownership Graph Properties

The DOG is *well-formed* if any path through it terminates at a data subject table. K9db rejects any schema that results in a DOG that is not well-formed.

Although the DOG is a graph of tables, its edges represent relations between rows in the source and destination tables based on the values of the underlying FK columns. Each DOG edge maps to a *relation* between rows in the two tables, where matching rows in the destination table own (or access) the rows in the source table. Intuitively, this relation can be evaluated as a query over the destination table, which yields exactly the owning row (or rows, in the case of variable ownership). Well-formedness guarantees that the transitive closure of these relations terminates at data subject tables.

Several key properties follow from this. First, if no matching rows exist in any destination table when evaluating the relations along *all* of the table’s outgoing ownership edges, data is orphaned (i.e., has no owner). This gives rise to the necessary (but insufficient<sup>1</sup>) *no orphaned data* compliance condition: any row in a database table connected to the DOG must resolve to  $\geq 1$  owning data subjects. Second, the transitive closure of relations corresponding to ownership edges in the DOG, starting from any row, identifies the set of data subjects that own this row. Third, the DOG’s reverse transitive closure starting from a row in a data subject table yields:

1. the rows shared with and owned by that data subject, if considering accessor-typed and owner-typed edges; or
2. the rows owned by that data subject, if considering only owner-typed edges.

The former set corresponds to the data that needs returning from a right-to-access request, and the latter identifies the data that needs deleting for a right-to-erasure request, provided no other owners exist.

### 5 Compliant by Construction Storage

In principle, the DOG and its relations are sufficient to identify a data subject’s data, and one could imagine adding it as a metadata layer over an existing database. But in practice,

<sup>1</sup>Sufficiency would require the *correct* owners, not just any owner.

compliance is more complex. Although the DOG identifies all data owned by a data subject, K9db needs to take the correct actions on this data. For example, K9db must avoid prematurely deleting jointly-owned data, and deletion must cover backups outside the live database. K9db must also have efficient ways to decide if a given database operation will break compliance, e.g., by violating the *no orphaned data* invariant, something that the DOG alone fails to provide.

K9db therefore introduces ownership as a first-class notion into the storage layer. This makes it simple for K9db to handle SARs, and to enforce invariants that must hold for compliance. Specifically, K9db's storage layer is organized around per-data subject logical "micro-databases" ( $\mu$ DBs), such that each  $\mu$ DB contains all of its data subject's owned data. For jointly-owned data, K9db stores copies of that data in the  $\mu$ DB of every data subject that owns it.

This design has several advantages. First, it ensures data deletion is correct relative to the DOG. When a data subject requests to delete their data, it is sufficient to delete their  $\mu$ DB. Data shared with other data subjects survives as copies in the other  $\mu$ DBs. Second, this design provides an easy way to check whether data is orphaned, as such data can only exist outside of all data subjects'  $\mu$ DBs. Third, this design lets K9db use a per-data subject key to encrypt data in each  $\mu$ DB. This simplifies deletion alongside external and replicated backups of the data, as deleting the owner's key makes all backups and copies inaccessible (i.e., "crypto-shredding").

### 5.1 Storage Layout and Logical $\mu$ DBs

K9db determines the  $\mu$ DBs to store each row in using the DOG. In a well-formed DOG, every table reaches at least one data subject table via its outgoing ownership edges. K9db splits the contents of such a table into different  $\mu$ DBs, each of which contains the rows owned by a particular data subject, and encrypts them with a key specific to that data subject. A table also includes an orphaned data section that may be used temporarily within sequences of operations (§5.5). A data subject's  $\mu$ DB therefore includes rows from every table that stores data owned by them. Note that even though  $\mu$ DBs store physical copies of rows that have multiple owners, they are a logical abstraction and realized over a single underlying physical datastore (e.g., RocksDB in our prototype).

Viewing the datastore as a whole, a previously single row in a table may now be multiple rows due to copies being stored in each owner's  $\mu$ DB. The value of the primary key of that row refers to all these copies. Internally, K9db identifies the different copies using a pairing of the data subject identifier (the value of its primary key in the data subject table) and the value of the primary key in the row.

K9db maintains on-disk secondary indexes separate from tables and  $\mu$ DBs, which K9db uses to execute queries efficiently. K9db creates an on-disk index for each unique and foreign key column and for the primary key. K9db on-disk indexes differ from traditional database indexes in two key

aspects: they map keys to ( *$\mu$ DB identifier, primary key*), and they point to all copies of any jointly-owned row that match the indexed key. K9db creates a special index for the primary key column(s) of owned tables, which maps the PK value to data subject identifiers that own the corresponding row.

K9db stores tables unconnected to the DOG in the same way as other databases. Such tables contain data that is not owned by any data subject, e.g., all available tags in Lobsters or all majors in a university database, and thus are outside any  $\mu$ DB. Note that this is distinct from orphaned data, which are rows without owners in tables that *are* connected to the DOG.

### 5.2 $\mu$ DB Integrity

The storage layer maintains an important invariant for compliance,  *$\mu$ DB completeness*: data owned by a data subject is exactly identical to the data stored in their  $\mu$ DB.

To maintain  $\mu$ DB completeness, K9db must identify the  $\mu$ DBs to insert new data into, and correctly apply application updates that change who owns rows. Changes to the data in a table may have cascading effects on who owns data in dependent tables connected to this table via some ownership path in the DOG. For example, changes to the `member` table in `ownCloud` affect who owns records in the `group` table. K9db utilizes the DOG to handle these situations correctly.

**Inserting Data.** When K9db receives an INSERT statement, it uses the DOG to identify the owners of this data. In particular, K9db analyzes the outgoing edges from the DOG vertex for the affected table. For a direct ownership edge, the data subject identifier is already present in the new row in the form of a foreign key. K9db determines this by introspection on the new row and without querying other tables. If an edge indirectly leads to the data subject table, identifying the owner becomes more complex. K9db can find the owner(s) by querying the database along the transitive edges between the table and the data subject. But such a query may be expensive—for example, the DOG for the Shuup e-commerce application [53] contains a chain of five edges from the `payments` table to the owning data subject. Instead, K9db memoizes the query by building and maintaining in-memory *ownership indexes*, which essentially provide "shortcut" relations over the DOG that point directly to the owning data subjects. In practice, K9db can often avoid or reuse ownership indexes (§6.1).

**Cascading Updates.** INSERT, UPDATE, or DELETE statements may have cascading effects on the ownership of records in dependent tables. After applying such statements to their target table, K9db identifies dependent tables from the DOG. It then queries the rows in each dependent table that match the updated row. K9db moves or copies the matched rows between  $\mu$ DBs appropriately, and cascades again into any further dependent tables. K9db requires no additional indexes to perform this matching efficiently, as it can rely on standard on-disk indexes over foreign keys' source and destination columns. In many cases, K9db avoids cascades via optimizations based on foreign key integrity (§6.1).

### 5.3 Handling Subject Access Requests

K9db needs to handle two types of SARs: the *right to access* and the *right to erasure*. K9db handles both with a similar high level procedure: (i) K9db traverses the DOG to identify all tables and edges connected to the data subject; (ii) K9db finds the data owned by the data subject in their  $\mu$ DB; (iii) K9db locates data accessed, but not owned, by the data subject in other  $\mu$ DBs; and (iv) K9db performs anonymization as specified by the developers in the schema.

For either type of request, K9db identifies the data subject’s data by following paths in the DOG, starting from the data subject table, and moving against incoming edges. A path that consists solely of ownership edges signifies data owned by the data subject, while paths that contain one or more access edges reflect accessed data. K9db locates the relevant rows in a table before moving on to any dependent tables. For every incoming edge, K9db uses the rows it located in the parent table to identify dependent rows in the dependent table. K9db finds these either in the same  $\mu$ DB for ownership paths, or in other  $\mu$ DBs using on-disk indexes for access paths.

After traversing an edge and retrieving data in its source table, K9db selects the anonymization annotations in the schema that apply to that edge. The anonymization annotations specify the columns to anonymize (e.g., the sender of a chat message). For access requests, K9db anonymizes retrieved rows before sending them back to the client. On deletion requests, K9db removes the data subject’s  $\mu$ DB from the database, and anonymizes any remaining copies of the data, which it locates in other  $\mu$ DBs using on-disk indexes.

### 5.4 Atomicity, Consistency, Isolation, and Durability

A single SQL statement may result in several underlying operations over K9db’s storage, as it may update rows in several  $\mu$ DBs or cascade over dependent tables. It is critical for compliance that we ensure that these updates are all ACID, to avoid data races that could lead to a non compliant state (e.g., by creating orphaned data, or breaking the  $\mu$ DB completeness invariant). Therefore, K9db executes every SQL statement as a single statement ACID transaction (similar to MySQL). This includes all underlying operations over any  $\mu$ DBs and all updates to on-disk secondary indices or the integrated in-memory cache (§6.2). Our prototype does not support general multi-statement SQL transactions yet (see §7).

K9db guarantees that concurrent SQL statements have *repeatable reads* isolation, which is the default in MySQL. Any weaker isolation level is insufficient for compliance, as it cannot guarantee that K9db’s compliance invariants hold in the presence of concurrent updates.

### 5.5 Compliance Transactions

An application may itself perform operations that risk violating compliance. Consider the example from ownCloud shown in Figure 9: ① the application deletes user “A”’s membership in group 1, of which “A” is the last remaining

START COMPLIANCE TX

① DELETE FROM member WHERE uid=A AND gid=1;

② K9db applies cascading effect;

gid=1 is orphaned

COMPLIANCE BROKEN

③ DELETE FROM group WHERE gid=1; COMPLIANCE RESTORED

COMMIT COMPLIANCE TX

Figure 9: K9db’s *compliance transactions* help developers check that the database is in a compliant state after multiple operations (here, (1) deleting the last owner of a group, and (3) then deleting the group). Without a compliance TX, K9db would report an error instead of applying step (2).

member. This deletion from *member* has a cascading effect on the dependent *group* table. Since the group with *gid* 1 no longer has any owners, K9db ② moves it into the table’s orphaned data region. This breaks compliance, as it violates the DOG’s *no orphaned data* invariant. A correct application must now perform some operation that restores compliance, e.g., by deleting group 1 in a separate SQL operation, which ③ removes the orphaned row, restoring the invariant.

K9db supports this pattern with the idea of a *compliance transaction* (CTX). A CTX wraps a set of operations that may temporarily violate compliance, but commits only if the database is back to a compliant state at the commit point. Within a CTX, K9db stores orphaned data in orphaned regions attached to each table. On subsequent operations that reintroduce owners for this data, K9db migrates the rows from the orphaned regions to the corresponding  $\mu$ DBs; if deleted, K9db removes the data. At the end of a CTX, K9db ensures that every record moved to the orphaned region during the CTX has an owner again (or was deleted), and produces an error to the developer otherwise.

Finally, K9db forbids statements that write to the orphaned region unless they are part of a CTX. In particular, step ① in Figure 9 will error unless contained in a CTX. This means that developers need to modify applications that contain such patterns to use CTXs when necessary. Requiring such limited modification is desirable, as disallowing compliance-breaking changes outside of CTX helps developers identify issues and forces them to fix buggy and in-compliant applications. For example, K9db would reject a buggy version of ownCloud that does not clean up groups with no members ③. Introducing a CTX allows an application to have benign temporary in-compliance; if K9db instead required applications to only

perform operations that move the database between compliant states (e.g., deleting groups before deleting their last member), it would likely require more substantial rewrites.

CTX are different from regular SQL transactions, which serve to ensure consistency under concurrent execution. CTX are lightweight and required for compliance, while SQL transactions are expensive and web applications often (but not always) avoid them. In a privacy-compliant database with SQL transactions, each such transaction must also be a CTX.

## 6 Query Execution

When K9db executes a query, it must identify the  $\mu$ DBs affected to locate the relevant rows. Depending on the operation, this may involve finding one or all copies of shared rows.

Queries that refer to a single table, such as DELETE and UPDATE statements, and most SELECT queries issued by web applications (e.g., point lookups), run directly against K9db's  $\mu$ DBs with the aid of on-disk indexes. K9db analyzes the columns that appear in the WHERE condition of the query, and selects the index that matches the most columns. Like other databases, K9db finds all the rows that may match the query using the selected index, and then filters these rows with any remaining columns. If no index matches, K9db runs a scan over the table. Developers may create additional indexes using CREATE INDEX, similar to traditional databases.

When data has multiple owners, an index may refer to multiple copies of the same row. For DELETE and UPDATE, K9db atomically operates over all these copies, ensuring that all copies are consistent. K9db may need to remove or add some of the affected rows from/to  $\mu$ DBs, and may need to cascade into dependent tables as described in §5.2. For SELECT queries, K9db identifies a single copy of each matching row and skips any remaining index entries for other copies. This avoids overheads for deduplicating copies of the row.

K9db serves some complex SELECT queries from materialized view, described in §6.2.

### 6.1 Optimizations

K9db speeds up query execution and reduces its memory footprint with a set of optimizations designed to avoid deep cascades and to reduce the number of in-memory ownership indexes (§5.2) required. Some of these optimizations rely on *foreign key integrity*, which K9db enforces (like many other databases) to prevent application operations that result in dangling foreign keys. With FK integrity, rows cannot be inserted into a table if they contain references to non-existent rows in a destination table, and rows in the destination table cannot be deleted as long as source table rows refer to them.

**Avoiding Cascades.** K9db needs to cascade into dependent tables along incoming DOG edges to update dependent rows affected by a write (i.e., those owned by a modified row). But FK integrity guarantees that no such rows exist when K9db handles INSERT and DELETE queries to a table  $T$  that is the destination of a FK from a dependent table. This lets

K9db skip cascades along  $T$ 's incoming DOG edges if the edge is in FK direction; otherwise, K9db must cascade.

**Ownership Indexes.** K9db relies on two techniques to reduce the number of ownership indexes. First, multiple incoming DOG edges that require an ownership index and point to the same column of a table (usually the primary key) may reuse the same index. Second, K9db omits ownership indexes for edges in the DOG that correspond to OWNS annotations, such as the edge from `group` to `member` in `ownCloud`. These edges point in opposite direction to the underlying foreign key. FK integrity ensures that a row must exist at the source of such an edge (e.g., `group`) before any rows referring to it can be inserted to the destination table (e.g., `member`). Hence, K9db always inserts new rows from the source table into the orphaned region, and defers moving them to the correct  $\mu$ DB to future inserts into destination tables in the DOG (which must cascade), as discussed in §5.5. These optimizations, for example, help K9db create only one ownership index for `Lobsters` (which gets re-used three times), and avoid the need for any ownership indexes in `ownCloud`.

**Queries With Inlined Owners.** SQL Statements sometimes directly refer to the owner of their target rows, e.g., by constraining a foreign key that corresponds to an ownership edge in the DOG. Queries that fit this pattern are common in the web applications: e.g., in `Lobsters`, `SELECT * FROM stories WHERE author = ?` selects stories by their author, which is an annotated foreign key to `users`. K9db detects this situation by statically analyzing the WHERE condition and determines the relevant  $\mu$ DB without an on-disk index lookup.

### 6.2 Materialized Views

K9db serves complex SELECT queries, such as joins, aggregations, and those that reorder data, from materialized views. This design makes sense for two reasons. First, it is simple and avoids the need to engineer a sophisticated query planner that understands the nuances of ownership and indexes to efficiently execute these queries over K9db's  $\mu$ DBs. Second, developers often cache the results of complex SELECT queries in external systems (e.g., `memcached`). Privacy compliance while using an external cache requires setting appropriate expiration policies for the cache [59, §4.5] or explicit invalidation of cache entries related to a data subject if they request deletion of their data. This can be painful for developers and may require manually tracking metadata, e.g., when caching aggregates over many data subjects' data. Instead, K9db provides an integrated privacy-compliant cache using materialized views.

When K9db receives a complex SELECT query for the first time, it creates a materialized view and serves further instances of the query from it, until the view is removed or times out. K9db keeps the materialized views up to date via an incremental, streaming dataflow computation triggered by writes to  $\mu$ DBs, as well as  $\mu$ DB deletion. This makes inserts, updates, and deletes more expensive, but speeds up reads.

K9db updates the materialized views atomically prior to acknowledging the corresponding operation to the client. This, along with our storage layer, ensures *repeatable reads* isolation for concurrent operations whether cached or not.

K9db’s ownership indexes are special-case materialized views, maintained with the same dataflow infrastructure.

## 7 Implementation

Our K9db prototype consists of 35k lines of C++, 500 lines of Rust, and 2k lines of Java. It relies on RocksDB for  $\mu$ DB storage, on Apache Calcite [6] for query planning, and on libsodium [15] for encryption. Our implementation is similar to the MyRocks MariaDB storage engine [30], but extends it with compliance and  $\mu$ DB capabilities.

**MySQL Compatibility Layer.** K9db exposes a MySQL binary protocol interface, so unmodified applications can treat K9db as a MySQL server. The interface to K9db’s materialized views is primarily through prepared SQL statements: when an application registers a prepared statement, K9db creates a view if necessary and serves future executions of the prepared statement from it. Developers can also create additional views manually.

**Storage.** K9db relies on RocksDB for persistent data storage. Each table in the schema is a RocksDB column family. Rows in K9db are keyed by a combination of their owner and primary key, to uniquely identify each owner’s copy of a row. Our prototype stores rows ordered by their owner identifier, and uses that identifier as a RocksDB prefix. This allows it to extract and delete  $\mu$ DBs using RocksDB prefix iterators. Our prototype creates and maintains on-disk indexes as RocksDB column families, and formats their content to allow writes to retrieve all the copies of a row, and reads to retrieve a single arbitrary copy, skipping the rest. Like MySQL, K9db creates indexes for primary, unique, and foreign keys.

**Encryption at Rest.** K9db uses hardware-accelerated AES256-GCM to encrypt all data in a  $\mu$ DB with the key of its owner. The key ( $\mu$ DB identifier, primary key) associated with every row is encrypted deterministically with a global key to allow consistent lookup. This has leakage, but is sufficient to satisfy the GDPR’s “security of processing” requirement (Art. 32), which is often interpreted to require encryption of data at rest [4]. It is possible to use blind indexes [5] which also allow consistent lookup but reduce leakage. K9db’s design is independent of the particular encryption scheme used, and can benefit from future advances in searchable encryption. Information in materialized views and secondary indexes remains unencrypted, but K9db deletes it when deleting a user’s data. K9db destroys the decryption key when a user removes their account, making any remaining backups inaccessible.

**ACID.** K9db executes each application SQL statement in a RocksDB transaction, which is based on row-level locking. This includes all updates to secondary indices (similar to MyRocks) and all  $\mu$ DBs and cascade operations. As in MyRocks, K9db serves reads from a consistent RocksDB

snapshot. K9db also updates all relevant materialized views prior to committing. Unlike MyRocks, K9db enforces foreign key integrity and appropriately locks FK targets during execution. Overall, this ensures that concurrent SQL statements are atomic and consistent with *repeatable reads* isolation, which is the default in MySQL and MyRocks.

**View Updates.** K9db’s materialized view updates follow a standard design akin to differential dataflow [32, 35] and Noria [18]. Each table in the schema is associated with an input vertex in the dataflow graph, and when K9db performs updates to a table, it injects the updates into its dataflow input vertex. The dataflow processes the updates through a sequence of operators to derive an incremental update to the materialized view (or secondary index), and applies this update. Dataflow operators are stateless (e.g., projections, filters, unions) or stateful (e.g., joins, aggregations). K9db’s materialized views are indexed for ordered and unordered lookups.

**Limitations.** Our prototype lacks support for general, multi-statement SQL transactions. These are rare in web applications, and can be supported using existing RocksDB primitives and techniques for versioned dataflow processing [31, 35]. While our prototype does not yet support schema changes, RocksDB is schema-oblivious, and our prototype’s storage layer could be extended to support schema changes with some engineering effort, using similar techniques to MyRocks. Finally, K9db’s dataflow graph operators sometimes store copies of a record; by using a record pool, our prototype’s memory footprint could be reduced.

## 8 Evaluation

We evaluate K9db with three applications, Lobsters [27], ownCloud [43], and Shuup [53]. We ask three questions:

1. What is K9db’s impact on end-to-end application performance? (§8.1)
2. What is the impact of K9db’s design features on performance? (§8.2)
3. What effort by application developers does using K9db require? (§8.3)

We run experiments on a Google Cloud n2-standard-16 VM, storing databases on a local SSD. Our baselines use MariaDB v10.6.5 (a MySQL fork) with the RocksDB-based MyRocks storage engine, and memcached v1.6.10.

### 8.1 Application Performance

We start by analyzing K9db’s performance with two applications: Lobsters and ownCloud.

#### 8.1.1 Lobsters

Lobsters ([lobste.rs](http://lobste.rs)) is an open-source discussion board, similar to Reddit. Lobsters currently lacks GDPR compliance [26], and has a schema that consists of 19 tables, which store posts, comments, nested replies, upvotes, invitations and other information. We annotated this schema for K9db with three DATA\_SUBJECT tables, 14 OWNED\_BY, one ACCESSES, and

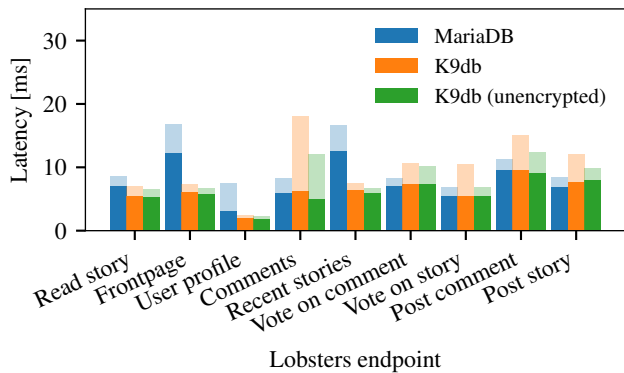

Figure 10: K9db matches or beats MariaDB’s median (solid) and 95<sup>th</sup> percentile (shaded) latency on the Lobsters workload, and encryption has low overheads except on the “Comments” endpoint, which reads thousands of rows in the tail.

two anonymization annotations (details in §8.3). We use an existing open-source, open-loop benchmark for Lobsters based on public workload statistics [19]. The benchmark models ten endpoints in the Lobsters webapp that correspond to different pages and each issue between six and fifteen SQL queries, most of which are reads. We load the database with data that models the current production Lobsters deployment (15k users, 100k stories, 313k comments, and 416k votes) [19]. K9db therefore maintains 15k logical  $\mu$ DBs in this experiment. We compare MariaDB, and K9db with and without data encryption. (Encryption with per-user keys isn’t possible in the MariaDB baseline.) Lobsters on most requests runs an expensive query to determine the user’s recently read stories. This query joins four tables, including the (large) stories and comments tables. This query is slow in MariaDB ( $\approx 30$ ms) and dominates its latency for all endpoints, while K9db serves this query from a materialized view. To make the comparison fair, we remove the expensive query in the MariaDB baseline. A good result for K9db would show latencies comparable to MariaDB for all endpoints, and a low overhead for encryption.

Figure 10 shows the results. Endpoints that mostly read (on the left) benefit from K9db’s materialized views and are up to  $2.1\times$  faster than in MariaDB, but endpoints with many writes (on the right) are comparable in both systems. This makes sense, as K9db performs similar work to MariaDB, except that some read queries are served from materialized views, and writes need to be encrypted and must update any corresponding views. K9db without encryption is on-par with K9db in most endpoints. For the “Comments” endpoint, K9db is  $2.1\times$  slower than MariaDB and  $1.5\times$  slower than K9db without encryption in the 95<sup>th</sup> percentile. This happens when the endpoint retrieves comments and votes on a popular story from the database, which requires K9db to decrypt thousands of records. Developers could manually add materialized views in K9db to speed up this endpoint, at the cost of additional memory. Other endpoints read fewer rows or rely on (unen-

Figure 11: K9db’s 95<sup>th</sup> percentile latency on the Lobsters workload remains stable as the number of users (and thus,  $\mu$ DBs) increases. Each bar shows a distribution of endpoint latencies.

rypted) materialized views. This shows that K9db achieves good performance for a practical web application, and that encryption has acceptable cost. All further experiments show results for K9db with encryption enabled.

We chose the load in this experiment to saturate the hardware for the MariaDB baseline ( $\approx 760$  pages/second, which results in 10k queries/second) and used the same load for K9db. K9db supports a up to a  $4.8\times$  higher load without latency degradation, thanks to its caching for complex queries via materialized views; we compare to a caching MariaDB+memcached baseline below.

**Subject Access Requests.** We now measure the time required by K9db to satisfy SARs. We issue an access and a deletion request for each of the top 1000 users with most data in the database, and run these requests sequentially through K9db SARs API. Performance of SARs is secondary as they are rare operations and can be executed asynchronously. A good result shows that K9db handles SARs correctly (which it does by construction) and within reasonable time. In our experiment, K9db on average takes 1 ms to retrieve and 45 ms to delete the correct data for a user.

**Scalability.** We designed K9db to have performance independent of the number of  $\mu$ DBs. We confirm this using the Lobsters benchmark with different numbers of users. Adding users increases the number of  $\mu$ DBs and the amount of data in the database, but keeps the average amount of data per user constant. A good result for K9db would show latencies remaining constant as the number of users grows.

Figure 11 shows the results as box-and-whisker plots over the nine endpoints (i.e., the bottom and top whiskers are the fastest and slowest endpoints, respectively). K9db’s latency remains constant as the number of users—and, consequently,  $\mu$ DBs—grows, because K9db satisfies queries either from  $\mu$ DBs directly, via indexes, or from materialized views. These results confirm that K9db’s logical  $\mu$ DB partitioning is practical for applications with large numbers of users.

**Comparison to Caching Baseline.** In the previous experiment, K9db had an unfair advantage over MariaDB: it serves some data from materialized views, while Mari-

Figure 12: K9db matches MariaDB+memcached on a common Lobsters query (solid: median; shaded: 95<sup>th</sup>-ile).

aDB recomputes queries every time. We now use one common query from Lobsters to compare three setups: (i) standalone MariaDB; (ii) MariaDB with an in-memory cache (“MariaDB+Memcached”); and (iii) K9db. The MariaDB+Memcached setup is a demand-filled cache [37]: writes invalidate the cached query result in memcached, and the next read re-runs the query against the database when it misses in memcached. In K9db, writes update views via its dataflow graph. We generate a skewed workload with a Zipfian distribution ( $s = 0.6$ ) where 95% of requests in the benchmark read the details of a random story and its vote count, and 5% of requests insert new votes. A good result for K9db would show competitive read performance with memcached and low overheads on write processing (since K9db does more work on writes); and MariaDB+Memcached and K9db would show lower latencies than MariaDB alone.

Our results are in Figure 12. For reads, MariaDB+Memcached and K9db are on par in the median, but K9db has a lower 95<sup>th</sup> percentile latency as K9db updates the cache via streaming dataflow, while MariaDB+Memcached queries the database on a read miss. All systems perform similarly on writes, as this query requires little dataflow update work in K9db and the caching baseline must make an extra RPC to invalidate memcached.

**Memory Overhead.** K9db’s materialized views and ownership indexes add memory overhead compared to a traditional database. We measure this cost and compare it to a caching setup with memcached. We consider a setup that caches query results that developers would typically store in memcached, such as the output of expensive joins and aggregates. These queries are identical to the ones that K9db caches using materialized views. The experiment caches query results with the query parameters (? in prepared statements) as the key, and the concatenated records as the value. K9db stores additional in-memory data for internal dataflow state and ownership indexes. A good result for K9db would therefore show moderate overheads compared to MariaDB+Memcached.

The Lobsters database is 61 MB on disk, and a typical memcached caching approach stores an additional 97 MB of in-memory state. K9db’s memory footprint is 197 MB ( $3.3 \times$  DB size, and  $2 \times$  memcached’s footprint), which includes

Figure 13: K9db matches the baseline setups’ performance on the ownCloud workload (solid: median; shaded 95<sup>th</sup>-ile).

6.5MB for the stories ownership index, and 56 MB for caching the expensive query we removed from MariaDB (without this query, K9db’s overhead is  $2.4 \times$  DB size/ $1.5 \times$  memcached). The overhead comes from K9db’s dataflow state, which allows K9db to incrementally update materialized views.

### 8.1.2 ownCloud

ownCloud is a popular open-source application that allows users to upload files and share them with other users [43]. Recall ownCloud’s schema (Figure 5): each file has a single owner—the original uploader—but users can share files with other users and with groups. Files shared with a group are accessible to all members of the group—i.e., a many-to-many relationship between users and files (a pattern absent in Lobsters). We measure five common queries: (i) listing the files a user can access (“view files”); (ii) sharing a file with another user (“share with user”); (iii) sharing a file with a group (“share with group”); (iv) retrieving a file using its primary key (“Get”); and (v) updating the retrieved file (“Update”). Our setup uses 100k users who each own three documents; each document is shared uniformly at random with three users and two groups; and each group has five members. Our workload is 95% read and 5% writes, equally split among the two types of sharing and file updates. Reads and writes target users drawn from a Zipf distribution ( $s = 0.6$ ). We batch ten reads and measure the per-request latency for the same setups as in the previous experiment. A good result for K9db would show comparable read latency to MariaDB+Memcached and low overheads on writes.

Figure 13 shows the results. “View files”, which returns all files shared with a user (directly or via a group), involves five tables and three joins, which MariaDB executes on every read. MariaDB+Memcached and K9db serve precomputed results from memory instead, which is fast. The 95<sup>th</sup> percentile for MariaDB+Memcached suffers because it queries MariaDB on a cache miss, which occurs when a query retrieves files of user(s) invalidated by a previous write. K9db is fast and stable because it updates the views via dataflow on writes. All systems perform similarly for the two share queries—a good result for K9db, as it also updates views.

Figure 14: K9db matches the baseline setups’ performance on the ownCloud workload (solid: median; shaded 95<sup>th</sup>-ile).

## 8.2 K9db Design Drill-Down

To evaluate the impact of design decisions central to K9db, we run ownCloud workload from the previous experiment against versions of K9db that disable key components. We start with K9db set up to naïvely store every  $\mu$ DB in its own database (without cross- $\mu$ DB indexes); without support for accessor edges in the DOG; and without materialized views (i.e., queries always run over data in RocksDB). This guarantees strict separation of user’s data, a solution sometimes adopted for GDPR compliance in practice [46, 47], although this lacks support for shared data (accessors) or anonymization. We then add separation into logical  $\mu$ DBs (“+ Logical  $\mu$ DBs”), accessor support (“+ Accessors”), and materialized views (“+ Views”). A good result would show that these features improve K9db’s performance.

Figure 14 shows the results. The naïve  $\mu$ DB design is very slow because every query that K9db cannot statically resolve to the affected  $\mu$ DBs requires scanning all  $\mu$ DBs; we only ran this setup with 1k users (vs. 100k for the others). Making  $\mu$ DBs a logical abstraction much improves performance, justifying our design choice. Accessor-typed DOG edges are important for expressivity: without them, ownCloud would be restricted to a policy where users jointly own shared files. In addition, accessor support reduces the number of copies stored and the fan-out of writes, which slightly reduces query latency. Finally, materialized views improve latency of the “View files” query by 5 $\times$ , as the results are cached in memory. Since the view update is cheap, writes do not suffer much overhead. The runtime of “View files” without no views is comparable to the runtime of the same query in MariaDB (Figure 13). This illustrates that views are beneficial, but not essential to good performance in K9db.

## 8.3 Schema Annotation Effort

To understand the developer effort K9db’s schema annotations require, we now consider annotations for three applications (Lobsters, ownCloud, and Shuup [53]) in detail,

**Lobsters.** The Lobsters schema contains 19 tables. To use K9db, we had to annotate the schemas for eight tables. Three tables (users, invitations, and

invitation\_requests) contain data subjects. We annotated two FKs in each of hats, messages, and moderations with OWNED\_BY to model joint ownership. We annotated 8 other tables with a single OWNED\_BY. For example, votes has multiple foreign keys that lead to the users table (one direct, two indirect), and thus requires a single OWNED\_BY annotation to disambiguate and ensure votes are stored with the voter, rather than the author of the story or comment voted on. Finally, we used one ACCESSES in taggings, and two anonymization rules in messages, as shown in Figure 4.

**ownCloud.** ownCloud’s schema has 51 tables. We focused on the file sharing core, which consists of six tables and has the most complex relationships. In addition to the annotations in Figure 5, we added an OWNS annotation to the FK in the share table that points to the corresponding file in the file table (omitted from Figure 5 for brevity).

ownCloud’s original schema “overloads” the share\_with column to either hold a user or a group ID, and includes a share\_type column to distinguish these cases. K9db could support such de-normalized schema with more advanced conditional annotations; for our benchmarks, we modified the schema to track users and groups in separate columns.

**Shuup.** Shuup [53] is an open source e-commerce platform and supports customers with accounts, guests who do not have accounts, and shop owners, all of whom have GDPR rights. The Shuup code lets users request their account to be anonymized, but retains information for tax compliance, e.g., payment data, customers’ countries of residence, and tax ID numbers, a form of data retention provided for in the GDPR.

Shuup provides GDPR compliance via a manually-implemented module with 4k lines of Python code (2.7k lines of implementation and 1.3k lines of tests), developed in 137 commits over three years. At the time of writing, Shuup’s anonymization behavior is inconsistent; it only anonymizes default shipping and billing addresses, but retains previous addresses in cleartext in the mutable\_address table [55]. Moreover, downloading data for a user is not supported [54].

We implemented Shuup’s anonymization policy in K9db using all annotations (Figure 3) over 17 of Shuup’s 278 tables. We annotate personcontact with DATA\_SUBJECT. This table stores natural persons, and has FKs to their contact information (in contact) and their logins (in auth\_user) if they have accounts. Thus, personcontact contains users with and without accounts, i.e., guests. Using K9db, Shuup correctly anonymizes data, lets users download the data and fixes the bug of not anonymizing previous default addresses.

Shuup’s schema has several tables that might correspond to data subjects. K9db’s EXPLAIN COMPLIANCE helps developers understand that they need to annotate personcontact. An in-compliant (but plausible) alternative would be to annotate auth\_user, the login details table. This results in contact being unconnected to the DOG, as there are no foreign keys to auth\_user. The personcontact table has such a foreign key, but it is nullable (e.g., for guests who lack

Application	Tables	Data Subject	Owner	Access	Anon
Commento [12]	12	3	8	1	3
ghChat [1]	6	1	7	2	4
HotCRP [22]	26	2	15	10	7
Instagram clone [50]	19	1	18	1	0
Mouthful [25]	3	1	1	0	0
Schnack [48]	5	1	1	0	0
Socify [34]	19	1	10	0	0

Figure 15: K9db requires few DATA\_SUBJECT, ownership (OWNED\_BY and OWNS), access (ACCESSED\_BY, ACCESSES), and ANON annotations to support real web applications.

accounts), and thus some of its rows will be stored in  $\mu$ DBs and others in the orphaned region. EXPLAIN COMPLIANCE helps developers identify and rectify these issues:

- 
- ```

1 Table "contact": GLOBAL
2 [Compliance Warning] Column "email" suggests personal
  data, but the table is not connected to any owners.
3 Table "personcontact": in  $\mu$ DB for auth_user.id
4 [Compliance Warning] Table has owners, but nullable
  foreign key may prevent correct deletion of data.

```
- 

A developer might also annotate `contact` with DATA\_SUBJECT, but that table includes entries for customers and companies. Annotating it makes companies into data subjects, which duplicates company-related tables across  $\mu$ DBs. EXPLAIN COMPLIANCE also alerts developers to this.

**Other Applications.** Our schema annotations were sufficient to express reasonable compliance policies for seven additional applications (Figure 15). We briefly highlight several interesting patterns in these applications.

In `ghChat` [1], a chat application for GitHub, and the `Instagram clone` [50], a group is owned exclusively by its admin and accessed by its members. This is unlike `ownCloud`, which lacks group admins and has members jointly own the group.

`Mouthful` [25] is a commenting service that embeds in a host application (e.g., a blog) to allow users to comment on the host content (e.g., a blog post). `Mouthful` has no notion of users; instead, the host application provides a string that represents the user identity alongside the comment they posted. We added a DATA\_SUBJECT table to store user identifiers, and created a FK constraint from the `Comment` table’s `author` column to it.

Finally, the `HotCRP` [22] review system associates data subjects to papers via a many-to-many `PaperConflict` table. The table has a `conflictType` column that specifies the relationship, such as “co-author” or “institutional conflict”. While this schema is normalized in the traditional SQL sense, it is not normalized for ownership: rows with the co-author type signify ownership, while other conflict types do not imply any ownership or access rights over the paper. We resolved

this by adding a new `PaperAuthors` table that only stores authorship associations, and refer to papers from it using `OWNS`. We reserve the existing `PaperConflict` to record other conflict types with an un-annotated reference to papers.

**Migrating Applications to K9db.** We identify some common challenges when migrating applications to K9db. First, annotating an application schema requires knowledge of the application functionality and its compliance policy, but also summarizes the policy in an easy-to-maintain way alongside the schema. Many web applications also lack explicit FK constraints in their schema; developers must identify the columns that act as implicit FKs and annotate them if needed.

Second, applications often have schemas that are not normalized in the traditional SQL sense (e.g., `ownCloud`’s `share_with`) or with regards to ownership (e.g., `HotCRP`’s `PaperConflict`). Developers must normalize these schemas by introducing new columns or tables, and apply the corresponding changes to the application code. K9db could support such schemas via new annotations that condition on other columns, but this would complicate the annotation language and DOG model. Instead, K9db guides developers to good, normalized schema designs.

Finally, applications with variable ownership (e.g., `ownCloud`, `Shuup`, `HotCRP`) often have endpoints that temporarily orphan data. Developers must wrap such endpoints in compliance transactions in order to use K9db. This modification is relatively unobtrusive, and K9db can be configured to automatically wrap sessions in a CTX. This alleviates the need to manually introduce CTX to applications that open new sessions for each endpoint or sequence of operations, but is not suitable for applications with long-lived sessions.

## 9 Conclusion

K9db is a new database system that achieves compliance with the requirements of privacy laws by construction.

K9db models data ownership to capture the ownership patterns of real world applications, and handles requests for access and deletion correctly. K9db matches or exceeds the performance of a widely-used database and manual caching setup, and supports the privacy requirements of real-world applications. K9db is open-source and available at <https://github.com/brownsys/K9db>.

## Acknowledgements

We are grateful to Deniz Altınbüken, Hannah Gross, Frans Kaashoek, Franco Solleza, Lillian Tsai, and the ETOS group at Brown for helpful feedback on drafts of this paper. Feedback from the anonymous reviewers and our shepherd, Nat-acha Crooks, greatly improved the paper. We also thank Vedant Gupta, Mithi Jethwa, and Colton Rusch for contributions to K9db’s implementation.

## A Artifact Appendix

### Abstract

Our open source artifact contains our prototype implementation of K9db. It also includes the harnesses and scripts for running and plotting the experiments described in this paper.

Our prototype provides a MySQL-compatible interface layer, which applications and developers can use to issue SQL statements and queries to and retrieve their results. Our prototype is compatible with the standard MySQL connectors and drivers for several languages, including C++, Rust, and Java. It is also compatible with the command line MySQL and MariaDB clients.

## Scope

Our prototype serves as a demonstration of the following:

1. The application scenarios described in the paper work with K9db and its schema annotations.
2. K9db's system design and guarantees can be realized with a familiar MySQL-compatible interface suitable for web applications.
3. The performance of compliant-by-construction databases is comparable to traditional databases, such as MariaDB.

## Contents

**K9db.** The artifact includes our prototype implementation and its MySQL-compatibility layer. The artifact contains instructions for building, running, and using this K9db.

**Application Harnesses.** The artifact includes harnesses for Lobsters, a Reddit-like discussion board (§8.1.1), and own-Cloud (§8.1.2), a file sharing application. The harnesses create the database schema and load the database with data; they also execute loads with representative queries, and measure the time required to process them. We used these harnesses to evaluate our prototype and the baselines shown in our experiments. The Lobsters harness is a pre-existing open source harness that we adapted to work with our prototype [38].

**Documentation.** The artifact wiki on GitHub contains a tutorial on using K9db and its schema annotations. The artifact also includes unit and end-to-end tests that validate that our prototype handles application SQL operations correctly and provides correct compliance with SARs.

## Hosting

Our artifact is hosted on GitHub at <https://github.com/brownsys/K9db>. The version of the repository corresponding to this paper is available at <https://github.com/brownsys/K9db/releases/tag/osdi2023>, with commit hash *df2bcdffa05f70f508fad95a11e2a6de8a7efe14*. The corresponding wiki commit hash is *c720b085ca34edc16246f296991e623a29933f9b*.

## Requirements

We developed our prototype on x86-64 machines running Ubuntu 20.04 and 22.04. We provide a Docker container that includes the necessary software dependencies. We ran our experiments on Google Cloud using `n2-standard-16` machines with a local SSD.

# Encrypted Databases Made Secure Yet Maintainable

## Abstract

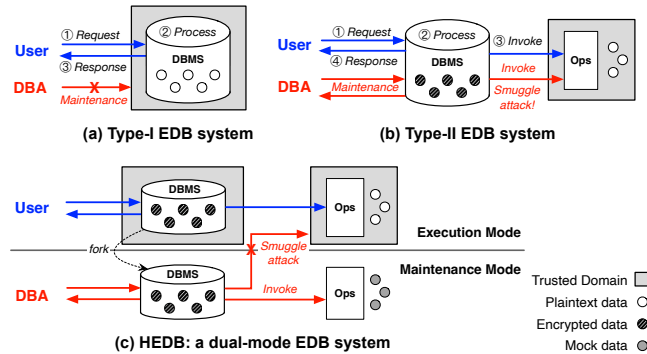

State-of-the-art encrypted databases (EDBs) can be divided into two types: one that protects the whole DBMS engine in a trusted domain, and one that protects only operators that support queries over encrypted data. Both types have limitations when dealing with malicious database administrators (DBAs). The first type either exposes the data to DBAs or makes maintenance operations difficult if the DBA role is eliminated. The second type is vulnerable to abuse of the operator interfaces; in particular, we devise a smuggle attack that enables DBAs to secretly and effectively access data.

We introduce HEDB, which prevents smuggle attacks and preserves database maintainability. HEDB uses a dual-mode EDB design based on our analysis of DBA maintenance tasks. Execution Mode handles user queries by isolating DBAs from operators to prevent smuggle attacks, while Maintenance Mode enables DBMS maintenance and operator troubleshooting through *authenticated replay* and *anonymized replay*, respectively. Our evaluation shows that HEDB blocks smuggle attacks and supports common maintenance tasks with 5.88% runtime cost and 9.26% storage cost.

## 1 Introduction

With approximately 60 ZB of data stored in database systems [6], much of which is sensitive, data breaches pose one of the most serious security threats today, causing an average loss of \$4.35 million per incident [4]. To protect against external attacks, database security features such as role-based access control and encryption at rest have become *de facto* standards. However, these features are not effective at preventing attacks from malicious insiders, who create new internal threats. This is especially true for Database as a Service (DBaaS) scenarios, where cloud platform operators and database administrators (DBA) have full access to the database engine and customer data. To address this threat, several encrypted database (EDB) systems have been proposed by academia [15, 17, 26, 42, 44, 48] and industry [14, 30, 50].

Despite a broad spectrum of prior efforts [14, 15, 17, 26, 30, 42, 44, 48, 50], EDB systems with (i) full-SQL functionality, (ii) maintainability and (iii) strong security have remained an unsolved problem for the past decade. State-of-the-art EDB systems can be largely categorized into two types: (1)

**Figure 1:** Existing EDB systems can be categorized into two types: Type-I lacks maintenance and Type-II lacks interface security. HEDB leverages a dual-mode design to support both.

a monolithic EDB design that isolates the whole database engine in a trusted domain, and (2) a plug-and-play EDB design that leverages protected operators to process user secrets. We name them Type-I and Type-II for brief, as depicted in Figure 1. Both types reuse existing database engines, inheriting (almost) all features of modern databases such as SQL execution and ACID transactions.

For Type-I EDBs [17, 44, 45], a system operator or DBA can only monitor an end-to-end secure channel between an isolated database engine and a remote user. However, the conventional role of DBAs conflicts with customer privacy. Consider a maintenance task that DBAs help to diagnose a database misconfiguration bug [40]. After curious DBAs log into the database server, they can read whatever user data of interest because of their high privilege. Notably, eliminating the role of DBAs from the database engine requires non-trivial engineering efforts. Furthermore, excluding DBAs will give up the benefits of their expertise in managing, optimizing and diagnosing the outsourced databases.

Type-II EDBs [14, 15, 30, 42, 43, 48, 50] typically use database extensions to enable various primitive operators over encrypted data. Operators include arithmetics, comparisons, string searching, etc. The primary advantage of Type-II is that operators have a small trusted computing base (TCB) compared to Type-I. Furthermore, the low complexity of the operator’s codebase also makes it easy to develop and simple to vet. Most importantly, Type-II surpasses Type-I in terms of

maintainability, as DBAs can connect to the database server, examine query plans, attach powerful profilers and debuggers, and collect crash dumps without concerns of data breaches, since user data is always encrypted. Type-II EDBs are therefore well adopted by cloud database vendors [14, 30, 50]. Regarding data privacy, Type-II leaks information such as ordering and frequency, which may compromise sensitive columns with the aid of sophisticated background knowledge [27–29, 32, 39].

Even worse, under existing database access control, an adversarial DBA can arbitrarily invoke Type-II EDB’s operator interfaces. As Type-II exposes various operators, DBAs can exploit a sequence of carefully constructed invocations to recover the victim’s sensitive data [16]. We devise an efficient and stealthy attack, named *smuggle attacks*, which applies to all basic encrypted types (i.e., numerics, time, text) and can recover 100% data items of 35,243 health records within 2 minutes with no prior knowledge. Conceptually, smuggle attacks is similar to Iago attack [21], as both abuse interfaces. But unlike Iago, defending smuggle attacks is more challenging because it does not tamper with the correctness of invocation results. Hence, we opt for a new approach to defeating smuggle attacks, while retaining Type-II’s advantages of DBA maintainability.

**Our proposal: HEDB<sup>1</sup>.** HEDB is a new EDB design that can provide interface security (namely, smuggle attacks-resilient) and maintainability. HEDB’s design is based on two insights: (a) without authenticated access, interface security cannot be achieved, and (b) in most cases, accessing plaintext secret data is not essential to EDB maintenance. Hence HEDB introduces two modes: *Execution Mode* where operators authenticate valid requests for user queries (defending against smuggle attacks), and *Maintenance Mode* where mock data is used during DBA maintenance (minimizing privacy leakages). In Execution Mode, HEDB adopts Type-II’s design by decoupling the DBMS and operators, and protects them using two trusted domains with an authenticated channel. When switching to Maintenance Mode, HEDB forks a new DBMS instance from the protected DBMS to an unprotected domain, and feeds operators (also in the unprotected domain) with mock data. Figure 1 overviews this process.

This dual-mode EDB design is non-trivial and has several technical challenges. First, switching EDB components between modes requires execution environment reconstruction for maintenance purposes. Second, too accurate maintenance may help DBAs infer secret data easily, while simply using fake data hinders maintenance. Third, after maintenance, there should be a secure way to apply hotfixes to the protected DBMS instance, without invoking any new attack surfaces.

To overcome the above challenges, HEDB introduces several key techniques. To allow DBAs to inspect the stateful DBMS, HEDB employs DBMS-located VM fork across two

hypervisors using existing hardware (i.e., ARMv8.4 S-EL2). For execution environment reconstruction, HEDB relies on record-and-replay. HEDB records the operator invocation trace in Execution Mode, and proposes *authenticated replay* to reproduce DBMS issues in Maintenance Mode. To preserve buggy control flows and protect user data privacy at the same time, HEDB proposes *anonymized replay*, which employs concolic execution to capture path constraints, translates data masking rules also into constraints, and exploits constraint solving for operator troubleshooting in Maintenance Mode. Finally, HEDB uses *maintenance templates* to securely apply hotfixes in Execution Mode. HEDB accomplishes these features with low implementation complexity (~2K lines of C and Python code). HEDB’s record incurs 5.88% runtime overhead; replay supports fixing configuration bugs, reproducing functional bugs, and debugging most performance bugs. Our optimizations speed up HEDB’s TPC-H execution by 2.49×, and improve HEDB’s constraint solving-based log anonymization by up to two orders of magnitude.

**Contributions.** We highlight the following contributions:

- A study of existing EDB systems and the introduction of smuggle attacks for Type-II EDBs.
- A dual-mode EDB design, based on empirical studies of typical maintenance issues and DBA operation tasks.
- A new system called HEDB, which prevents smuggle attacks while allowing DBAs to maintain EDB with reasonable overhead.

While HEDB provides, for the first time, interface security and maintainability for existing Type-II EDB systems, it does have some limitations. HEDB’s current implementation does not support non-deterministic bug reproduction (e.g., concurrent transactional writes such as in TPC-C, though TPC-C is not vulnerable to smuggle attacks). In addition, HEDB does not cover all DBA tasks (e.g., arbitrary query rewriting) and may not reproduce all bugs (when using strict masking rules). Nonetheless, HEDB fills a critical gap in encrypted databases.

## 2 Background and Motivation

### 2.1 Database as a Service (DBaaS)

In “Database as a Service” (DBaaS) [31], service providers take care of the installation, update, backup, and maintenance of databases. DBaaS provides managed databases with a transparent software stack and infrastructure. This design releases users from the duty of database administration, which is complex, time-consuming, and requires deep expertise. In DBaaS, these maintenance tasks are delegated to database administrators (DBAs). In brief, DBaaS empowers users to focus on their core business.

### 2.2 Encrypted Database (EDB)

Data privacy is a major concern of adopting DBaaS. Service providers might not be fully trustworthy [4]; even if they

<sup>1</sup>HEDB is named after He (Helium), the 2nd element, implying its two modes.

**Table 1:** Survey of existing EDB systems. *F*: Functionality; *S*: Security; *M*: Maintainability.

are, curious staff may leak private information. For instance, Swiss bank DBAs were reported to have sold customer information [12]. This is why an encrypted database (EDB) comes into place; an EDB executes queries over fully encrypted data.

Ideally, an EDB system should provide a compatible set of traditional DBMS features (e.g., transactions, recovery) and most importantly, support all common SQL queries on the encrypted data. For example, users can perform equality checks to the highly sensitive personally identifiable information (PII) such as names and credit card numbers. As another example, users should be able to apply arithmetic operations and range predicates on the encrypted financial data (e.g., billings) and healthcare records (e.g., heart rates) to calculate the maximum expense or to compute the average heart rates.

Both academia [15, 17, 26, 42–44, 48] and industry [14, 30, 50] have shown great interest in EDB systems. We surveyed state-of-the-art EDBs as listed in Table 1, and classified them into two categories: (1) a monolithic EDB design, and (2) a plug-and-play EDB design. For simplicity, we name them Type-I and Type-II, respectively.

### 2.3 Type-I EDB: Putting a Database in TEE

**Overview.** Trusted execution environments (TEE) are a hardware-assisted approach that offers the essential abilities of secure isolation, memory encryption and remote attestation. They are widely available on commercialized processors (e.g., AMD SEV [13], Intel SGX [11] and TDX [9], ARM S-EL2 [35] and CCA [36]) or implemented using a secure co-processor or FPGA. The monolithic EDB design places an existing DBMS engine into TEE to protect user data and queries. User secrets are encrypted outside TEE and remain plaintext inside the trusted database. This design brings a large trusted computing base (TCB); an operating system or library OS must be ported into the TEE [17, 44, 45].

**Workflow.** A user queries the Type-I EDB as follows: ❶ The client-side user or the DB-backed application issues a SQL query to DBMS through a secure channel. ❷ DBMS parses the query, generates a plan, optimizes it and executes the plan, by reading the encrypted tables from the untrusted storage, and writing the updated tables after encryption. ❸

DBMS returns the query result through the secure channel.

**Implications.** In Type-I EDB systems, the data privacy and database implementations are tightly coupled, which raises several issues. First, simply putting a database into TEE does not make the database immune to rogue DBAs. For today’s DBMSes, DBAs have unlimited access to users’ data, including secret data in the TEE. To ensure privacy, Type-I EDBs must either modify DBMS engines or disable the role of DBAs. However, refactoring the DBMS codebase to preclude the existence of DBAs and their privileges may require significant engineering efforts. Even if a DBMS eliminates DBAs, it would give up maintainability—this DBMS loses the major benefit of DBaaS that experts (i.e., DBAs) manage, optimize, and diagnose users’ outsourced databases. People might not use DBaaS in the first place.

### 2.4 Type-II EDB: Putting an Operator in TEE

**Overview.** The plug-and-play EDBs are another type of EDB. They leverage customizable extensions of modern database systems (e.g., PostgreSQL, MySQL) to encrypt data on-the-fly. The extension is written as a database plugin (normally in the form of a user-defined function or UDF). To implement Type-II EDBs, developers typically create and register new data types—encrypted data types—into the database. When the database execution engine processes encrypted data types, it invokes the UDF-based operators that are responsible for handling encrypted data operations.

There are two ways to implement Type-II EDBs. For one, developers implement different cryptographic schemes in operators to compute directly on the encrypted data [42, 43, 47]. We call them crypto-based Type-II EDBs. For the other, developers implement operators in TEEs. We call these TEE-based Type-II EDBs [14, 15, 30, 48, 50]. TEE-based EDBs rely on hardware modules to provide integrity and confidentiality, and data are decrypted only when they are within TEEs. Crypto-based Type-II EDBs fall short in functionalities (e.g., floating-point arithmetics and text concatenation); they must either rely on a trusted proxy [42, 43] or move the unsupported computation to the client [47]. In this paper, we focus on the TEE-based Type-II EDBs that have full-SQL supports and are preferred in production [14, 30, 50].

**Workflow.** A user queries the Type-II EDB as follows: ❶ The client-side user or the DB-backed application sends a SQL query whose sensitive constants are encrypted. ❷ DBMS parses the query, and reads the encrypted data from storage. The DBMS engine generates, optimizes, and executes an execution plan. Upon each computation of the encrypted data type, DBMS prepares a tuple,  $\langle \text{ciphertext}_1, \text{ciphertext}_2, \dots \rangle$ , and feeds it to the operator. ❸ The operator receives the tuple, decrypts the ciphertexts, performs the operation, encrypts the result (except when returning plaintext boolean values, e.g., comparisons), sends the result to DBMS, and waits for the next invocation. ❹ The DBMS

engine finishes the entire query execution by returning the (encrypted) result to the client.

**Advantages.** In comparison with Type-I EDBs, the Type-II EDBs have the following advantages.

- *Small TCB:* Compared with putting a full-fledged DBMS in TEE, Type-II EDBs run only operators in TEE which is a tiny fraction of the entire DBMS.
- *Development friendly:* The Type-II EDBs leverage DBMS extension systems and require no modifications to DBMS engines. The low complexity of operators also makes upgrades simple and easy.
- *Maintenance friendly:* The DBMS engine does not touch plaintext data, so it is accessible to DBAs. DBAs can perform maintenance operations such as examining query plans for performance, collecting crash core dumps for troubleshooting, or even attaching a debugger to inspect the execution of a SQL query.

These advantages make Type-II EDB preferable to cloud vendors such as Azure [14], Huawei [30] and Alibaba [50].

**Implications.** Compared to Type-I, Type-II EDBs however expose a larger attack surface. First, unlike Type-I, Type-II does not protect the integrity of query execution as it relies on an unprotected DBMS engine. Second, the data-level computation allows an honest-but-curious DBA to learn the data volume, distribution, frequency, ordering, and correlations between columns. With prior knowledge, an adversary may be able to infer secret data [27–29, 32, 39]. Finally, if a malicious DBA can issue arbitrary operator invocations, they can conduct a full database breach. We call it *smuggle attack*.

## 2.5 Smuggle Attack

This section describes how a DBA can mount a smuggle attack to recover encrypted data types and real-world datasets. We emphasize that the smuggle attack requires no background knowledge, and its recovery is deterministic.

**Attack overview.** We use a minimal working example that recovers encrypted integers in a Type-II EDB.

- *Constructing basic ciphers:* By division ( $\div$ ), a DBA can obtain the ciphertext of ‘1’ (dividing a number by itself). With the basic ciphers of ‘1’, in principle, the DBA can construct all encrypted integers by iteratively asking operators to add (+) the cipher ‘1’ to a counter.
- *Recovering user secrets:* With the equality operator ( $=$ ), the DBA can recover the victim’s encrypted values by observing the plaintext boolean values by comparing them with known ciphertexts. To recover an encrypted integer  $x$ , the DBA can use a binary search to compare  $x$  with some candidate known ciphertexts (using  $<$ ,  $>$ , and  $=$ ).

Other encrypted types (e.g., decimal, text, and time) can also be attacked (see § A.1). Extending their data domain to a larger range (e.g., 64-bit) does not prevent the attack because binary search is efficient to search on even a 64-bit range.

| System | Example    | API numbers      | Interface attack |
|--------|------------|------------------|------------------|
| Kernel | Linux      | 200+ POSIX APIs  | Iago attack      |
| DBMS   | PostgreSQL | 79 operator APIs | Smuggle attack   |

**Table 2:** *The analogy between Iago [21] and smuggle attacks.*

Removing operators used by smuggle attacks will disable OLAP workloads because these workloads (e.g., TPC-H) require all the mentioned operations (e.g.,  $\div$ ,  $+$ ,  $>$ ,  $=$ ).

**Attacking real-world datasets.** We illustrate smuggle attacks against a real-world dataset, SPARCS<sup>2</sup>, with 2.54 million records [8]. We use an open-source Type-II EDB, StealthDB [48] (commit 1ca645a), which exposes operators such as arithmetics, comparisons, mathematics, aggregations ( $+$ ,  $-$ ,  $*$ ,  $/$ ,  $\%$ ,  $<$ ,  $=$ , `power()`, `MAX`, `AVG`, `SUM`). Only comparison operators return boolean values in plaintext; others return the computation results in ciphertext.

We first select 6 columns of SPARCS patients’ sensitive information from 239 hospitals in 9 areas, and protect these columns using StealthDB with the AES-128-GCM encryption. We then log into StealthDB using a DBA account and can call operators with crafted parameters, but cannot see the internals of operators (i.e., cannot see decrypted user data). Lastly, we issue binary-search SQL queries to conduct smuggle attacks; these queries do not return to users nor impact their queries’ results. In the end, smuggle attacks recover 100% ciphertexts in 92 seconds without any prior knowledge.

**Defending smuggle attacks is challenging.** We argue that smuggle attacks are hard to defend by today’s EDB designs. This is because smuggle attacks are an interface attack that targets the exposed operator interfaces, rather than any particular implementations. We have seen interface attacks before, for example, Iago attack [21] that targets OS interfaces (i.e., system calls). We summarize the two attacks in Table 2.

In fact, defending smuggle attacks is even harder than preventing Iago attack because Iago attack can be identified by checking if a syscall follows its specification. For example, the return value of `sbrk()` must not fall into any range of the allocated memory areas; otherwise, there is a data corruption (and this is likely an Iago attack). Unlike Iago attack that is conducted by few syscalls (usually just one syscall), smuggle attacks require a series of invocations. Neither operators nor users can resist smuggle attacks because (1) operators within TEEs cannot distinguish user’s invocations from others (e.g., malicious DBAs); (2) invocations issued by smuggle attacks do not alter the correctness of user queries, and hence users cannot realize that a smuggle attacks is happening.

**Attack summary.** The core principle behind smuggle attacks is not new, as it has been established that any column that enables both computation and comparison operations could be vulnerable (as noted on page 6, “Write query ex-

<sup>2</sup>The dataset we use does not contain protected health information (PHI) under Health Insurance Portability and Accountability Act (HIPAA); all data elements considered individually identifiable have been redacted.

ecution” in [43]). However, we are the first to successfully apply this principle to a real-world EDB system. Prior EDB attacks have identified several types of leakage attacks, such as Count Attack [19], Non-Crossing Attack [29], Access Pattern Attack [32], and Frequency Analysis [39], which are also applicable to both Type-I and Type-II EDBs. What sets smuggle attacks apart is that it requires zero prior knowledge, making it even more potent than previous leakage attacks. Additionally, smuggle attacks are not exclusive to DBAs, as anyone who can access operator interfaces can carry out smuggle attacks. For instance, an attacker who knows a victim’s password but not the encryption key could not decrypt the victim’s data, but they could bypass access control with the password and then use smuggle attacks to breach the data.

We have studied Type-I and Type-II EDB system designs, where there is tension between (a) database maintenance and (b) interface security. In short, Type-I is immune to (b) but lacks (a), while Type-II provides (a) but suffers from (b). However, both (a) and (b) are essential for EDBs; we need both. This motivates our system, HEDB.

### 3 HEDB Design

We first introduce our design goals and present a new EDB architecture that HEDB uses. We then describe our threat model and how HEDB works.

**Design Goals.** HEDB has three goals.

- *G1: smuggle attack resilience.* HEDB must protect user’s sensitive data from smuggle attacks (§ 2.5) which Type-II EDBs [14, 30, 50] suffer from.
- *G2: database maintainability.* A DBA should be able to configure, manage, diagnose, and troubleshoot the HEDB as a traditional DBMS.
- *G3: backward compatibility.* HEDB aims to be compatible with the existing database ecosystems. We do not expect to reimplement HEDB in new frameworks (e.g., verifiable computation [51] or secure multi-party computation [41]) which invalidates existing DBMS tools.

**HEDB architecture.** HEDB uses a new three-zone architecture (depicted in Figure 2) because we observe that different roles—DBAs, DBaaS providers, and database users—have different duties and requirements. (1) DBAs are responsible for managing resources and performing maintenance tasks, and they want to do these jobs in a low-drama way. (2) DBaaS providers are supposed to deploy DBMS as services, and they want their services running correctly. (3) Users are the data owners whose secret data is stored in the database. They want the database to be easy to use (e.g., maintained by DBAs), and meanwhile, users need their data stored securely (i.e., having data integrity and confidentiality).

These observations inspire HEDB’s architecture: unlike prior EDBs [17, 44], HEDB *decouples integrity from privacy*. In particular, HEDB’s architecture detangles DBAs’ mainte-

Figure 2: HEDB’s high-level architecture.

nance jobs from users’ data confidentiality requirements by using three zones: *integrity zone*, *privacy zone*, and *management zone*. The integrity zone provides execution integrity but not confidentiality; it runs the DBMS engine. The privacy zone guarantees data confidentiality; it runs operators and is the only place containing users’ plaintext data. The management zone allows DBAs to troubleshoot both DBMS engine and operators. This design brings the opportunity to serve both interface security (*G1*) and maintainability (*G2*).

**Threat model and security guarantees.** HEDB assumes TEE hardware works as expected; that is, hardware isolation and security guarantees are reliable and trustworthy. Further, HEDB assumes remote attestation for authentication. HEDB uses remote attestation to confirm the integrity of the EDB executables. We also assume that database users and DBaaS providers agree on the EDB code and configurations.

In HEDB’s threat model, DBaaS providers are not trusted, as they could access server-side states over the network, on disk, or in memory that are not protected by TEE. They may also tamper with the database logs and data, and drop network connections to the EDB systems. These attacks can be detected by HEDB. Likewise, cloud administrators (who manage the cloud’s physical resources) and database administrators (DBAs) are not trusted either and can behave arbitrarily, including conducting smuggle attacks. Conversely, HEDB assumes that users will not intentionally attack themselves or leak their own data. However, co-tenant users may pose potential threats and they can be blocked using the DB’s access control. Finally, the developers of HEDB are trusted, but the source code must be verified. Thanks to the small pieces of code in Type-II operators, HEDB is made easy to verify.

As security guarantees, HEDB ensures no plaintext data outside TEEs, the same as Type-I and Type-II EDBs. In addition, HEDB is smuggle attacks resilient. In terms of metadata privacy (e.g., frequency, ordering), HEDB provides the same security guarantees as Type-II EDBs. Both HEDB and Type-II EDBs may leak metadata [27]. Nonetheless, this is a fundamental trade-off between functionality and privacy because revealing these metadata is sometimes necessary for core database functionalities, for example, database indexing. Production systems have made the trade-off by choosing Type-II EDBs as the de facto method [14, 30, 50]. Finally, similar to

both Type-I and Type-II EDBs, HEDB does not prevent exploitations of DBMS bugs or vulnerabilities (e.g., code-reuse attacks), which is an orthogonal line of security problems.

### 3.1 HEDB Workflow

HEDB provides two modes: *Execution Mode* and *Maintenance Mode*. Execution Mode is when HEDB normally runs. HEDB serves user queries by running the DBMS engine in the integrity zone and executing operators in the privacy zone. When performing maintenance, DBAs switch HEDB to Maintenance Mode, in which operators stop responding to new requests and DBMS is forked to the management zone. Management zone enables DBAs to inspect the internal states of the DBMS engine. After locating issues and suggesting solutions, DBAs switch HEDB back to Execution Mode and resume the service.

**Normal execution.** To launch a HEDB instance, a hypervisor starts a virtual machine (VM) in the integrity zone, and runs a DBMS instance in the VM. The hypervisor calculates the digest of the VM and ensures its integrity. Meanwhile, the hypervisor initializes operators that run in the privacy zone.

After HEDB's initialization, a user can remotely attest both HEDB's VMs (containing DBMS and operators). Then, the user establishes a secure channel with the DBMS instance and starts sending queries. Note that the query constants are encrypted. For example, in a query `SELECT . . . WHERE year < 2022`, the number 2022 will be encrypted. This is a must because the integrity zone does not provide confidentiality.

In Execution Mode, DBAs are isolated from the HEDB. DBAs cannot log into the database VM or access operator interfaces hence cannot start attacks. HEDB achieves this by disabling the logins for VM superusers and DBA accounts when booting. Users can verify this by checking the booting script and attesting that the script is the one that runs.

To monitor resources while HEDB is running in Execution Mode, VM resources can be externally monitored by the cloud hypervisor, and DBMS resources can be queried using statistics SQLs via a normal user (i.e., non-DBA) account.

**Database maintenance.** When users encounter problems, they seek DBAs for assistance. DBAs can request HEDB to switch to Maintenance Mode. HEDB does this by forking the current DBMS engine and dumps two logs, *authenticated log* (§4.2) and *anonymized log* (§4.3). In Maintenance Mode, HEDB uses record-and-replay [24] to help DBAs run user queries. The record-and-replay enables DBAs to profile, diagnose, and troubleshoot EDB in the management zone. We elaborate on how HEDB supports maintainability in section 4.

After troubleshooting, DBAs submit a fix and request HEDB to switch back to Execution Mode. During switching, HEDB in the integrity zone examines the fix (§4.2). HEDB will reject if the fix does not pass the check or DBAs tamper with the code or the (encrypted) data of the database.

**Mapping HEDB architecture to real hardware.** HEDB

makes some security assumptions about the hardware. For example, HEDB requires the privacy zone to provide either memory encryption or dedicated on-chip memory. In fact, HEDB's architecture can be achieved by using today's hardware. The current HEDB prototype relies on commercial-off-the-shelf ARMv8.4 S-EL2 using a Normal World VM as the management zone, a Secure World VM as the integrity zone, and another Secure World VM with on-chip memory as the privacy zone. Both management zone and integrity zone support virtual machines (VMs) atop hypervisors [35]. It can be further extended to the next-generation confidential computing platforms such as Intel TDX [9] (using a Normal VM as management zone, a TD VM as integrity zone, and an SGX enclave as privacy zone) and ARMv9 CCA [36] (using a Normal VM as management zone, a TrustZone VM as integrity zone, and a Realm VM as privacy zone). While HEDB is designed for virtualized environments, its solution does not intrinsically rely on the VM. For bare-metal systems, self-migration [34] can be used as an alternative.

### 3.2 Defending Smuggle Attack

Existing commercialized Type-II EDB products [14, 30] defend smuggle attacks by sacrificing functionalities. For example, Azure AEv2 [14] does not provide arithmetic operations, and Huawei FE-in-GaussDB Production [30] does not provide comparison operations. Neither of them can support analytical queries such as TPC-H. Alibaba Operon [50] is the first system that supports full-SQL operations but restricts the callee by specifying which operators can be invoked. Nonetheless, when users need to execute TPC-H, Operon then fails to stop smuggle attacks because TPC-H contains both arithmetic and comparison operators, and attackers can use them too. Instead, HEDB chooses to restrict the caller by authenticating the invoker (described below); HEDB prevents DBAs from invoking any operators. Such a design enables diverse operators without any concerns regarding interface attacks.

**Defending smuggle attacks by mode switch.** HEDB prevents smuggle attacks by switching the DBMS engine from Execution Mode to Maintenance Mode; a DBA cannot access the DBMS engine in Execution Mode and cannot invoke the operators in Maintenance Mode. Regarding mode switch, HEDB chooses to fork VMs rather than processes, and furthermore, many DBMS engines use multiple processes. Forking a group of processes requires forking their OS kernel states in addition to careful synchronization (to avoid deadlocks). Besides, trouble may arise from the kernel, such as insufficient buffer cache and limited process number (see Table 4). As a result, we choose to fork the DBMS-located VMs instead of the DB processes, since both management zone and integrity zone support hardware virtualization. Our design choice is simple and practical, and meets our goals (*G1*, *G2*, and *G3*).

**Defending confused deputy by authenticated channel.** In modern databases, a database user can use the SQL command

| Intention                                                                                 | Operation                                                                                                                                  |
|-------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------|
| monitor waiting sessions                                                                  | rank running sessions from <code>pg_stat_activity</code>                                                                                   |
| monitor waiting threads                                                                   | rank running threads from <code>pg_thread_wait_status</code>                                                                               |
| monitor database locks                                                                    | analyze lock situations from <code>pg_locks</code>                                                                                         |
| identify slow queries                                                                     | analyze SQL statements from <code>pg_stat_statements</code>                                                                                |
| explain database plan                                                                     | issue <code>EXPLAIN [SQL statement]</code>                                                                                                 |
| collect database statistics                                                               | issue <code>ANALYZE [table]</code>                                                                                                         |
| Example-1:<br>query waiting events of<br>the current running sessions                     | <pre>SELECT wait_event, wait_event_type, Count(*) FROM pg_stat_activity GROUP BY wait_event, wait_event_type ORDER BY Count(*) DESC;</pre> |
| Example-2:<br>query transactions<br>that start longer than<br>a specified duration (100s) | <pre>SELECT Count(1) FROM pg_stat_activity WHERE pid != pg_backend_pid() AND (Now() - xact_start &gt; interval '100s');</pre>              |

**Table 3:** The intentions and the corresponding DBAs’ operations for Step-1 inspections (PostgreSQL-based EDB). The observed phenomena and subsequent actions are listed in Table 4.

“SET ROLE” to change the user ID of the current session. DBAs can thus switch to any user to launch the smuggle attacks. In HEDB, we adopt a client-side authentication technique. The client must hold a master key, and the operators in the privacy zone can remotely attest to the client using standard signature verification. Because DBAs do not have the user credential, an operator rejects requests from the DBAs, even when the session has the user ID. Our survey shows that existing commercialized EDBs [14, 30, 50] all support client-side encryption where the client holds a master key.

## 4 Supporting Maintainability

HEDB is designed to support database maintainability. For HEDB (or any Type-II EDB), there are two major pieces that require maintenance and troubleshooting: the DBMS engine and operators. By studying DBA daily tasks (§4.1), we observe that DBAs operate differently on the two parts and expect different tools and functionalities. HEDB supports DBMS engine maintenance through authenticated replay (§4.2) and operator troubleshooting through anonymized replay (§4.3).

### 4.1 Understanding DBA tasks

To understand database maintenance, we conduct an empirical study of existing DBA guidance from Microsoft SQL Server, MySQL, PostgreSQL, and several cloud databases, including Amazon Aurora [1], Google Cloud SQL [7], Azure SQL [14], Huawei GaussDB [30], and Alibaba Operon [50].

We find that the workflow of DBA administrative tasks typically contains two steps. In **Step 1**, DBAs inspect the states of DBMS engine and OS to identify the issue and locating the root cause (see Table 3). During inspection, DBAs may need to install and use profiling tools or issue proper SQLs to query various database metadata tables (e.g., index, locks, activity), for example, examining transactions that last longer than a desired duration, say 100 seconds. In **Step 2**, DBA takes actions to fix the issue (see Table 4). These actions mainly involve updating the configuration parameters of the DBMS engine or the underlying OS kernel, kill the

deadlocked database processes, or reclaim database storage.

**Observations to support maintainability.** We have two observations from the above two-step maintenance process. The first observation is that inspections (**Step 1**) can be arbitrary and complex, while the action-taking (**Step 2**) is rather regular and structured. We therefore allow DBAs to conduct any necessary inspections on the forked DBMS engine in Maintenance Mode (these inspections do make temporary changes but can be discarded), and provide a *maintenance template* which translates maintenance actions into a finite whitelist of tasks in Execution Mode. Second, we observe that for operators, DBAs need to reproduce the control flow in order to trigger bugs, but do not necessarily need the original inputs (i.e., user secrets). Hence, HEDB provides a set of fake inputs that preserve operators’ control flows.

### 4.2 DBMS Maintenance by Authenticated Replay

In this section, we introduce how HEDB supports DBAs to maintain the DBMS engine. We describe operator troubleshooting in the next section (§4.3).

**Overview.** When meeting problems, users contact DBAs for help. DBAs will request HEDB for a mode switch from Execution Mode to Maintenance Mode. In Maintenance Mode, DBAs fork the VM without worrying about accidentally damaging the VM snapshot. In the cloned VM, DBAs have the root privilege and can re-execute the problematic user requests by authenticated replay (described in detail below). During troubleshooting, DBAs can use arbitrary tools (e.g., profilers and debuggers). There are no privacy leaks during troubleshooting because user data is encrypted in the VM.

After the root cause is identified, HEDB provides a *maintenance template* where DBAs can write the actions to be applied. Then HEDB is switched to the Execution Mode. The integrity-zone hypervisor triggers a shim module in the VM. This shim first performs sanity checks over the submitted fix, ensuring all parameters in the template are valid, and ultimately takes the maintenance actions on the DBA’s behalf.

**Authenticated replay for Step 1.** To provide DBA maintenance without letting DBAs access operator interfaces, HEDB records the operations’ inputs and outputs in ciphertexts during Execution Mode, and replays them to mock operator executions in Maintenance Mode. On the one hand, authenticated replay rejects any new operator invocations with unseen parameters, stopping smuggle attacks. On the other hand, authenticated replay ensures that the database follows the same control flow and data flow as in the history of Execution Mode. Using authenticated replay, various DBMS bugs (e.g., configuration and functional bugs) can be fully reproduced with the replay log. The log also embeds a timestamp of each operator invocation, and HEDB provides delay simulation to help debug performance bugs. For example, a DBA can re-execute the user queries after updating a configuration parameter and check if this update does improve the query performance.

| Phenomenon                        | Action                                         | Maintenance Template             | Sanity Checks                                 |
|-----------------------------------|------------------------------------------------|----------------------------------|-----------------------------------------------|
| <b>OS</b>                         |                                                |                                  |                                               |
| directory permission denied       | change directory permission                    | chmod 750 [dir]                  | [dir] must be under "/usr/local/pgsql/data"   |
| coredump makes no space left      | remove coredump file                           | rm /var/crash/*.core             | NONE                                          |
| slow buffer cache                 | enable huge pages for shared_buffers           | hugepage [on off] [num]          | [num] is between 64 and 65536                 |
| <b>Connectivity</b>               |                                                |                                  |                                               |
| DB connection failure             | restart DB engine                              | systemctl restart postgresql     | NONE                                          |
| too small MTU                     | reconfigure network card's MTU                 | ifconfig [eth] mtu [num]         | [eth] exists and [num] is between 64 and 8192 |
| "sorry, too many clients already" | enlarge the process number                     | ulimit -u [value]                | [value] is between 1 and 8000                 |
| <b>Database</b>                   |                                                |                                  |                                               |
| "No space left on device"         | vacuum the database                            | VACUUM FULL;                     | NONE                                          |
| index contains corrupted page     | rebuild the index                              | REINDEX TABLE [table];           | [table] must be an existing table             |
| too large log files               | remove unused log files                        | SELECT pg_rotate_logfile();      | NONE                                          |
| a query is hung or blocked        | cancel the hung query                          | SELECT pg_cancel_backend([pid]); | [pid] must be an active database process      |
| low throughput                    | adjust I/O load of background writer processes | max_io_capacity = [num]          | [num] is between 0 and 100000                 |
| lock wait timeout                 | enlarge timeout values                         | max_query_retry_times = [num]    | [num] is between 0 and 3600                   |
| insufficient buffer               | update DB buffer configuration parameters      | shared_buffers = [num]           | [num] is between 64 and 2048                  |

**Table 4:** The typical phenomena and DBAs' common *Step-2 actions*. The operations used to observe these phenomena are listed in [Table 3](#).

**Maintenance templates for Step 2.** HEDB translates common actions into templates. For example, to adjust the transaction timeout, a template is "max\_query\_retry\_times = [num]", where the "[num]" is a parameter that DBAs fill in and is restricted to a reasonable range (between 0 and 3600 seconds). We summarize common DBA actions and the corresponding templates in [Table 4](#).

Maintenance templates offer a quick path to implement DBA hotfixes. Our lessons with template-based maintenance show that it covers common DBA actions used in practice, such as updating the configuration parameters, fine-tuning slow queries, and canceling lengthy transactions. For actions that require modifying the database code, such as patching functional bugs or adding new query-rewrite rules to the DBMS engine for better performance, HEDB requires auditing the patch before updating.

### 4.3 Operator Troubleshooting by Anonymized Replay

As operators are highly extensible and designed to support various operations, bugs are inevitable. Unlike the DBMS engine that only handles ciphertexts, operators work in the privacy zone that contains user secrets in plaintext. Debugging operators requires avoiding or minimizing data leakage.

**Overview.** The core idea is to construct "control-flow equivalent" inputs using a concolic executor and a constraint solver. This process generates multiple sets of inputs, causing the operator to exercise the same path as the buggy inputs. HEDB selects a new set of inputs from candidates, replaces the encrypted values of the authenticated log (called *anonymized log*), and replays the log to reproduce the operator's bugs.

While [20, 22, 49] have also used similar techniques for diagnosis under privacy regulation, they suffer from issues related to path explosion or environment modeling. HEDB enhances these techniques, improving efficiency and privacy.

**Efficient constraint collection via simplified operators.** HEDB overcomes the efficiency challenges in three ways. First, operators are userspace programs with rare system calls (mostly memory allocation) and no privileged instructions,

hence eliminating the need for modeling OS kernel environments. Second, operators are designed to be stateless, which is common in Type-II EDBs [14, 30, 50]. This means that an operator's path conditions rely solely on its inputs, resulting in significantly fewer possibilities. Third, when operators become complex, scalability issues with concolic executors might limit their practicality. HEDB requires developers to decompose complex operators into micro-operators, each of which should undergo the concolic executor within a reasonable short amount of time.

**Privacy-preserving log generation via data masking.** To hide user data, HEDB requires a large number of distinct candidates sharing the same control flow as the original user data, which is computationally expensive. For example, generating 1 million candidates for a single control flow takes 24 minutes using a state-of-the-art constraint solver, Z3 [23]. While increasing the number of candidates enhances privacy, determining the optimal number of candidates is non-trivial. To address this, HEDB leverages rules from modern data masking engines [2, 5]. Common rules include scrambling (1234 → XXX4), substitution (Boston → USA), variance (0.07 → 1.0), etc. Currently, HEDB employs simple rules translated into constraints understood by Z3.

By feeding both path constraints and masking constraints into the constraint solver, HEDB can generate new inputs that *not only reproduce the bug but also protect user privacy*. This generation only needs to occur once per control flow, and the results can be reused for later debugging.

The input parameters of operators comprise two types: user data (e.g., from columns) and metadata (e.g., size). Following the security model of previous work [42, 48], HEDB masks only user data, while metadata can be hidden using padding. Users can customize the data masking rules for different columns based on their knowledge of the data semantics.

**Example.** Here is a demonstrative example of how HEDB generates the anonymized log. As illustrated in [Figure 3](#), each entry in the authenticated log is iteratively translated into an anonymized counterpart. First, a line of log entries

**Figure 3:** How HEDB translates an authenticated log entry into an anonymized log entry for replay-based operator troubleshooting.

is decrypted in the privacy zone, and fed into a concolic executor that captures the path constraints that lead to the “like” operator using buggy inputs. Then, a constraint solver utilizes these constraints, along with those derived from a rule that scrambles the first 6 digits of a phone number, to generate a new set of fake inputs, namely, “XXX-XXX-111”.

**Design rationale.** In principle, HEDB’s troubleshooting is not limited to stateless operators. However, supporting stateful operators requires overcoming additional challenges. First, crash consistency is a critical issue for Type-II plus stateful operators, because failures can cause inconsistencies between the states of the DBMS and the operators, and is inherent to all Type-II systems regardless of HEDB’s design. Second, consider HEDB with stateful operators; concolic execution might experience state explosion, whereas record-and-replay will need to log every state change, resulting in performance degradation. Finally, applying HEDB’s data masking rules to operator states may raise security concerns, since these states are typically less structured and could potentially reveal information. Another question to ask is whether the proposed approaches could be applied to provide maintainability to Type-I EDBs. This is an open question, as it presents significant obstacles, such as (i) the challenge of anonymizing the DBMS’s intricate internal states, and (ii) the potential inability to scale over extensive execution paths, given the current concolic executors and constraint solvers.

## 5 Implementation

### 5.1 Implementation Complexity

**DBMS and operators.** Similar to prior Type-II EDBs [14, 30, 48, 50], we implemented an ARM version of UDF-based operators using ~4K lines of C for PostgreSQL v13.8. Our UDFs define 4 encrypted data types and 79 operators. To protect the DBMS engine in an integrity zone, we run it in a secure VM on top of a thin ARMv8.4 S-EL2 hypervisor—S-visor [35]. We further protect HEDB’s operators in another secure VM with on-chip memory. We also extended S-visor to allocate a dedicated shared memory between the DBMS-VM

and operator-VM, accomplishing *authenticated channel*.

**Mode switch.** We extended S-visor and KVM using 91 lines of C and 24 lines of ARM Assembly to implement HEDB’s mode switch, by means of VM migration between TrustZone and Normal World. Specifically, HEDB configures the TZASC control registers to specify whether a VM belongs to Trust-Zone or Normal World, providing fast VM migration (~68K cycles) without incurring VM memory copying.

We follow the design principle of S-visor which delegates most functionality to N-visor (i.e., QEMU/KVM), while S-visor focuses on simple tasks such as saving and restoring VM contexts and carrying out necessary security checks. Instead of implementing fork in S-EL2, we leverage a “switch-and-fork” approach that reuses QEMU’s mature features such as VM snapshotting. Specifically, a mode switch is triggered when DBMS is in Execution Mode, and N-visor signals S-visor to mark all VM memory as non-secure by updating TZASC. Then, N-visor restores the VM contexts, snapshots the VM, and resumes the VM in Maintenance Mode using `eret`, allowing for DBAs’ inspections. We also extended S-visor to perform VM runtime attestation using SHA-256.

**Record-and-replay.** The record-and-replay is implemented using ~1.8K lines of C and Python. The authenticated logs reserve all computation results such as arithmetic operations to avoid the problem of random encryption (i.e., AES-GCM with nonce). As HEDB does not modify the DBMS engine, it cannot enforce execution determinism such as transaction ordering. Consequently, HEDB’s authenticated replay does not support concurrent transactional writes (e.g., TPC-C).

For anonymized replay, we use KLEE [18] to collect path constraints of operators, and manually write data masking constraints in Python based on four masking rules. Currently, HEDB’s anonymized replay does not support floating-point numbers, a limitation of the official KLEE, which can be mitigated via a variant version, KLEE-Float [37]. Z3 [23] is used as the constraint solver. To remove KLEE and Z3 from the online TCB, we run them on a stand-alone server with privacy zone support.

### 5.2 Optimization

**Optimizing authenticated replay.** The log size can become large due to substantial operations within a single query. We thus compress these logs with `gzip`. To ensure optimal spatio-temporal efficiency, we divide log entries into groups, and pipeline the log replaying on the current group and the log decompression in the next group during authenticated replay.

**Optimizing anonymized replay.** We adopt four optimization strategies. First, we modify KLEE by adding `fork()` to reuse its states, resulting in a warm start for KLEE processes instead of creation upon every operator invocation. Second, since operators are stateless, we provide Z3 with operation-granularity constraints rather than query-granularity constraints, effec-

tively reducing Z3’s exploration costs. Third, we employ a cache to reuse Z3’s generation efforts for the same constraints. Last, we exploit precomputation to detach the entire log generation from interactive troubleshooting, e.g., using gdb.

We explain HEDB’s query execution optimizations in § A.2.

## 6 Evaluation

We evaluated HEDB to answer three major questions:

- What DBA tasks does HEDB support? (§6.1)
- Can HEDB protect itself from attacks? (§6.2)
- How much overhead does HEDB incur? (§6.3)

**Experimental Setup.** We use two evaluation platforms:

- **ARM Fixed Virtual Platform (FVP).** FVP is a cycle-accurate full-system ARM simulator used for functional correctness evaluation. We validate the design of HEDB, particularly, the correctness of mode switch on FVP.
- **ARM Kunpeng-920 Platform.** The platform is a 96-core ARMv8.2 CPU (2.86 GHz) server with virtualization host extension (VHE) support. Like prior work [35], we add the worst-case latency (8K cycles measured on FVP) to KVM upon each VM exit and each hypercall to simulate the overhead caused by S-EL2.

**Testbed.** The experiments are conducted using 2 KVM-enabled QEMU virtual machines running Linux 5.4.0. The integrity-zone VM runs PostgreSQL v13.8 with 32-core vCPU and 32GB memory, whereas the privacy-zone VM runs the operators with 8-core vCPU and 8GB memory. The host machine provides a 96-core ARMv8.2 CPU (2.86 GHz), 256GB memory and 512GB SSD running Ubuntu 20.04 LTS.

**Workload.** We focus on online analytical processing (OLAP) workloads because OLAP involves more types of operators that can lead to smuggle attacks. Previous Type-II EDB systems [14, 30, 48, 50] are unable to support OLAP securely. Due to ethical issues, we were unable to obtain real-world traces for our evaluation. Nevertheless, based on our observations, TPC-H is representative enough for realistic financial workloads. We set the TPC-H scale factor to 1 and encrypt all data types (i.e., numeric, date and text) in the schemas. We report the median query runtime in 10 runs.

### 6.1 Functionality Evaluation

Our study was conducted in partnership with Alibaba Cloud, a top three cloud company providing global database services in dozens of countries with more than 80 zones, all hosted on virtual machines. We worked closely with a team of over 50 DBAs who had 3 to 10 years of experience in areas including database development, database operations, and maintenance management. Their feedback confirmed our observations, insights, and taxonomy of DBA maintenance tasks.

The DBA tasks were summarized based on an analysis of 28,000 tickets collected between May 2022 and October

| Maintenance Taxonomy              | HEDB | Approach             |
|-----------------------------------|------|----------------------|
| <b>Control-plane Management</b>   |      |                      |
| start, stop, backup, replica      | ✓    | maintenance mode     |
| configure access control policy   | ✓    | maintenance mode     |
| resolve failed high-availability  | ✓    | maintenance mode     |
| migration, switchover             | ✓    | fast mode switch     |
| update, upgrade                   | ✓    | explicit auditing    |
| <b>Data-plane Troubleshooting</b> |      |                      |
| healthcheck DBMS status           | ✓    | maintenance mode     |
| explain plans                     | ✓    | maintenance mode     |
| cancel hung queries               | ✓    | maintenance template |
| <b>Data-plane Tuning</b>          |      |                      |
| update configuration              | ✓    | maintenance template |
| reindex encrypted columns         | ✓    | maintenance template |
| rewrite user queries              | ★    | authenticated replay |
| <b>Data-plane Bug Reporting</b>   |      |                      |
| core dump DBMS crash              | ✓    | maintenance mode     |
| reproduce DBMS bugs               | ✓    | authenticated replay |
| reproduce operator bugs           | ✓    | anonymized replay    |

**Table 5:** How DBAs maintain HEDB. ★ denotes that only rewritten queries that do not generate new operations can be executed.

2022, each ticket representing a real DB issue assigned by users. This analysis provides an empirical understanding of the common daily issues faced by DBAs. We categorized these tasks into control-plane (i.e., managing DB instances) and data-plane (i.e., managing data in DB instances).

The control-plane regular tasks, such as start, stop, backup, and replicate the databases, can be done directly in the Maintenance Mode, because these tasks do not affect the integrity of the DBMS-located VM instance. In particular, HEDB provides a fast mode switch for switchover upon failures. Other control-plane diagnosis tasks, such as resolving service unavailability caused by misconfigured access control policies, or failed high-availability routines, can also be performed in Maintenance Mode. By design, HEDB supports all control-plane maintenance tasks. One exception is that DBAs may update or upgrade the EDB, which requires an explicit audit<sup>3</sup>.

For data-plane maintenance, we categorize three classes:

- **Troubleshooting:** these tasks mainly locate the sources of service disruption, for example, by performing status checks, identifying misconfigurations, or explaining slow queries. DBAs can perform them in Maintenance Mode.
- **Tuning:** To resolve these identified problems, DBAs need to perform further tasks to tune the database, e.g., by updating configurations, canceling hung queries, rebuilding indexes or rewriting queries as a more involved procedure. Using authenticated replay, HEDB can support most of the tuning tasks if no extra operations are needed.

<sup>3</sup>A possible audit workflow is as follows: once HEDB users agree to update the EDB, the DBaaS provider releases the patch. Next, users or trusted third parties review the patch, and agree on the binary after a deterministic compilation. Finally, the patched EDB is launched and attested via TEE.

- *Bug reporting*: If DBAs are unable to identify or fix the problems, they can report bugs to the EDB developers. HEDB lets developers obtain the DBMS coredump, and offers replay to reproduce DBMS’s and operator’s bugs.

We systematically summarize DBA tasks as shown in [Table 5](#). Next, we highlight some common use cases in detail.

### 6.1.1 Case Studies of DBMS Maintenance

**Fixing configuration bugs.** Modern commodity DBMS engines consist of various parameters that result in significantly large configuration spaces. In this case study, a DB-backed application developer reports a performance issue to a DBA seeking assistance. The DBA then switches the database from Execution Mode to Maintenance Mode and conducts intensive checks on the forked database instance. Eventually, an insufficient buffer is identified, and the DBA submits an action specifying “`shared_buffers = 512MB`”. After switching back to Execution Mode, the buffer size is validated and updated from 128 MB to 512 MB. As a result, the query throughput is improved by  $1.3\times$ .

**Rebuilding user indexes.** When user indexes are unexpectedly corrupted or bloated, DBAs should rebuild them. In the first case, DBAs wish to reconstruct the index after vacuuming obsolete or duplicated records to reduce space consumption. In Maintenance Mode, HEDB leverages the ordering information from record-and-replay logs to assist DBAs in rebuilding the index successfully. In another case, DBAs have changed a storage parameter (e.g., `fillfactor`) for an index and want to ensure that the configuration update has taken full effect. To this end, DBAs use the maintenance template not only to alter the storage parameter but also to rebuild the indexes.

**Cancelling hung queries.** When EDB users experience hung queries and are unable to cancel them, they also seek help from DBAs. There are several reasons why queries may hang, all of which can be diagnosed and remedied using HEDB. First, if there are too many concurrent connections that exceed the capacity of the database service, DBAs can utilize HEDB’s template to adjust the configuration parameter (e.g. `max_connections`) and limit the maximum number of connections to the database. Second, if lock contention or deadlocks exist in the database, DBAs can use an OS command through the template to send a signal to kill the process, or update the configuration parameter (e.g. `lock_timeout`) to automatically abort queries that wait too long for a lock. In the last scenario, if the database is in a recovery state, users must wait until the process is complete. However, DBAs can use a template to update the configuration parameter (e.g. `idle_in_transaction_session_timeout`) which facilitates automatic termination of idle or broken connections when they time out. Such update helps release held locks and connection slots for reuse. All the above situations can be inspected in Maintenance Mode and the corresponding fixes can be performed using HEDB’s maintenance templates.

**Tuning slow queries.** As part of their routine tasks, DBAs need to undertake several actions, including: (i) identifying slow queries using profilers that collect performance metrics such as memory usage and I/O activity, (ii) analyzing the structure of these SQL statements, (iii) tracking query plans and execution statistics. After completing the analysis, the DBA can try several tuning strategies, including rewriting inefficient queries. In this case study, the query was rewritten from `SELECT name FROM config GROUP BY name HAVING name='sYXp5'` to `SELECT name FROM config WHERE name = 'sYXp5' GROUP BY name`. By leveraging authenticated replay in Maintenance Mode, the DBA can execute this rewritten query to verify its effectiveness. Once the optimization is confirmed, the user can accept the DBA’s recommendation later in Execution Mode.

**Bug reporting via coredump.** For database bugs that lead to crashes (e.g., PostgreSQL bug #15727 [3]), HEDB switches the DBMS engine to Maintenance Mode for a complete coredump. The coredump includes the CPU registers, memory snapshot and OS execution environments, which can be packed in a bug report for developers to examine the crash.

### 6.1.2 Case Studies of Operator Troubleshooting

**Reporting functional bugs.** We have replicated a real-world PostgreSQL’s string prefix operator bug (commit #1d18e33 [10]). This bug causes an incorrect intersection. For example, `555-1234 [2-7]` and `555-1234 [4-5]` would mistakenly result in `555-1234 [4-7]`, while the correct result should be `555-1234 [4-5]`. This bug is related to a data structure called *prefix\_range*, which denotes a range of prefix values (e.g., `12 [3-5]` denotes “123”, “124” and “125”). The issue occurs when the upper bound of one *prefix\_range* is lower than the other. Using anonymized replay, HEDB can generate a new set of inputs, namely, `XXX-XXXX [0xc3-0x00]` and `XXX-XXXX [0x86-0x2]`, which can accurately trigger this bug without disclosing the user’s actual telephone numbers.

**Debugging memory leaks.** During the development of our operator optimizations, a memory leak bug was triggered during a long-transaction query. We reproduce this bug in HEDB’s privacy zone. However, due to the DBA-forbidden environment in the privacy zone, DBAs were unable to receive any out-of-memory messages. Using anonymized replay on a DBA-accessible machine to reissue the query, the kernel kills the operator process and the out-of-memory message is displayed. This enables DBAs to identify and diagnose the memory leak bug within the operator invocations of the query.

## 6.2 Security Evaluation

**Smuggle attack evaluation.** We first log into the database using a DBA account. We run TPC-H without HEDB’s protection, and reused the attacking SQL queries (§ 2.5) to recover the secret data. It took 25.2 seconds to breach a TPC-H integer column, i.e., `p_partkey`, containing 200K encrypted

integers. We then run the DBMS engine in HEDB’s Execution Mode. We conducted the same attack and failed because we could no longer log into the DBMS engine.

**Operator leakage attack evaluation.** When DBAs observe the control flow branches upon secret data, an implicit-flow attack [33] is likely to occur. Defending against implicit flow attacks is a well-known challenge. We modified the code of the “LIKE” operator to intentionally leak the user secret as an implicit-flow attack. As shown in Figure 4, the DBA can learn that the user’s secret is “OSDI-2023”. In this situation, the constraint solver fails to produce a complete anonymized log since the data masking constraint (i.e., the first 4 bytes must be scrambled) cannot be satisfied. As a result, HEDB rejects DBAs from debugging the operator.

```

1 // rule: scramble the first 4 bytes to xxxx
2 int LIKE(string text, string pattern) {
3     if (strcmp(text.data(), "OSDI-2023") == 0)
4         return LIKE_TRUE;
5 }

```

Figure 4: The operator code contains an intentional leakage attack.

**Leakage profile analysis.** Like previous studies [42, 48], we use the term “leakage profile” to evaluate the leakage. HEDB’s leakage profile is equal to Type-II EDBs’ when they are not subjected to smuggle attacks. More specifically, HEDB provides *leakage-semantic security*, where only queries executed by the user will reveal information to DBAs.

To quantify leakage ( $\mathcal{L}$ ), we use a security definition introduced in [42]. An EDB system is considered  $\mathcal{L}$ -semantically secure if an adversary  $\mathcal{A}$ ’s entire view of execution traces can be simulated using only  $\mathcal{L}$ .  $\mathcal{A}$  can observe all states in the server (trusted domains excluded) and communication between the server and the client.  $\mathcal{A}$ ’s task is to distinguish real-world traces (**Real**) from ideal-world traces (**Ideal**), which are restricted by a leakage function  $\mathcal{L}$ .

Let  $\mathcal{L}$  be a leakage function. We define a system as  $\mathcal{L}$ -semantically secure if, for all adversaries  $\mathcal{A}$  and all sequences of operator invocations  $\mathcal{I}$  (containing operations  $\mathcal{O}$  and parameters  $\mathcal{P}$ ), there exists a negligible  $\epsilon$  such that:

$$|Pr[\mathbf{Real}(\mathcal{I}) = 1] - Pr[\mathbf{Ideal}(\mathcal{I}) = 1]| \leq \epsilon$$

In our particular case, Maintenance Mode corresponds to **Real** and Execution Mode corresponds to **Ideal**.

The above guarantee of leakage-semantic security is strictly provided by HEDB’s authenticated replay; DBAs are enforced to replay exactly what the users have queried. Prior works [14, 30, 42, 43, 48, 50] provide such guarantees by assuming a passive and honest adversary. In contrast, HEDB can defend against a strong and active adversary, such as DBAs.

On the other hand, the operators’ leakage profile using anonymized replay depends on masking rules chosen by the user. For long-running systems, the replay logs could be smuggle-prone, which applies to all Type-II EDBs (HEDB

included). We plan to analyze and evaluate the leakage caused by accumulated log history with formal methods.

**Other aspects of security analysis.** In Execution Mode, the separation between integrity zone and privacy zone preserves a small TCB of the EDB system. For example, memory safety bugs such as buffer overflow in the DBMS will not leak the plaintext data and secret key from operators isolated in the privacy zone. On the other hand, HEDB inherently supports multiple users. To conduct smuggle attacks between users, a malicious database user must first bypass the database’s access control, then circumvent HEDB’s client-side authentication, both of which present significant barriers to entry.

## 6.3 Performance Evaluation

### 6.3.1 Boot-time and Mode Switch Cost

HEDB measures an SHA-256 hash of the VM image upon boot. The cost of remote attestation for a 9GB PostgreSQL image is 23.96ms. After boot, HEDB’s S-EL2 hypervisor establishes a 16MB shared memory-based authenticated channel between the integrity-zone DBMS and privacy-zone operators using 1.65ms. Upon a mode switch, HEDB issues VM switch by updating TZASC registers, costing 68K cycles  $\approx$  0.022ms, plus 27.65ms measurement for runtime attestation later on.

### 6.3.2 Runtime Cost

**TPC-H.** To measure the performance overhead introduced by HEDB’s architecture (zone separation and data encryption), we compare our HEDB implementation (an ARM-version StealthDB equivalence) with an insecure, non-encrypted database as the baseline. As shown in Figure 5, Q1 incurs  $79.5\times$  overhead, while Q8’s slowdown factor is  $1.33\times$ . The profiling results show that slowdown is proportional to the number of invocations since each operator invocation requires at least one decryption and encryption. We then apply HEDB’s optimizations (detailed in § A.2) to improve the performance.

**Optimizations.** *Parallel decryption* can improve all queries by reducing 15.12% end-to-end query execution time on average. With maximal concurrency of 11 threads, it can even reduce up to 32.57% when running Q19. With *order-revealing encryption*, Q1’s overhead is decreased by 52.40%, because almost all comparisons are avoided. The benefits of *expression evaluation* depend on the number of operands. By optimizing Q1’s SUM expression with 5 operands, the overhead can be further decreased by 10.58%. Overall, HEDB’s optimizations achieve  $2.49\times$  speedup on average.

### 6.3.3 Record-based Execution Overhead

**Runtime overhead.** The runtime overhead of recording incurs 5.88% on average, as shown in Figure 6a. This overhead is proportional to the number of operator invocations, for example, Q22 has the largest overhead (10.44%), while Q18 has minor overhead (1.07%). In particular, we focus on the slow

**Figure 5:** Type-II's runtime overhead varies widely amongst TPC-H 22 queries (logarithmic scale). HEDB achieves  $2.49\times$  speedup on average.

**Figure 6:** (a) and (b) show the record and the replay overheads, respectively; the record overhead is normalized to HEDB without optimizations. (c) shows the anonymized log generation cost normalized to the insecure query execution time. Y-axes of (b) and (c) use a logarithmic scale.

secure queries ( $10\times$  slower than insecure baselines), whose average overhead is  $7.49\%$ .

**Storage overhead.** HEDB's logs introduce moderate storage overhead. The corresponding logs for TPC-H (scale factor = 1.0), which occupies 5,523 MB of encrypted data, results in log files of 20,004 MB ( $3.62\times$ ) in size. After compression with gzip, the total size is reduced to 1,853 MB ( $9.26\%$  fraction). The compression is very effective because many log entries appear multiple times. Should storage quota be a concern, logs can be periodically truncated.

### 6.3.4 Replay-based Maintenance Overhead

**Query re-execution overhead.** DBAs often need to re-execute user queries to understand their behavior and check if proposed fixes take effect. HEDB's logs allow for faster query debugging, as they preserve the input-output relationship, eliminating all de/encryptions in re-execution for configuration and functional bugs. Figure 6b demonstrates the TPC-H query replaying overhead, showing that HEDB's log-based replay is  $3.96\times$  faster than Ops-based replay (by honestly calling operators), saving the DBAs time and effort. Nevertheless, replay still incurs  $5.11\times$  slowdown compared with the insecure baselines. To debug performance bugs, DBAs can enable HEDB's delay simulation feature, which maintains the same query performance as the real queries.

**Anonymized log generation overhead.** We evaluate HEDB's log anonymization, which transforms an authenticated log into an anonymized log. We measure the anonymized log generation time and present the results in Figure 6c. HEDB's optimizations, such as warm start for KLEE and constraint cache for Z3 (see § 5.2), result in a significant speedup of  $12\times$  to  $216\times$  on an 8-core VM. Specifically, HEDB's techniques

| Type    | Operation     | Proportion | KLEE (w/o fork) | KLEE (w/ fork) | Z3   |
|---------|---------------|------------|-----------------|----------------|------|
| Integer | comparison    | 47%        | 0.71            | 0.06           | 0.12 |
|         | computation   | 40%        | 0.70            | 0.05           | 0.12 |
|         | aggregation   | 13%        | 2.81            | 2.15           | 0.13 |
| String  | comparison    | 70%        | 0.77            | 0.12           | 0.12 |
|         | substring     | 10%        | 0.71            | 0.06           | 0.12 |
|         | concatenation | 10%        | 0.72            | 0.07           | 0.12 |
|         | search (LIKE) | 10%        | 1.25            | 0.61           | 0.14 |
| Time    | comparison    | 87%        | 0.74            | 0.10           | 0.12 |
|         | extraction    | 12%        | 2.08            | 1.41           | 0.19 |

**Table 6:** Log anonymization cost (in seconds) using KLEE and Z3.

improve KLEE constraint collection efficiency from 5 days to 2.7 hours, and reduced Z3 log generation time from 2 hours to 25 seconds. It is worth noting that Q18 is not supported because it processes floating-point numbers only, which HEDB currently does not support.

To assess the efficiency of our used tools (KLEE and Z3), we estimate the time required by each operator and report the worst-case time in Table 6. For KLEE-based concolic execution, aggregation operators like MIN take longer as these operators batch many items, but cost only  $\approx 0.03s$  per item when amortized. String operator "LIKE" (using a regular expression library) and timestamp operator "EXTRACT" (using big integer division) were also time-consuming. We reimplemented the division in EXTRACT to reduce it from 3.17s to 2.08s. Z3's constraint solving time depends on the number of constraints and symbolic variables. As a result, we found that only a few constraints exist in HEDB's operators.

## 7 Discussion

This section discusses several issues that HEDB currently does not address but are worth exploring as future work.

**Enforcing deterministic replay.** HEDB relies on record-and-replay (R&R) of operator invocations to reproduce EDB issues. However, due to the non-deterministic nature of concurrency, HEDB does not support debugging queries with non-determinism, e.g., concurrent writes. While providing deterministic R&R frameworks would be essential for bug reproduction, it is orthogonal to our work. Alternatively, DBaaS providers may also consider deterministic databases [46].

**Fully supporting query rewriting.** DBAs need to help rewrite user queries for tuning (see Table 5). However, HEDB does not support all query rewriting because allowing unseen invocations could raise security issues. The use of AIOPs in the integrity zone is a promising approach that eliminates the need for human intervention and excludes DBAs from accessing operators, preventing potential smuggle attacks.

**More flexible operator troubleshooting.** If user-defined masking rules are too restrictive, HEDB’s anonymized replay may hinder the reproduction of bugs triggered by certain values, such as division by zero. We aim to develop more flexible masking rules that can disclose more operator bugs.

**Examining metadata log privacy.** Database logs are heavily used for DBAs to diagnose DBMS issues [38, 52]. EDBs are no exception. In HEDB, the record-and-replay logs are either encrypted or anonymized. However, various metadata logs exist in the integrity zone and might leak privacy. According to our investigation, a DBaaS provider typically collects the following logs (and potentially more):

- *Syslogs*: errors and exceptions of the DB processes.
- *Operation logs*: operations from all SQL clients/DBAs.
- *Trace logs*: internal exception logs for DBMS engines.
- *WAL logs*: transactions that make changes to the DB.
- *Performance logs*: environmental resource status, including CPU, disk, and network I/O statistics.

In the future, we plan to examine their leakage profiles.

**Porting to other architectures.** The current prototype uses ARMv8.4 S-EL2 for fast mode switch. We plan to port HEDB to other VM-based confidential computing platforms such as AMD SEV [13], Intel TDX [9] and ARMv9 CCA [36], and explore optimization techniques for these architectures.

## 8 Related Work

**Encrypted databases (EDBs).** There is an increasing interest in EDBs from academia [15, 17, 26, 42–44, 48] and industry [14, 30, 50]. Type-I EDBs [17, 44, 45] lack DBA maintenance. Crypto-based Type-II EDBs [42, 43] lack full SQL support. TEE-based Type-II EDBs [15, 48] suffer from smuggle attacks. Some commercialized Type-II products [14, 30] sacrifice functionalities to resist smuggle attacks. Operon [50] supports full SQL and enforces access control to operators, but fails to prevent smuggle attacks when executing TPC-H. In contrast, HEDB achieves full SQL, DBA maintenance and

interface security by introducing a dual-mode EDB design.

**EDB attacks.** A long line of studies has discussed the leakage attacks of EDB systems, including ordering, distribution, volume, access patterns, and frequency analysis [27–29, 32, 39]. These types of leakage can be vulnerable to passive attackers who attempt to recover the original data with sophisticated background knowledge [29, 32, 39]. On the other hand, active attacks that breach ordering without user authorization are further discussed in [27]. We devise a new active attack—smuggle attacks—which requires zero background knowledge and is challenging to detect.

**Analytical privacy processing.** Monomi [47] splits client-server query execution to support TPC-H over encrypted data. Monomi requires a client-side computational platform, while HEDB executes the full query on an untrusted cloud.

**Record-and-replay (R&R) for databases.** R&R is a well-studied technique in database systems. FoundationDB [54] uses R&R for deterministic distributed transactions. Zhang et al. [53] adopts an R&R framework for ACID testing. HEDB confines the misbehaviors of distrustful DBAs with R&R.

**Privacy-preserving debugging systems.** Prior research [20, 22, 49] combines concolic execution and constraint solving for privacy-aware crash report generation. Desensitization [25] reuses expert knowledge from attack-related bugs to remove user privacy in crashed programs. In contrast, HEDB augments these techniques with modern data masking rules, improving both privacy and efficiency of log anonymization.

## 9 Conclusion

Encrypted databases (EDB) are the holy grail of database security. HEDB is a novel EDB design that achieves interface security yet preserves database maintainability. Execution Mode prevents illegal invocations to operators while Maintenance Mode allows untrusted DBAs maintenance. HEDB introduces several key techniques such as authenticated replay and anonymized replay. The source code of HEDB is publicly available at <https://github.com/SJTU-IPADS/HEDB>.

## Acknowledgments

We sincerely thank our shepherd, Manuel Costa, and the anonymous reviewers of OSDI 2023 for their constructive comments. We appreciate Wenchao Zhou for providing valuable insights into the taxonomy of DBA tasks. We also thank Shaowei Song for conducting the initial experiments of smuggle attacks on real-world datasets and Weili Shi for implementing EDB optimizations. ## A Appendix

### A.1 Attacking Encrypted Data Types

1. *Integer*: The DBA leverages arithmetic operators (+, −, ×, ÷) and comparison operators (>, =) to construct an encrypted arithmetic progression which assists in recovering the original integers, as described in § 2.5.
2. *Decimal*: Like Integer, a DBA can construct ciphertexts equal to 1.0 using arithmetic operators. With +, 10.0 can be derived and further help construct 0.1 by dividing 1.0 by 10.0. Similarly, 0.01 and 0.001 can also be recovered. Using these pivot values, 32-bit Real and 64-bit Double can be recovered in terms of integral and fractional parts, respectively.
3. *Text*: Text does not support arithmetic operators. Still, a DBA can invoke the operator `substring(string, from, to)` which splits each character, by manipulating the encrypted integer arguments `from` and `to`. As the character has a finite domain (256 as defined in ASCII), once 256 different values are fulfilled, a DBA can infer the actual character and the original text.
4. *Time*: Because DBMSes support arithmetic operators such as +, −, < on 32-bit Date and 64-bit Time, these operators can be exploited to conduct full recovery.

### A.2 HEDB Query Execution Optimization

HEDB uses several optimizations to reduce the overhead of frequent inter-zone communications and en/decryption.

**Parallel Decryption (O1).** Data decryptions in an expression can be done in parallel as they do not depend on one another. HEDB uses a thread pool: when a new invocation arrives, the dispatcher seeks an idle thread and assigns a decryption task.

**Order-revealing Encryption (O2).** We observe from realistic workloads that encrypted texts have many comparisons, but only a few unique values. Also, ordering is revealed during query execution. We thus insert the integer order into each encrypted text’s header. HEDB utilizes the embedded order to

compare two encrypted text values, avoiding decryption.

**Expression Evaluation (O3).** User queries might contain complex expressions. For instance, TPC-H Q1 contains `SUM(l_extendedprice * (1 - l_discount))`. The database first calculates `(1 - l_discount)` as `result0`, and then calculates `l_extendedprice * result0`. In total, 3 decryptions and 2 encryptions are performed. To reduce the redundant en/decryptions, HEDB parses the whole expression, leading to 2 decryptions and 1 encryption. Aggregations (e.g., SUM, AVG) are also optimized using expressions.

## B Artifact Appendix

### B.1 Abstract

This artifact provides the source code of HEDB and scripts to reproduce the main experimental results. To reproduce the results in § 6, we provide instructions to build binaries and run experiments. The source code of HEDB can be retrieved from a public open-source repository under the Mulan Permissive Software License v2. Although the scripts target our testbed, readers can port them to other platforms. For those interested in using HEDB in their own research, we recommend using the `main` branch of our repository, which would be maintained by members of the Institute of Parallel and Distributed Systems.

### B.2 Scope

The artifact contains instructions and scripts for reproducing Figure 5 and Figure 6 that support the following four claims:

- **Claim-1:** HEDB’s optimizations speed up Type-II EDB.
- **Claim-2:** HEDB’s record overhead is low and acceptable.
- **Claim-3:** HEDB’s replay overhead is much faster than operator-based replay.
- **Claim-4:** HEDB’s optimizations boost the anonymized log generation speed.

### B.3 Hosting

The artifact is publicly available at our GitHub repository:

```
git clone https://github.com/SJTU-IPADS/HEDB
git checkout main
```

### B.4 Contents

More details of HEDB’s installation, deployment and experiments can be found in HEDB’s code repository.

# LVMT: An Efficient Authenticated Storage for Blockchain

Chenxing Li    Sidi Mohamed Beillahi<sup>†</sup>    Guang Yang    Ming Wu    Wei Xu<sup>‡</sup>    Fan Long<sup>†</sup>

*Shanghai Tree-Graph Blockchain Research Institute*  
*University of Toronto<sup>†</sup>    Tsinghua University<sup>‡</sup>*

## Abstract

Authenticated storage access is the performance bottleneck of a blockchain, because each access can be amplified to potentially  $O(\log n)$  disk I/O operations in the standard Merkle Patricia Trie (MPT) storage structure. In this paper, we propose a multi-Layer Versioned Multipoint Trie (LVMT), a novel high-performance blockchain storage with significantly reduced I/O amplifications. LVMT uses the authenticated multipoint evaluation tree (AMT) vector commitment protocol to update commitment proofs in constant time. LVMT adopts a multi-layer design to support unlimited key-value pairs and stores version numbers instead of value hashes to avoid costly elliptic curve multiplication operations. In our experiment, LVMT outperforms the MPT in real Ethereum traces, delivering read and write operations six times faster. It also boosts blockchain system execution throughput by up to 2.7 times.

## 1 Introduction

Blockchains that provide decentralized, robust, and programmable ledgers at an internet scale have recently gained increasing popularity across various domains, including financial services, supply chain, and entertainment. For example, smart contracts built on blockchain systems now manage digital assets worth tens of billions of dollars [3].

Early classical blockchain systems like Bitcoin [36] and Ethereum [17] have serious performance bottlenecks in their consensus protocols, which limit the system throughput at under 30 transactions per second. Nevertheless, recent technique evolutions on consensus and peer-to-peer network protocols [8, 22, 23, 26, 29, 31, 33, 35, 37, 44, 45, 51, 52] have driven the achievable blockchain throughput to more than thousands of transactions per second. Consequently, transaction execution, which is dominated the storage access, has emerged as the new system bottleneck. Our investigation (see Sec. 6)

shows that 81% of transaction execution time is consumed at the storage layer.

This inefficiency in the blockchain storage layer originates from the requirement for *authentication*. A standard permission-less blockchain system has two types of blockchain nodes: the full nodes and the light nodes. A full node synchronizes and executes all transactions, maintaining the blockchain ledger state. A light node (client) only synchronizes the block headers, excluding transactions and the blockchain ledger state. Blockchain ledger states take the form of key-value pairs. When a light node needs to ascertain the value of a given key, it queries a full node. However, since blockchain nodes are permissionless, light nodes should not trust the responses from full nodes. Therefore, the blockchain protocol requires the block proposer to compute a commitment (termed the *state root*) for the latest ledger state and insert it into the proposed block header. A block header with an incorrect commitment is deemed invalid. When responding to the queries from light nodes, a full node can generate proofs corresponding to the commitments to convince the queriers. This leads to the naming of the ledger state as *authenticated*.

Typically, authenticated storage employs the Merkle Patricia Trie (MPT) [5] structure, a specific variant of the Merkle tree. Each leaf node in an MPT stores a value, and the path from the root to the leaf node corresponds to the key of the stored value. Each inner node in the MPT stores the crypto hash of the concatenated contents of all its children. The MPT's root hash serves as the commitment of the blockchain state for authentication.

Unfortunately, this authentication comes with a heavy performance price. Modifying a key-value pair in the state requires an MPT to update hashes of all nodes along the path from the corresponding leaf node to the root. If not cached, each state update operation could be amplified to  $O(\log n)$  disk I/O operations, where  $n$  represents the storage size. Note that even a basic payment transaction involves at least two ledger

state updates, – decreasing the sender’s balance and increasing the receiver’s. As the throughput of recent blockchains approaches thousands of transactions per second, it is not surprise that storage becomes the new bottleneck.

This paper presents LVMT, a novel high-performance authenticated storage framework with significantly reduced disk I/O amplifications. LVMT achieves high efficiency by integrating a multi-level Authenticated Multipoint evaluation Tree (AMT) and a series of append-only Merkle trees. AMT is a cryptographic vector commitment scheme that can update commitment (i.e., the hash root) in constant time [50]. Despite its constant commitment update time, there are several key challenges to address when incorporating AMT into the LVMT design.

The first challenge arises from the expensive elliptic curve multiplication operations employed by the AMT commitment update algorithm. A naive approach would paradoxically result in a slower state update operation on the AMT than the MPT, despite the theoretically reduced amplification. LVMT addresses this challenge with its novel *key-versioned-value* design. It assigns each key a version, incrementing as the value evolves. Rather than storing key-value pairs in the AMT, LVMT employs AMT to keep key-version pairs and uses Merkle Trees to maintain an append-only authenticated list of *key-version-value triples*. Thus, every update in LVMT results in an increment of the stored version within the AMT. Since the AMT algorithm multiplies a precomputed elliptic curve point with the difference between the old value and the new value (i.e., one for a version increment) during a commitment update, LVMT effectively eliminates the expensive multiplication. Also, because the key-version-value triple list is append-only, LVMT only needs to construct these Merkle Trees once during the block commit time, and therefore the process is very efficient.

The second challenge emerges from AMT’s limitation in supporting the necessary bit-depth for blockchain state keys. An AMT with  $k$ -bit key-space requires public parameters with  $2^k$  elliptic curve points. To enable efficient update, the AMT also requires pre-computation and caching of elliptic curve points proportional to the public parameters’ size. Even for a modest 32-bit key-space, the precomputed metadata size would exceed 256 GB, which is untenable, given that blockchain ledger keys typically comprise 256 bits. To address this challenge, LVMT operates with a novel *multi-level multi-slot structure*, integrating multiple AMTs. Each AMT in this structure has a 16-bit key-space, and the structure can automatically generate a sub-AMT on the next level to accommodate keys-version pair with collided prefix. Since collisions are rare after the first level and creating sub-AMT will make subsequent access more expensive, LVMT also makes each

entry in AMTs contain five slots. Therefore expansion to the next level only occur when more than five collisions arise.

The third challenge lies in the costly maintenance of proof generation metadata. While updating the root hash for AMT incurs constant time, maintaining the proof generation metadata still requires  $O(\log n)$  time and triggers the same degree of I/O amplifications as MPT. LVMT confronts this issue with a *proof sharding technique*, which distributes the proof generation metadata to multiple nodes. In LVMT, each full node only maintains the proof generation metadata for a shard of the blockchain state (e.g., keys sharing the same 4-bit prefix). Our observation reveals that there are typically thousands of full nodes in a production blockchain, and it’s unnecessary for all nodes to maintain proof generation capabilities for all key-value pairs in the total state. Even sharded, for any part of the state, there will still be enough nodes serving proof generation requests from light clients. Within the current Ethereum ecosystem, most light nodes access full nodes from specialized providers, such as Infura, who operate several full nodes to balance query workload. By maintaining proof shards across their nodes, these providers can efficiently generate proof for any key. Note that unlike other sharding designs [18, 29, 34, 51, 53], our proof sharding does not alter the essential obligation of each full node to synchronize and validate blocks, process all transactions, and accurately maintain the state root, thereby preserving security.

We have implemented LVMT [1] and integrated it into Conflux [2, 33], an open-sourced high-performance blockchain production with smart contract support. We evaluated LVMT against OpenEthereum’s MPT implementation, RainBlock’s MPT structure [40], and LMPTs [20], considering both stand-alone read/write workload and end-to-end blockchain processing tasks. Our results show that LVMT achieves up to 10x higher throughput on random state read/write operations. When integrated end-to-end with a high-performance blockchain, LVMT achieves up to 2.7x higher throughput for simple payment transactions and up to 2.1x higher throughput for ERC20 [41] token transfer transactions. This boost in performance stems from the considerable reduction in disk I/O amplifications. In terms of amplification, LVMT performs up to 4.1x better than MPT on read operations and up to 8.2x better on write operations.

## 2 Background

In this section, we recall some background on cryptographic concepts that our system builds on. In particular, we introduce the cryptographic building blocks of the Authenticated Multipoint evaluation Tree (AMT) [50], an efficient vector commitment protocol.

**Notations:** We denote  $[n]$  as the integers in  $\{x \in \mathbb{Z}^+ | 1 \leq x \leq n\}$ .  $\mathbb{G}$  signifies an elliptic curve group and symbols in upper cases like  $G, P$  represent elements in the elliptic curve groups.  $\mathbb{Z}_p$  refers to an additive group with order  $p$ .

## 2.1 Authenticated Storage in Blockchain

In a standard permission-less blockchain system, blockchain nodes can be distinguished into two types: full nodes and light nodes. A full node synchronizes and executes all transactions, maintaining the blockchain ledger state accordingly. A light node (client) synchronizes only the block headers, excluding transactions and blockchain ledger state.

When a full node proposes a new block, it is required to execute transactions in that block and incorporate the commitment of the post-execution ledger state into the block header. The node keeps a write-back cache during transaction execution, committing all modifications to the storage after executing all transactions in a block. The authenticated storage needs to provide two interfaces to the execution engine:

- $\text{Get}(k) \rightarrow v$ : Retrieves the value  $v$  associated a given key  $k$ .
- $\text{Set}(\{(k, v)_i\}, e) \rightarrow \text{comm}$ : Flushes a series of key-value pairs  $(k, v)$  to the storage with block number  $e$ , obtaining the commitment  $\text{comm}$  of the ledger state after changes.

When a light node wants to know the value of a specific key, it queries a full node, expecting a response of the value along with proof with respect to the ledger commitment. The light client examines whether the commitment exists within the set of verified valid commitments, then checks the validity of the associated proof. So the authenticated storage must provide two algorithms for proof generation and verification:

- $\text{Respond}(k) \rightarrow (v, \pi, \text{comm})$ : Returns the value  $v$  of key  $k$  with proof  $\pi$  with respect to the most recent commitment  $\text{comm}$ .
- $\text{Verify}(k, v, \pi, \text{comm}) \rightarrow \text{true/false}$ : Validates the response from the full node.

## 2.2 Elliptic Curve Group

The *elliptic curve group* plays a fundamental role in various cryptographic protocols. This group conducts an additive operation over points on an elliptic curve, such as  $\{(x, y) \in \mathbb{Z}_q^2 | y^2 = x^3 + x + 7\}$ , where  $q$  is a large prime number. An infinite point is included as the identity element. The operation  $a \cdot P$  represents  $P$  added to itself  $a$  times within the group, where  $a$  is a positive integer, and  $P$  is a point on the curve. An elliptic curve group is characterized by a *starting point*  $G$ , from which a sequence of points  $G, 2 \cdot G, 3 \cdot G, \dots$  can be generated. If the elliptic curve group is cryptographically secure, this sequence exhibits the following properties:

1.  $n \cdot G$  is periodic in  $n$ , with the period being a large prime integer  $p$ , i.e.,  $n \cdot G = (n + p) \cdot G$ ;
2. For a randomly selected  $n$ , deriving  $n$  from  $n \cdot G$  is computationally unfeasible.

## 2.3 KZG Commitment

Kate et al. proposed KZG polynomial commitment protocol [28], enabling someone to commit a polynomial function  $f$  to a commitment, and prove the value  $f(x)$  of any given position  $x$  with respect to that commitment.

The KZG commitment protocol is built on a bilinear map. Consider  $G_1$  and  $G_2$  as the starting points of two elliptic curve groups  $\mathbb{G}_1, \mathbb{G}_2$  respectively, each with the same group order  $p$ . The bilinear map  $e : \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_T$  is homomorphic such that the equation  $e(a \cdot G_1, b \cdot G_2) = ab \cdot e(G_1, G_2)$  holds for any  $a, b \in \mathbb{Z}_p$ . Here,  $\mathbb{G}_T$  denotes another group of the same order  $p$ . BLS12-381 [14] from BLS families [9] and BN254 [11] from BN families [10] are widely-used deployed systems implementing bilinear maps. The groups  $\mathbb{G}_1$  and  $\mathbb{G}_2$  are elliptic curve groups of order  $p$ , and  $G_1$  and  $G_2$  are their perspective starting points.

For a given polynomial function  $f : \mathbb{Z}_p \rightarrow \mathbb{Z}_p$  of degree  $n$ , the KZG commitment assumes a series of public parameters  $\tau \cdot G_1, \tau^2 \cdot G_1, \tau^3 \cdot G_1, \dots, \tau^n \cdot G_1$  in a trusted setup and commits function  $f$  to  $C := f(\tau) \cdot G_1$ . The public parameters are generated by a trusted party using a random  $\tau$ , which is forgotten after generation. Secure multi-party computation protocols [15, 16, 25] enable multiple participants to collaboratively generate these public parameters, ensuring that no participant can ascertain the exact value of  $\tau$ .

For any index  $i \in \mathbb{Z}_p$ , the expression  $x - i$  should divide  $f(x) - f(i)$ . This suggests that  $h_i(x) := \frac{f(x) - f(i)}{x - i}$  is indeed a polynomial. Hence, the proof  $\pi$  of  $f(i)$  is defined as  $h_i(\tau) \cdot G_1$ . Given that  $h_i(x)$  is a polynomial, the prover can compute the coefficients of  $h_i(\tau)$ . Thus,  $h_i(\tau) \cdot G_1$  forms a linear combination of the public parameters with known coefficients. The prover can compute it in a short time. A verifier, querying  $i$  with answer  $y = f(i)$  and proof  $\pi := h_i(\tau) \cdot G_1$ , can verify the proof by checking if

$$e(\pi, (\tau - i) \cdot G_2) = e(C - y \cdot G_1, G_2).$$

If the proof  $\pi$  is correctly constructed, the check must pass because

$$\begin{aligned} e(\pi, (\tau - i) \cdot G_2) &= (h(\tau) \cdot (\tau - i)) \cdot e(G_1, G_2) \\ &= e((f(\tau) - f(i)) \cdot G_1, G_2) \\ &= e(C - y \cdot G_1, G_2). \end{aligned}$$

If  $f(i) \neq y$ ,  $h(x)$  becomes a fraction, making it difficult to find a proper proof without knowing  $\tau$ . Kate et al. proved the binding property of this protocol [28].

The KZG commitment also supports the proof of a batch of positions. To prove that  $f(x)$  equals to 0 at a set of positions  $S$ , the proof  $\pi$  is constructed by  $\frac{f(\tau)}{\prod_{i \in S} (\tau - i)} \cdot G_1$ .

A vector commitment scheme can be built with KZG commitment by converting a vector  $\vec{a}$  to a polynomial function  $f$  by Lagrange interpolation. Formally, for an input vector  $\vec{a}$  with  $n$  elements, the interpolated function  $f$  is defined by  $f(x) = \sum_{i=1}^n a_i \cdot I_{i,n}(x)$ , where  $a_i$  is the  $i$ -th element of  $\vec{a}$  and  $I_{i,n}(x)$  is a Lagrange function that satisfies  $I_{i,n}(i) = 1$  and  $I_{i,n}(x) = 0$  for  $x \neq i$  and  $1 \leq x \leq n$ .

When updating the value at position  $i$  from  $a_i$  to  $a'_i$ , the corresponding commitment  $C$  can be simply updated to

$$C' := C + (a'_i - a_i) \cdot I_{i,n}(\tau) \cdot G_1. \quad (1)$$

If the prover caches results  $I_{i,n}(\tau) \cdot G_1$  for all  $i$ , updating commitment requires only one multiplication and one addition on the elliptic curve  $\mathbb{G}_1$ , which takes  $O(1)$  time.

## 2.4 Authenticated Multipoint Evaluation Tree

Although the KZG commitment enables constant-time updates to the commitment  $C$ , it requires  $O(n)$  time to construct a proof for a given position or to maintain proofs for all positions. In a blockchain system, where the vector being committed to is frequently changing, the KZG commitment cannot generate proofs efficiently for queries with arbitrary indices  $i$ .

To address this issue, Alin et al. proposed the Authenticated Multipoint evaluation Trees (AMT) commitment protocol [50], which maintains auxiliary information of size  $O(n \log n)$  and can generate a proof in  $O(\log n)$  time.

Consider an example with  $n = 8 = 2^3$ . For an input vector  $\vec{a}$  with eight elements, AMT computes its Lagrange interpolation  $f(x)$  which satisfies  $f(i) = a_i$  for  $1 \leq i \leq 8$ . The function  $f(x)$  is then partitioned into two functions  $f_0(x)$  and  $f_1(x)$ . In the subset  $x \in [8]$ ,  $f_1(x)$  mirrors  $f(x)$  for even  $x$  and is zero otherwise, while  $f_2(x)$  mirrors  $f(x)$  for odd  $x$  and is zero otherwise. For values of  $x$  outside this subset,  $f_1(x)$  and  $f_2(x)$  are determined by Lagrange interpolation. Consequently,  $f(x)$  can be re-expressed as  $f(x) = f_0(x) + f_1(x)$ . AMT continues to subdivide  $f_0(x)$  recursively into two functions:  $f_{0,0}(x)$  and  $f_{0,1}(x)$ . Here,  $f_{0,0}$  mirrors  $f(x)$  for  $x \in \{4, 8\}$ , and  $f_{0,1}(x)$  mirrors  $f(x)$  for  $x \in \{2, 6\}$ . This recursive process of partitioning generates a full binary tree, where each node corresponds to a function. Each inner node's function is the sum of the function at its child nodes, and each leaf node is a multiplication of an identity Lagrange function because it mirrors  $f(x)$  at a single point  $x$ . For example,  $f_{0,0,1}(x) = a_4 \cdot I_{4,8}(x)$ .

Each inner node of the AMT is associated with two elements: 1) the KZG commitment of its corresponding function and 2) a batch proof for the indices at which the function is zero according to the partitioning process. Detailed definitions of these elements are provided in the appendix. When proving the value of a given entry, e.g.,  $a_4$ , the prover finds the path from the root to the corresponding leaf node:  $f(x) \rightarrow f_0(x) \rightarrow f_{0,0}(x) \rightarrow f_{0,0,1}(x)$ . It then iteratively decomposes functions along this path to express  $f(x)$  into as a sum of four components:  $f_1(x) + f_{0,1}(x) + f_{0,0,0}(x) + f_{0,0,1}(x)$ . The prover then outputs the associate commitments for  $f_1(x)$ ,  $f_{0,1}(x)$ , and  $f_{0,0,0}(x)$ , alongside their batch proofs demonstrating these functions equal to zero at  $x = 4$ . The verifier checks the correctness of these batch proofs and the consistency among commitments: whether the sum of commitments for  $f_1(x)$ ,  $f_{0,1}(x)$ ,  $f_{0,0,0}(x)$ , and  $f_{0,0,1}(x) = a_4 \cdot I_{4,8}(x)$  equals to the commitment for  $f(x)$ .

Updating an entry in the AMT involves traversing from the root to the leaf corresponding and updating the associate elements along this path. The remaining are not affected, enabling AMT to maintain the proofs in  $O(\log n)$  time.

The nodes of the AMT serve as *auxiliary information* for generating proofs only. In a blockchain system, a miner without serving client queries may discard this auxiliary information and only maintain the commitment, which can be updated in constant time.

## 3 Overview

Recent works [32, 42] have shown that the majority of transactions execution time is spent on operations that access the blockchain state. For instance, a profiling experiment [32] shows that read and write operations to the blockchain state account for more than 67% of the execution time for the transaction executing the transfer function of ERC-20 smart contract [4, 41]. In this section, we present an overview of how LVMT tackles this problem. In particular, we propose a new authenticated storage system to reduce the amplification of read and write operations that access the blockchain state.

Our proposed system is based on AMT since it has an ideal time complexity, i.e., constant cost in updating the commitment. In particular, our proposed system solves several challenges to implement an efficient blockchain storage system using AMT:

First, although AMT costs constant time in updating the commitment, the constant ratio is large for a blockchain system. Table 1 shows the result of a micro-benchmark carried on an Intel i9-10900K CPU machine. It shows the time cost for basic cryptographic operations. Note that an elliptic curve multiplication takes about 0.1 ms, which is even much slower

(a) Multi-level AMTs

(b) Versioned key-value database

(c) Maintenance and proving on Multi-level AMTs

Figure 1: LVMT architecture.

| Pairing engines | BLS12-381 | BN254 |
|-----------------|-----------|-------|
| Addition        | 0.68      | 0.34  |
| Multiplication  | 169       | 92    |

Table 1: Time cost of operations over the primary curve  $\mathbb{G}_1$  of pairing functions ( $\mu s$ ).

than an updating operation in MPT.

Second, to support data with  $n$  maximum entries, AMT requires precomputed parameters in size of  $O(n \log n)$  and maintains auxiliary information in size of  $O(n \log^2 n)$ . Thus, AMT cannot support key-value pairs for an arbitrary-length bit string. As the size of the blockchain ledger state continues to grow, AMT is not a scalable solution.

Last, a blockchain system must consider the slowest node. Even if most miners do not need to maintain the auxiliary information for proof, the authenticated storage must guarantee the nodes for responding queries can keep up.

We propose the following techniques to resolve the challenges above. First, we design a versioned database that only stores the version number of keys in AMT, thereby avoiding

the elliptic curve multiplications. This design also supports arbitrary lengths of values, as they are not stored in AMT. Second, we extend AMT to multiple levels to accommodate version numbers for unlimited keys, making the AMT size relatively small to optimize cache for parameters. To support arbitrary key lengths and minimize deep updates in the multi-level hierarchy, we utilize key hashes to allocate slots for version numbers. Last, we introduce proof sharding to reduce the single node's cost in maintaining auxiliary information for proofs.

### 3.1 Versioned Key-value Database

We designed a versioned authenticated storage to avoid multiplication on the elliptic curve during commitment updates. As shown in Figure 1b, the multi-level AMTs store key-version pairs, which only serve to identify the recent version number of a key. LVMT accumulates the key-version-value tuples in an append-only authenticated data structure consisting of a series of Merkle trees, with each block constructing one Merkle tree from the key-version-value tuples for value changes in

that block.

Imagine a scenario where the blockchain processes a block, setting a key-value pair  $(key, val)$ . LVMT first locates the corresponding entry of  $key$  in the multi-level AMTs to increment the stored version number by one. Assume the new version number for  $key$  is  $ver$ . LVMT then appends a new tuple  $(key, ver, val, loc)$  to the Merkle tree being constructed for the block. Here,  $loc$  is a tuple  $(level, slot)$  that records the level and slot in the multi-level AMTs where the key's version is located. The construction cost of a Merkle tree is linear with the number of version tuples. Once constructed, the Merkle tree for a block remains immutable, except for garbage collection of obsolete nodes. As the blockchain is append-only, the list of these Merkle trees is also append-only.

When generating a proof for a key-value pair  $(key, val)$ , LVMT first use the multi-level AMTs to prove the most recent version  $ver$  of the key  $key$ . It then uses Merkle trees to prove the existence of a tuple  $(key, ver, val, loc)$ . Since the roots of the Merkle trees are endorsed by the blockchain consensus protocol, light clients can trust that the Merkle trees are generated correctly without duplicate tuples having the same  $key$  and  $ver$ . As the location of the version slot is included in the version tuple of the key, the prover can not cheat by providing a version number proof of another slot.

Note that updating one element  $a_i$  to  $a'_i$  in an AMT requires computing  $(a'_i - a_i) \cdot I_{i,n}(\tau) \cdot G_1$  (equation 1), multiplying  $a'_i - a_i$  to the elliptic curve point  $I_{i,n}(\tau) \cdot G_1$ . In the versioned key-value database,  $a_i$  is essentially a version number and  $a'_i - a_i$  always equal 1. Thus, we eliminate an elliptic curve multiplication in each storage write, saving approximately 100  $\mu s$ .

Since the frequency of bumping version number is limited by the block generation rate, we can conserve the bits used for storing version number and store multiple version numbers in a one vector entry. For example, when employing BN254 as the underlying bilinear mapping parameter, each entry is an element in  $\mathbb{Z}_p$ , where  $p$  is a prime integer in  $(2^{254}, 2^{255})$ . This suggests that implies each entry can store at most 254 bits. In a blockchain system generating 10 blocks per second, the version number will not exceed  $2^{40}$  in 3000 years. So each entry can be divided into six slots with 40 bits as shown in Figure 1a.

## 3.2 Multi-level AMT

To make AMT scalable and allow it to store the version number for an unlimited number of keys, we introduce multi-level AMTs as shown in Figure 1a. The authenticated storage is initiated by one AMT as *the root AMT*. Each entry in the AMT contains several slots for storing version numbers. One slot in each entry is reserved for storing the version number

of the commitment hash of the sub-AMT, with the remaining slots utilized for key-value pairs.

Let  $k$  denote the height of the AMT. When allocating a slot for a new key, LVMT accesses the entry in the root AMT whose index aligns with the first  $k$  bits of the key hash. If this entry lacks a vacant slot, LVMT accesses the corresponding sub-AMT and locates the entry in the sub-AMT whose index matches the next  $k$  bits of the key hash. LVMT recursively visits the sub-AMTs to find a vacant slot for the new key. Figure 1a presents an example with  $k = 2$  for allocating a version slot for a key with hash  $100111\dots$ . As the first two bits of key hash are 10, LVMT accesses the entry with index 2 and attempts to find a vacant slot. Since all slots in the entry are occupied, LVMT proceeds to the corresponding sub-AMT-2. Picking the next two bits 01, it accesses the entry with index 1, and recursively visits the sub-AMT-(2,1) because there is no vacant slot again. Finally, LVMT finds the third slot at the third level being vacant and allocates this slot.

The commitment of a sub-AMT is treated similarly to a key-value pair, where the key represents the index of the sub-AMT and the value is the commitment. The Merkle trees not only store key-version-value tuples for standard key-value pairs, but they also store the tuples of the sub-AMT index, the version of the sub-AMT commitment, and the commitment hash.

Figure 1c illustrates how LVMT maintains the AMTs and Merkle trees when a block changes the key with hash  $100111\dots$ . LVMT first increments the version number for this key by one. This in turn alters the commitment of sub-AMT-(2,1), prompting LVMT to also increase the version number for the commitment (the slot labeled "B") by one. Recursively, the commitment of sub-AMT-2 is changed and the version number labeled "A" is updated. Finally, LVMT gets the updated commitment of the root AMT. LVMT appends the tuples of changed keys and commitments into the Merkle trees along with the normal tuple of the key-value pair.

When generating a proof for this key, LVMT finds the most recent version of tuples for sub-AMT-2, sub-AMT-(2,1) and this key. LVMT proves the existence of these tuples in Merkle trees and confirms the correctness of appeared version numbers with respect to their AMT commitments. When proving the non-existence of a key, LVMT affirms that all the possible slots for this key are vacant or have been allocated to other keys.

## 3.3 Proof Sharding

We recall that the AMT maintains a binary tree, where each node holds a commitment and a batch proof. Each input entry corresponds to a leaf in this tree. When generating a proof, AMT picks commitments and batch proofs from the siblings

of nodes along the path from this leaf to the root. Each node can be updated independently of the other nodes, facilitating the parallelization of tree maintenance. Each blockchain node can maintain a shard of the proof. It picks a subtree of the root AMT and takes responsibility for generating proofs for the leaves in this subtree, and the sub-AMTs extended from these leaves. Multiple blockchain nodes can collaboratively generate proof for any key. Similarly, the storage for the Merkle tree can be distributed to multiple nodes by the block number.

## 4 LVMT Design

Now we formally define LVMT, which utilizes a key-value database as a backend and maintains a tuple of key-value maps (KM, AM, MM, VM, LM) where KM stores the key-value pairs, AM stores the AMTs data structures, MM stores the Merkle trees, VM stores the version slots metadata for keys, and LM records the position of the most recent tuple for a key or a sub-AMT in the Merkle trees. LVMT decouples the data storage and data authentication: KM stores unauthentication data; AM and MM store the authenticated information; VM and LM store the metadata and indices for authenticated information. Each AMT in LVMT encompasses the following components:

- comm: the commitment of AMT;
- proof\_tree: the proof tree of AMT;
- leaves: a list of leaves; leaves[ $i$ ] denotes the leaf corresponding to the  $i$ -th element of the input vector. Each leaf comprises the two lists vers and keys. vers[0] stores the version number for the sub-AMT. vers[1] to vers[5] store the version numbers for the keys keys[1] to keys[5], respectively. Note that only vers contribute to the AMT commitment.

### 4.1 Interfaces to the Transaction Execution

LVMT provides the following two interfaces (instructions) for the blockchain execution layer:

- Get( $k$ )  $\rightarrow$  val: Reads the value val stored in  $k$ ;
- Commit( $\mathbf{W}, e$ )  $\rightarrow$  (aroot, hroot): Flushes the changed key-value pairs in  $\mathbf{W}$  with block number  $e$  and produces the commitment of LVMT.

These interfaces match the requirements from the blockchain execution engine introduced in Section 2.1. The execution engine uses Get to fetch data from the storage and LVMT simply loads the value correspondingly from KM.

The instruction Commit is invoked after the execution of a block. LVMT commits the key-value pairs  $\mathbf{W}$  using the procedure COM defined in Algorithm 1. The returned commitments will be filled in the block header. The commit returned values

---

**Algorithm 1** A procedure to compute a commitment. It takes a list of key-value pairs  $\mathbf{W}$  and a block number  $e$ , and returns the commitments aroot and hroot.

---

```

1: procedure COM( $\mathbf{W}, e$ )
2:    $\mathbf{M} \leftarrow []$ ;  $\mathbf{T} \leftarrow \{\}$ ;
3:   foreach ( $k, val$ ) in  $\mathbf{W}$ 
4:     ( $lv, tid_x, sid_x, ver$ )  $\leftarrow$  ComKV( $k, val$ );
5:      $\mathbf{M} \leftarrow (k, ver, val, lv, sid_x) :: \mathbf{M}$ ;
6:      $\mathbf{T} \leftarrow \{(lv, tid_x)\} \cup \mathbf{T}$ ;
7:    $i \leftarrow$  maximum  $lv$  in  $\mathbf{T}$ ;
8:   while  $i \geq 0$ 
9:     foreach ( $lv, tid_x$ ) in  $\mathbf{T}$  with  $lv = i$ 
10:      ( $C, ver$ )  $\leftarrow$  UpdComVer( $lv, tid_x$ );
11:       $\mathbf{M} \leftarrow (lv, tid_x, ver, comm) :: \mathbf{M}$ ;
12:      if  $lv > 0$ 
13:         $\mathbf{T} \leftarrow \{(lv - 1, \lfloor tid_x/n \rfloor)\} \cup \mathbf{T}$ ;
14:   foreach ( $k, ver, val, lv, sid_x$ ) in  $\mathbf{M}$  with index  $i$ 
15:     LM[ $k$ ]  $\leftarrow (e, i)$ ;
16:   foreach ( $lv, tid_x, ver, C$ ) in  $\mathbf{M}$  with index  $i$ 
17:     LM[ $(lv, tid_x)$ ]  $\leftarrow (e, i)$ ;
18:   Build merkle tree of  $\mathbf{M}$  and store inner nodes in MM;
19:   mroot  $\leftarrow$  Merkle root of  $\mathbf{M}$ ;
20:   hroot  $\leftarrow$  Merkle root of the mroot of all the commits;
21:   aroot  $\leftarrow$  AM[ $(0, 0)$ ].comm;
22:   return (aroot, hroot);
```

---

---

**Algorithm 2** A procedure to compute the commit of a key-value pair. It returns the level  $lv$ , the tree index  $tid_x$ , the slot index  $sid_x$  of the changed AMT, and the version  $ver$ .

---

```

1: procedure COMKV( $k, val$ )
2:   if KM contains  $k$ 
3:     ( $lv, sid_x$ )  $\leftarrow$  VM[ $k$ ];
4:   else
5:     ( $lv, sid_x$ )  $\leftarrow$  ALLOCATESLOT( $k$ );
6:     VM[ $k$ ]  $\leftarrow (lv, sid_x)$ ;
7:     ( $tid_x, lf$ )  $\leftarrow$  LEAFATLEVEL( $lv, k$ );
8:      $ver \leftarrow lf.ver[sid_x]$ ;
9:      $lf.ver[sid_x] \leftarrow lf.ver[sid_x] + 1$ ;
10:    Update the corresponding commitments and proofs.;
11:     $ver \leftarrow ver + 1$ ;
12:    return ( $lv, tid_x, sid_x, ver$ );
```

---

---

**Algorithm 3** A procedure to allocate a version slot to a new key. It takes the key  $k$  to allocate a slot for, and returns the level and the allocated slot index.

---

```

1: procedure ALLOCATESLOT( $k$ )
2:    $lv \leftarrow 0$ ;
3:   while true
4:     ( $tid_x, leaf$ )  $\leftarrow$  LEAFATLEVEL( $lv, k$ );
5:     for  $j \in [5]$ 
6:       if leaf.ver[sid_x] == 0
7:         leaf.keys[ $j$ ]  $\leftarrow k$ ;
8:         return ( $lv, j$ );
9:      $lv \leftarrow lv + 1$ ;
```

---

consist of the roots of both the top-level AMT and MPT.

The procedure COM first commits the key-value pairs in  $\mathbf{W}$  (Lines 3 to 6) with the sub-procedure COMKV. Then it updates the version numbers of all the affected sub-AMTs from the deepest sub-AMT to the root AMT (Lines 7 to 13) using the procedure UPDCOMVER. This procedure maintains

---

**Algorithm 4** A procedure to compute the AMT index and the leaf index of a key  $k$  at a AMT level  $lv$ . It returns the tree index  $tidx$  and the leaf  $leaf$  corresponding to the key  $k$  at level  $lv$ .

---

```

1: procedure LEAFATLEVEL( $lv, key$ )
2:    $tidx \leftarrow$  first bit to  $(k \cdot lv)$ -th bit of  $H(key)$ ;
3:    $lidx \leftarrow$   $(k \cdot lv + 1)$ -th bit to  $(k \cdot (lv + 1))$ -th bit of  $H(key)$ ;
4:    $leaf \leftarrow AM[(lv, tidx)].leaves[lidx]$ ;
5:   return ( $tidx, leaf$ );

```

---

**Algorithm 5** A procedure to update the commitment and version of an AMT at level  $lv$  and tree index  $tidx$ . It returns the commitment  $C$  and the updated version number  $ver$ .

---

```

1: procedure UPDCOMVER( $lv, tidx$ )
2:    $C \leftarrow AM[(lv, tidx)].comm$ ;
3:    $ptidx \leftarrow \lfloor tidx/n \rfloor$ ;
4:    $plidx \leftarrow tidx \bmod n$ ;
5:    $ver \leftarrow AM[(lv, ptidx)].leaves[plidx].ver[0]$ ;
6:   Increase  $AM[(lv, ptidx)].leaves[plidx].ver[0]$  by 1;
7:   Update the corresponding commitments and proofs;
8:    $ver \leftarrow ver + 1$ ;
9:   return ( $C, ver$ );

```

---

the version number for commitments of sub-AMTs similar to COMKV. While maintaining the version numbers, LVMT collects the tuples of keys, versions, values, and other metadata in a list  $\mathbb{M}$  (Line 5). The system treats a pair of the sub-AMT index and its commitment similarly to a key-value pair (Line 11). LVMT builds a Merkle tree for  $\mathbb{M}$ , thereby authenticating the value of a given key and version (Line 19). It also stores the positions of these elements in the Merkle trees (Lines 15 and 17). So when generating a proof, the prover can locate the corresponding Merkle leaves of a key or an AMT commitment.

The sub-procedure COMKV (Algorithm 2) is implemented to maintain and update the version numbers. COMKV( $k, val$ ) first finds the allocated version slot for the given key  $k$  (Line 3). If the key has not been allocated a version slot, it allocates a slot to it (Line 5). It uses the sub-procedure ALLOCATESLOT (Algorithm 3) to find a vacant slot in the AMT to allocate. In particular, starting from the root AMT, ALLOCATESLOT computes the tree and leaf indices for the given key at each level, checks if the leaf has a vacant slot, and then returns the level and slot indices of the slot; if the leaf doesn't have a free slot, it proceeds to the next level.

Then, COMKV computes the corresponding tree index  $tidx$  and the leaf  $lf$  for  $k$  at level  $lv$  (Line 7) using the sub-procedure LEAFATLEVEL (Algorithm 4), which finds the corresponding AMT index and leaf for the key  $k$  at the level  $lv$  using the hash  $H(k)$  of  $k$ . Since each AMT has  $m$  levels and  $2^m$  leaves, the first  $m \cdot lv$  bits of  $H(k)$  decides the AMT index and the subsequent  $m$  bits locate the leaf in the tree. Finally, COMKV locates the slot for this key and updates its version and other information according to AMT's rule (Line 8 to 10).

---

**Algorithm 6** A procedure to generate a proof for an existing key  $k$ . It returns the proof of the key.

---

```

1: procedure GENPROOF( $k$ )
2:    $keypf \leftarrow$  PROVEKEY( $k$ );
3:    $(lv, sidx) \leftarrow VM[k]$ ;
4:   while  $lv > 0$ 
5:      $tidx \leftarrow$  first bit to  $(k \cdot lv)$ -th bit of  $H(k)$ ;
6:      $commpfs[lv] \leftarrow$  PROVECOM( $lv, tidx$ );
7:      $lv \leftarrow lv - 1$ ;
8:   return ( $keypf, commpfs$ );

```

---

**Algorithm 7** A procedure to verify the proofs  $keypf$  and  $commpfs$  with respect to an AMT root  $aroot$  and Merkle root  $mroot$ .

---

```

1: procedure VERIFYPROOF( $keypf, commpfs, aroot, mroot$ )
2:   Verify the AMT proofs and the merkle proofs in  $keypf$  and  $commpfs$ ;
3:   Verify the commitment in  $commpfs[1]$  equals to  $aroot$ 
4:   if all the verification pass
5:     return true;
6:   else
7:     return false;

```

---

The sub-procedure UPDCOMVER (Algorithm 5) updates the commitment and its version number given an AMT located by its level and index.

## 4.2 Proving Key-value Pairs

As an authenticated storage, LVMT provides the following two interfaces to allow a user to query a value from an untrusted server and to verify the value with the commitment.

- GenProof( $k$ )  $\rightarrow \pi$ : Generates proof  $\pi$  for key  $k$ ;
- Verify( $k, v, \pi, comm$ )  $\rightarrow$  true/false: Verifies the key value pair  $(k, v)$  with respect to a ledger state commitment.

When responding to a query  $k$  from a light node, a full node will generate proof  $\pi$  using the procedure PROVE and responde with the loaded value and the current commitment.

The procedure PROVE (Algorithm 6) consists of two parts: 1) the proof of the value  $val$  of the key  $k$  with respect to the sub-AMT it belongs to (line 2) using the sub-procedure PROVEKEY; 2) the proof of the commitment for all the sub-AMT along the path from  $k$ 's sub-AMT to the root AMT (excluding the root AMT) (line 4 to line 7) using the sub-procedure PROVECOM.

The generated proof consists of a merkle proof for the existence of the tuple of the key (or the AMT index), the value (or the AMT commitment) and the version, an AMT proof for the version number, and other metadatas. We provide the definition for the sub-procedures PROVEKEY (Algorithm 8) and PROVECOM (Algorithm 9) in the supplementary material. In the supplementary material, we also discuss how to generate a non-existing proof.

The light node verifies the proof using the procedure VERIFY (Algorithm 7), which recovers the tuple of Merkle leaves to be verified from the proof and verifies the AMT proofs and the merkle proofs.

## 5 Implementation

We implemented the AMT using Arkworks [21], a Rust library for elliptic curve operations. AMT is built using the pairing parameters BN254 and supports vector commitment in the length of  $2^{16}$ . Each entry contains 254 available bits and is divided into six slots with 40 bits. For the public parameters required by the KZG commitment, we utilize the output from the Perpetual-Powers-of-Tau ceremony [27], which conducts an MPC protocol among over 70 participants worldwide in generating secure parameters. Based on the above AMT implementation, we implemented LVMT in Rust [1]. LVMT is compatible with any backend database that provides a key-value interface as defined in rust crate “kvdb” [39].

We ported the implementation of MPT from the OpenEthereum client [48], the most popular high-performance Rust implementation of Ethereum. We also implemented a variant of RainBlock [40], which developed an efficient MPT for distributed in-memory systems, by referencing its implementation [6]. This variant incorporates significant RainBlock features, including caching of top layers in memory, in-memory construction of the Merkle tree using pointers, and the application of lazy hash resolution. Unlike RainBlock, our variant stores the bottom layers on local storage instead of a distributed in-memory system. These implementation are also compatible with the same interface.

For the implementation of LVMT, we applied several optimizations:

**Combining entries in different maps:** For a given key, we use three maps KM, VM, and LM to store its value, version slot index, and the position of the Merkle tree for the recent change, respectively. In our implementation, we combine these entries into a single key-value pair to save read and write operation for each key.

**Cache the root AMT:** The root AMT is frequently accessed. So its leaves and inner nodes of are always stored in memory. The commitments of the AMTs in the second levels are also cached. Each leaf and inner node of an AMT has two points on the elliptic curve. Given that we set the AMT height as 16, the root AMT and the commitments of AMTs in the second level store about 200,000 elliptic curve points in memory. Each point takes 96 bytes in our parameter, so roughly 20 MB of memory is needed to store them.

**Cache cryptographic parameters:** We expedited the com-

mitment update procedure by precomputing certain elliptic curve points. For instance, when the input entry at position  $i$  increases by  $\delta$ , the commitment can be updated as  $C' = C + P_i$ , where  $P_i = I_{i,n}(\tau) \cdot \delta \cdot G_1$ . Given that each entry is divided into six 40-bit slots, when the version number increases, the difference between the new and the previous version will be one of the following:  $1, 2^{40}, 2^{80}, 2^{120}, 2^{160}, 2^{200}$ . Thus, LVMT precomputes  $P_i^{(j)} = 2^{40j} \cdot P_i$  for all  $0 \leq j \leq 5$  and  $1 \leq i \leq n$ . So LVMT can simplify the commitment update procedure by merely incrementing a precomputed point. In our design, each elliptic curve point requires 96 bytes of storage. So a node excluding proof maintenance necessitates around 37 MB of memory. However, a node maintaining a shard of proof must cache additional parameters, resulting in a higher memory requirement, approximately 650 MB.

**Reduce the coordinates conversion time:** An elliptic curve point is uniquely represented by its affine coordinate  $(x, y) \in \mathbb{Z}_q^2$ , where  $q$  is a large prime number. These points can also be represented through projective coordinates  $(x, y, z) \in \mathbb{Z}_q^3$ , which accelerate arithmetic operations by eliminating division operations within a large prime field. The conversion of these projective coordinates back to the corresponding affine coordinates is given as  $(x/z^2, y/z^3) \in \mathbb{Z}_q^2$ . However, a challenge arises from the fact that a single elliptic curve point corresponds to multiple projective coordinates, leading to hashing inconsistencies. To address this issue, LVMT always converts the projective coordinates back to the affine coordinates when computing the hash of a sub-AMT commitment. This conversion process, however, is computationally intensive, taking approximately 60  $\mu$ s per conversion and can substantially impact the write speed. To alleviate this, we applied batch conversion of all projective coordinates to affine coordinates at the culmination of each block execution, decreasing the average conversion time to a mere 0.4  $\mu$ s.

**Garbage collection of append-only Merkle trees:** As a key’s version number increases, the old version tuples within the append-only Merkle trees become unnecessary for future proofs. When a subtree in a Merkle tree only has obsolete children, the entire subtree can be truncated, and only the subtree root is stored. A background thread performs this garbage collection to prevent impacting LVMT’s performance under heavy workloads. In a scenario where the append-only Merkle trees have accumulated  $m$  version tuples in the past, and only  $n$  tuples are currently active, the overhead of storing truncated Merkle trees is about  $(\log_2(m/n) + 1) \cdot 2n$ . (See appendix for the details.) While this introduces some additional overhead, it remains a practical approach.

(a) Transaction execution for balance transfers.

(b) Transaction execution for ERC-20 transfers.

Figure 2: Throughput of transaction execution

## 6 Evaluation

We evaluate LVMT’s performance and compare it to other authenticated storage systems using a machine with an Intel i9-10900K CPU, 32 GB DDR4 RAM, and SSD storages. All authenticated storage systems utilize RocksDB [47] as their backend key-value database.

We assess LVMT under different settings: 1) LVMT without associated information (no proof shard), 2) LVMT with 1/64 and 1/16 of the associated information (proof sharding), 3) LVMT with all associated information. In this context, LVMT-r represents LVMT without any associated information, while LVMT64, LVMT16, and LVMT1 signify LVMT with 1/64, 1/16, and complete proof sharding, respectively.

In addition to LVMT, we evaluate various authenticated storage systems for comparison. As previously mentioned, we have ported the MPT in OpenEthereum and have implemented a variant of RainBlock, which we refer to as MPT and RAIN, respectively. We also examine the Layered Merkle Patricia Tries (LMPTs) [20] utilized in Conflux [2, 33], a high-performance blockchain, represented by LMPTs. For reference, we also examine the performance of directly storing data into the backend, bypassing authenticated storage, denoted as RAW.

(a) Time cost breakdown for balance transfers.

(b) Time cost breakdown for ERC20 transfers.

Figure 3: Break down of the time usage in transaction execution on 5 million receivers.

**End-to-end performance:** We assess the end-to-end performance of authenticated storage on Conflux [2, 33], a high-performance blockchain. To gauge peak performance, we set a large block size of 20,000 transactions per block. Thus, all authenticated storage systems can finish executing one block within 0.5 to 5 seconds, aligning with the block generation intervals of major high-performance blockchains. To emulate the prevalent configuration of contemporary blockchains, we employ cgroup to restrict the memory consumption of a blockchain node to 16GB and allocate a 4GB RocksDB cache size. In the experiment, 10,000 senders randomly select addresses from the receiver space and transfer non-zero balances to them, representing simple payment transactions. We evaluate receiver spaces with one million, three million, and five million addresses. Conflux is run for an extended period, ensuring the number of executed transactions is three times larger than the receiver space.

Figure 2a shows that LVMT-r achieves a maximum throughput of 29669 TPS on average and is up to 2.7 times faster than MPT and 1.7 times faster than RAIN. We also evaluate the performance of transactions executing the transfer function of the popular ERC-20 smart contract [41], the most common transactions on the Ethereum blockchain [4]. As shown in Figure 2b, LVMT-r is up to 2.1 times faster than MPT and 1.5 times faster than LMPT in this workload.

To further study the time usage in execution of one transaction, we breakdown the time usage into three parts: 1) Execution Engine, i.e., transactions execution without access to the

authenticated storage, 2) Authenticated Structure, i.e., access to the authenticated storage without accesses the backend database, 3) Backend Database, i.e., accesses to the backend database. Figure 3a shows the breakdown of time usage in executing random balance transfer transactions with 5 million receivers. The execution engine takes the same time 16 us across the different storages. LVMT-r takes a similar time 11 us with RAW in accessing the backend. It implies LVMT-r almost eliminates the overhead of the authenticated storage from backend access. LVMT64 and LVMT16 take a similar time to LVMT. MPT requires 42 us and 33 us to access the authenticated structure and the backend database, respectively, which is more than 4x the time used in LVMT-r. As shown in Table 1, a single elliptic curve multiplication requires 92 us, which is even slower than MPT. Therefore, eliminating the expensive elliptic curve operation is necessary to make LVMT practical. Figure 3b shows the breakdown in executing random ERC20 transfers. The execution engine still takes the same time across the different storages but takes more time than the execution of the balance transfer. This is because the execution of ERC20 transfers requires more I/O accesses (e.g., loading contract bytecode). All the storages take about 20% more time than executing balance transfers.

This experiment shows that LVMT is able to maintain better throughput than MPT for both simple payment transactions and the typical ERC-20 smart contract transfer transactions.

**Stand-alone performance:** We also evaluate the stand-alone performance of authenticated storage systems in micro-benchmarks. We developed an authenticated storage benchmark tools [1] for evaluation. Since most transactions in the real world simply read the accounts of the sender and the receiver and update their balances, we launch a workload of 20 million random “read then write” operations and commit the changes every 100,000 operations, resembling a block being generated every several seconds. The authenticated storage is initiated with random key-value pairs whose size ranges from  $10^6$  to  $10^8$ . Both the key and the value are 256-bit strings. We use “1m”, “10m”, and “100m” to indicate the initialized size  $10^6$ ,  $10^7$  and  $10^8$ . Since LVMT needs to allocate version number slots for new keys, we also evaluate with a “fresh” setting: the storage has no initialization, and the workload accesses distinct keys.

In addition, to evaluate the performance under the real world access pattern, we extract the I/O trace on Ethereum, the largest smart contract platform. We choose transactions in 2021 winter, when Ethereum is going through its latest boom. We replay the Ethereum transactions from block 13,500,000 to block 13,600,000 to recover the I/O operations. These blocks access 22 million distinct keys, and make 97 million reads and 54 million writes in total. Each block contains an av-

erage of 1,500 operations. Considering that high-performance authenticated storage can process over 100,000 operations per second, having only 1,500 operations per block results in an unreasonably short block generation cycle. This considerably impacts RAIN’s optimization efforts for lazy hash resolutions. To address this issue, we aggregated operations from every 50 blocks into a single block, making the block size in the real trace workload more closely resemble the size in a random access workload. We use “real” to denote the workload from real world transactions.

The primary blockchain node like Geth recommends a minimum of 16GB RAM for optimal performance. We assume that half of this memory is allocated for executing smart contracts that access authenticated storage systems, while the remaining half accommodates other functionalities. Consequently, we limited the runtime memory to 8GB using cgroups in our micro-benchmarks. We observed that authenticated storage systems without inherent caching strategies, such as RAW and MPT, perform better when provided with a higher RocksDB memory budget. Conversely, authenticated storage systems incorporating caching strategies, like LVMT and RAIN, show improved performance at a lower memory budget due to the need for an adequate filesystem cache. To optimize performance, we allocated a 4GB RocksDB cache size for RAW and MPT and a 2GB cache size for LVMT and RAIN. As the implementation of LMPTs is highly coupled with the backend database, and the vague boundary separating the authentication structure from the backend database posed a challenge to accurately gauge LMPTs in the micro-benchmarks. We removed LMPTs in micro-benchmarks.

Figure 4a shows the throughput across various workloads. LVMT-r outperforms MPT and RAIN by at least 353% and 80%, respectively. When handling a shard of auxiliary information, LVMT64 and LVMT16 achieve roughly 80% and 60% of LVMT-r’s throughput across most workloads. LVMT1 consistently exhibits the weakest performance in all workloads, demonstrating the necessity of proof sharding. Within the Ethereum real trace workload, the ledger size initially comprises 4 million keys and eventually grows to 22 million keys. However, all the authenticated storage systems either outperform or match their performance in the ‘1m’ workload, as the real trace workload provides better access locality than random access.

Figure 4b illustrates the throughput for various ledger sizes. All authenticated storage systems experience a noticeable performance drop when reaching a specific ledger size threshold. This occurs because the ledger size surpasses memory limitations, preventing both RocksDB’s cache and the file system cache from effectively storing ledger data. RAIN and MPT performance begins to drop at a ledger size of 16 million,

(a) Throughput under different workloads.

(b) Throughput for various ledger sizes.

Figure 4: Throughput of authenticated storage systems.

whereas LVMT declines at a larger size. LVMT16, LVMT64, and LVMT-r demonstrate performance degradation starting from ledger sizes of 25 million, 63 million, and 100 million, respectively. This suggests that LVMT can provide efficient ledger access with a smaller memory usage.

**Read and write amplification:** We further study the read and write amplification at the backend database interface. Here, read amplification represents the ratio of backend read operations to those on authenticated storage systems' interfaces, and write operations are defined similarly. Figure 5a shows the read amplification under the different settings. As the ledger size grows, LVMT-r exhibits consistent read amplifications. The root AMT contains  $2^{16}$  entries, and the second level of AMTs  $2^{32}$  input entries in total. Since each entry has five slots for key-value pairs, the root AMT can only store 0.3 million keys, and the second level of AMTs accommodate 21 billion keys. So LVMT-r always requires two levels of AMT in all these workloads. The read amplification of a key grows linearly with its level in the AMTs, so it is reasonable for LVMT-r to exhibit similar read amplifications. In contrast, the read amplification of MPT grows from 2.4 to 4.1. RAIN demonstrates a smaller read amplification in the Ethereum real trace, indicating that its cache strategy benefits from better access locality in the real trace. For LVMT with proof shards, the read amplification grows linear with the size of auxiliary information. LVMT16 maintains four times the auxiliary information than LVMT64. So the surplus of LVMT16

(a) Read amplification of authenticated storage systems.

(b) Write amplification of authenticated storage systems.

Figure 5: Read and write amplifications of authenticated storage systems.

compared to LVMT-r is four times larger than the surplus of LVMT64. When accessing the fresh ledger state, allocating slots for the version number increases the read amplification of LVMT-r by 1.

Figure 5b displays the write amplification. The write amplification of LVMT is similar to the read amplification. MPT and RAIN have a larger write amplification than read amplification since MPT nodes are keyed by their hash digests. So each time the storage changes, a write operation and a deletion operation are applied to the backend.

Figure 6a and 6b present the average sizes of read and write operations on backend, while figure 6c and 6d provides a more in-depth analysis of data size percentiles for the "100m" workload. Considering that each MPT node can accommodate up to 16 children, each containing a 32-byte hash, an MPT node may store around 500 bytes. So MPT's performance is negatively impacted by the combination of extensive read amplification and large data size per read operation. By caching the top six layers of MPT in memory, RAIN effectively reduces data sizes for both read and write operations. In RAIN, the first layer on disk represents the seventh layer of MPT, which can house roughly 17 million nodes. Thus, at the largest ledger size in our experiment, which consists of 100 million keys, each node only needs to accommodate six children, leading to a 200-byte node. LVMT-r only accesses elliptic curve points, which are 65 bytes in size. LVMT with proof shards may load 65-byte elliptic curve points and 192-bytes auxiliary information for an AMT node from backend.

(a) Data size per read operation

(b) Data size per write operation

(c) Data size distribution of backend read operations

(d) Data size distribution of backend write operations

Figure 6: Data size of backend operations

Figure 6 indicates that around 40% of read operations for LVMT16 involve auxiliary information, while about 10% of LVMT64's read operations relate to auxiliary information.

## 7 Related Works

**Improved MPT structures:** mLSM proposes to maintain multiple levels of MPTs [43]. The most recent updates are in the lowest level (level 0). The key-value pairs in a lower level will be merged to higher levels periodically. LMPTs proposes maintaining three MPTs, one large MPT containing old state

and two small MPTs containing recent state changes [20]. LMPTs periodically merges small MPTs into large ones. For both mLSM and LMPTs, the concatenation of the Merkle roots of all the MPTs becomes the commitment for the ledger state.

Both LVMT and mLSM employ multi-level structures to minimize write amplification, but their approaches differ. mLSM maintains shallow top-level trees by regularly merging entries from the top-level Merkle trees into lower levels. Since write operations in mLSM only affect the top-level trees, the reduced depth decreases overall costs. LMPTs adopt a similar strategy, keeping a shallow delta MPT and periodically merging it into the snapshot. Conversely, LVMT's multi-level structure is akin to a tree, where each AMT serves as a node. When a write operation modifies an element in a lower-level AMT, all AMTs on the path from the root to the target AMT must be updated. With each AMT capable of accommodating up to 65,536 children, the high degree effectively reduces LVMT's overall depth, thus lowering write amplification.

Their techniques reduce the number of disk I/O operations on the critical path because the recently accessed state will be stored into MPTs with smaller depth, and the merge of MPTs can happen in a background thread. In contrast, LVMT almost eliminate unnecessary read amplification in practice. Our results show that when integrated end-to-end into Conflux, LVMT outperforms LMPTs by up to 2.5x. The mLSM paper only contains its conceptual design without implementation and evaluation [43]. It is unclear how mLSM would perform end-to-end with a blockchain in practice.

**Parallelize storage I/O:** RainBlock [40] introduces three different nodes in a blockchain system to accelerate the transaction execution: the storage prefetchers, the miners executing transactions, and the storage nodes. When executing transactions, the miners obtain needed data from multiple prefetchers and send the updates to multiple storage nodes. Each storage node maintains a shard of MPTs in memory. RainBlock changes the local storage I/O to network distributed storage I/O and benefits from the parallel I/O and in-memory storage. To reduce the read latency of network storage, RainBlock introduces I/O prefetchers and requires the miners to attach all the accessed key-value pairs and the witnesses (MPT nodes) when broadcasting blocks. RainBlock reports the average size of witnesses per transaction is 4 KB and their optimizations reduce the size of witnesses by 95%, so the additional network message per transaction is about 200 bytes, two times of a transaction. However, the inefficient usage of networks brings a bottleneck to a high-performance blockchain system [26]. RainBlock also suffers attacks in data availability. Since in-memory storage is costly, the number of replicas in RainBlock is much less than in Ethereum. As a comparison,

LVMT does not introduce additional network bandwidth consumption and data availability risk. Even if proof of shard in LVMT is lost, the other nodes can recover the auxiliary information of an AMT in minutes.

Both RainBlock and LVMT employ the sharding concept, but with different targets. RainBlock divides the ledger into multiple shards, preventing single nodes from accessing the entire ledger. To address this, RainBlock devised complex protocols between the prefetchers handling ledger reads and the miners executing transactions. Conversely, LVMT utilizes sharding solely to maintain auxiliary information for generating proof, allowing nodes to access the full ledger data during transaction execution. The proof sharding is mainly handled by blockchain node API providers. When users query a key, providers must direct the query to the corresponding node along with the relevant proof.

Another similarity between our RainBlock implementation and LVMT is caching top-level nodes. By default, RainBlock caches six layers of MPT nodes, while LVMT caches a single layer of AMT. As LVMT's nodes having a significantly higher degree than MPT (65,536 vs. 16), LVMT can use less memory to accommodate more entries in the first layer beneath the cached nodes.

**Vector commitment for data sharding:** Several vector commitment protocols [19, 24, 28, 30, 46, 49] have been proposed to reduce the proof size, support revealing elements in batch, or make the commitment efficiently updatable under some requirements. Some research also considers utilizing the vector commitment for data sharding on blockchain. Alin et al. [49] use KZG commitment protocol [28] to replace the underlying Merkle tree for data sharding. Unlike LVMT, the goal of this technique is not to improve the throughput but to reduce the data size of the blockchain storage. It requires the clients to maintain the proofs for their own data, keep updating the proof, and attach the values and proofs for the accessed storage in a transaction. Each client needs to be online and update the proofs of all of its data each time a write operation happens on the blockchain. Note that this protocol takes  $O(n)$  time to generate proof or maintain proofs for all data, which costs  $O(n)$  time to add a new key-value pair. It is therefore not designed for a high throughput blockchain system. When thousands of transactions are executed on the blockchain per second, a client cannot maintain its proofs efficiently.

Pointproofs [24] proposes an aggregatable and maintainable vector commitment protocol that can maintain the auxiliary information for proofs in  $O(\log n)$  time (like AMT) and reveal any  $k$ -element subset of elements in  $O(k)$  time with a batched proof. Pointproofs allows a consensus node to generate a batched proof for all the accessed key value pairs during block execution, so a node without the whole ledger

can verify the correctness of execution. However, for every 1024 transactions, Pointproofs takes 5 seconds to maintain the auxiliary information for proofs, which cannot match the requirements in a high throughput blockchain system.

**Accumulators:** Accumulators are cryptographic primitives that commit a set of elements to a short digest (commitment) while supporting operations like addition, deletion, membership proof, and non-membership proof. Merkle trees are one example of accumulators. A recent study [13] designed an RSA accumulator that supports batch operations and stores UTXO sets for a blockchain, with commitments updated in constant time.

In a zk-rollup blockchain [7], it is crucial to convince a light client with a SNARK proof [12] that the ledger root is updated correctly in a given sequence of operations. Ozdemir et al. replaced Merkle trees with RSA accumulators to accelerate SNARK proof generation [38]. Although RSA accumulators require  $O(n)$  time to generate a proof or update proofs for all elements, the time savings in SNARK proof generation outweigh the time spent in accumulator proof generation. However, in a high-performance authenticated storage, operations are processed in microseconds, rendering proof updates that require milliseconds per operation as relatively costly.

## 8 Conclusion

LVMT significantly reduces the disk I/O amplifications associated with each blockchain state access. When integrated into a high performance blockchain, LVMT has up to 2.7x higher throughput than the standard MPT structure. The promising results of LVMT demonstrate the potential of eliminating the performance bottleneck at the storage layer with vector commitment schemes.

## Acknowledgements

We express our gratitude to Peilun Li for his detailed guidance on the Conflux test framework, facilitating our end-to-end evaluations. We also appreciate the insightful suggestions from our shepherd, Micheal Wei, and the anonymous reviewers from EuroSys, S&P, and OSDI. Their critique and suggestions considerably improved our evaluation design and enriched our protocol discussion. ## Appendix

### Formal definition for inner nodes of AMT

We now provide formal definitions for the two elements associated with AMT inner nodes: a polynomial commitment and a batch proof about this polynomial function.

Since the auxiliary information is a binary tree, each node can be located by its depth and index. For a node indexed by  $i$  at depth  $d$ , its left and right children are assigned indices  $i$  and  $i + 2^d$ , respectively. The root is indexed by 0.

Let  $w$  be an  $n$ -th root of unity, such that  $w^n = 1$ , where  $n = 2^k$  for some integer  $k$ . Given an input  $\vec{a}$ , AMT constructs the vector commitment to  $\vec{a}$  to the polynomial commitment to  $f(x) : \mathbb{F}_p \rightarrow \mathbb{F}_p$  that satisfies  $f(w^i) = a_i$ , where  $\mathbb{F}_p$  is a prime field with order  $p$ . It is required that  $2^k | p - 1$ .

The interpolation for points is applied on roots in the  $\{i \in [n] \mid w^i\}$ , instead of  $[n]$ . This yields a Lagrange function which supports faster algorithms. The Lagrange function is defined as:

$$I_{i,n}(x) = \frac{\prod_{j \in [n] \wedge j \neq i} (x - w^j)}{\prod_{j \in [n] \wedge j \neq i} (w^i - w^j)},$$

where the numerator can be simplified to

$$\prod_{j \in [n] \wedge j \neq i} (x - w^j) = \frac{x^n - 1}{x - w^i} = \sum_{j=0}^{n-1} (x/w^i)^j,$$

and the denominator can be simplified to

$$\prod_{j \in [n] \wedge j \neq i} (w^i - w^j) = \sum_{j=0}^{n-1} (w^i/w^i)^j = n.$$

Thus,  $f(x)$  is built via Lagrange interpolation as:

$$I_{i,n}(x) = \frac{1}{n} \cdot \frac{x^n - 1}{x - w^i} \tag{2}$$

$$= \frac{\sum_{j=0}^{n-1} (x/w^i)^j}{n}. \tag{3}$$

So  $f(x)$  can be constructed by Lagrange interpolation as

$$f(x) = \sum_{i=1}^n a_i \cdot I_{i,n}(x).$$

Now we consider a node at depth  $d$  and index  $t$ , its associate function  $f_{d,t}(x)$  only mirrors  $f(x)$  at  $x = w^i$  where index  $i$  satisfies  $i \equiv t \pmod{2^d}$ , and then covers only the Lagrange interpolation terms of these elements:

$$f_{d,t}(x) := \sum_{i \in T_{d,t}} a_i \cdot I_{i,n}(x), \tag{4}$$

where  $T_{d,t} := \{i \in [n] \mid i \equiv t \pmod{2^d}\}$ . This node is associated with the commitment of function  $f_{d,t}(x)$  and the batch proof demonstrating  $f_{d,t}(w^i) = 0$  holds for all  $i \in [n] \setminus T_{d,t}$ . According to the KZG commitment, the commitment for  $f_{d,t}(x)$  is  $f_{d,t}(\tau) \cdot G_1$ , and the batch proof is  $h_{d,t}(\tau) \cdot G_1$ , where  $h_{d,t}(x)$  is defined by

$$h_{d,t}(x) := \frac{f_{d,t}(x)}{\prod_{i \in [n] \setminus T_{d,t}} (x - w^i)}, \quad (5)$$

with the denominator further simplifying to

$$\prod_{i \in [n] \setminus T_{d,t}} (x - w^i) = \frac{\prod_{i \in [n]} (x - w^i)}{\prod_{i \in T_{d,t}} (x - w^i)} = \frac{x^n - 1}{\prod_{i \in T_{d,t}} (x - w^i)}, \quad (6)$$

and where the denominator simplifies to

$$\prod_{i \in T_{d,t}} (x - w^i) = \prod_{i=0}^{2^{k-d}-1} \left( x - w^t \cdot \left( w^{2^d} \right)^i \right) = x^{2^{k-d}} - w^t \cdot 2^{k-d}. \quad (7)$$

For a leaf in subtree of this node with index  $s$ . If  $a_s$  increases by 1,  $f_{d,t}(x)$  and  $h_{d,t}(x)$  will be updated accordingly. By equation 4,  $f_{d,t}(x)$  will increase by  $I_{s,n}(x)$ , denoted as  $\tilde{f}_s(x)$ . By equation 5,  $h_{d,t}(x)$  will increase by  $\tilde{h}_{s,d}(x)$ , defined as:

$$\tilde{h}_{s,d}(x) := \frac{\tilde{f}_s(x)}{\prod_{i \in [n] \setminus T_{d,t}} (x - w^i)},$$

which can be simplified by equation 2, 6 and 7:

$$\begin{aligned} \tilde{h}_{s,d}(x) &= I_{s,n}(x) \cdot \frac{x^{2^{k-d}} - w^{s \cdot 2^{k-d}}}{x^n - 1} \\ &= \frac{1}{n} \cdot \frac{x^{2^{k-d}} - w^{s \cdot 2^{k-d}}}{x - w^s} \\ &= \frac{1}{n} \cdot \sum_{j=0}^{2^{k-d}-1} (w^s)^j \cdot x^{2^{k-d}-j}. \end{aligned}$$

In AMT, when increasing  $a_s$  by  $\delta$ , the commitments and proofs of the node along the path from the root to the corresponding leaf will increase by  $\delta \cdot \tilde{f}_s(\tau) \cdot G_1$  and  $\delta \cdot \tilde{h}_{d,s}(\tau) \cdot G_1$  respectively. The sequence of  $\{\tilde{f}_s(\tau) \cdot G_1\}_{s=1}^n$  and  $\{\tilde{h}_{d,s}(\tau) \cdot G_1\}_{s=1}^n$  for any  $d$  can be constructed by FFT. So the AMT can precompute  $O(n \log n)$  cached parameters in  $O(n \log^2 n)$  time and update the associated elements of each node with two multiplications and two additions on the elliptic curve.

## The overhead of storing the append-only Merkle trees

We provide a rough estimation of the overhead for storing truncated Merkle trees after garbage collection. Considering

**Algorithm 8** A procedure to prove a given key version. It returns the proof of the key version.

---

```

1: procedure PROVEKEY(k)
2:   (tidx, leaf) ← LEAFATLEVEL(lv, k);
3:   vers ← leaf.vers;
4:   C ← AM[(lv, tidx)].comm;
5:   (e, i) ← LM[k];
6:   val ← KM[k];
7:   (lv, sidx) ← VM[k];
8:   merklepf ← Prove the existence of (k, vers[sidx], val, lv, sidx)
   w.r.t. the current hroot
9:   amtpf ← Prove vers are the version numbers w.r.t. the commitment
   C
10:  return (merklepf, amtpf, vers, sidx, val, C);

```

---

**Algorithm 9** A procedure to prove the level lv and the tree index tidx of a sub-AMT. It returns the proof of the commitment of the sub-AMT.

---

```

1: procedure PROVECOM(lv, tidx)
2:   ptidx ← ⌊tidx/n⌋;
3:   plidx ← tidx mod n;
4:   vers ← AM[(lv - 1, ptidx)].leaves[plidx].vers;
5:   Cp ← AM[(lv - 1, ptidx)].comm;
6:   C ← AM[(lv, tidx)].comm;
7:   (e, i) ← LM[(lv - 1, ptidx)];
8:   merklepf ← Prove the existence of (lv, tidx, vers[0], C) w.r.t. the
   current hroot
9:   amtpf ← Prove vers are the version numbers w.r.t. the commitment
   Cp
10:  return (merklepf, amtpf, vers, Cp);

```

---

the roots of Merkle trees are organized in a tree, we can treat them as one large Merkle tree. We assume a full binary Merkle tree has  $k$  levels of inner nodes, accumulated  $m = 2^k$  version tuples, with  $n$  tuples currently active, where  $2^l \leq n < 2^{l+1}$  for some integer  $l$ . A node is not truncated if either itself or its sibling has active descendants, so each active tuple corresponds to at most two nodes per level. The bottom  $k - l - 1$  layers have at most  $2n \cdot (k - l - 1)$  nodes, less than  $2n \cdot \log_2(m/n)$ . The first  $l + 1$  levels have  $2^{l+1} - 1$  nodes, less than  $2n$ . Therefore, the maximum node count is  $(\log_2(m/n) + 1) \cdot 2n$ .

## Non-existence proof of LVMT

The process for generating a non-existence proof in LVMT is depicted in Algorithm 10. This procedure proves the non-existence of a key  $k$  by demonstrating that all potential version number slots for the key are already allocated to other keys.

It first allocate a version slot for  $k$  and followed by an immediate rollback of the allocation (lines 2-3). This process finds the next vacant slot for  $k$ .

Then, it proves the version number of this slot is zero, a process similar to Algorithm 6 except that it omits the merkle proof of the key (lines 5-12). This demonstrates that the slot is indeed unoccupied.

Last, it shows that all other potential slots for  $k$  are already allocated to different keys. It generates proof for them; the second fields of these proofs can be omitted since they have the same information as `commpfs` computed in line 11.

Thus, a non-existence proof in LVMT proves the absence of a key by showing that all its potential slots are occupied by other keys.

---

**Algorithm 10** A procedure to compute the non-existence proof for a given key.

---

```

1: procedure NONEXISTENCEPROOF( $k$ )
2:   ( $lv, sidx$ )  $\leftarrow$  ALLOCATESLOT( $k$ );
3:   Roll back the changes in allocating slot for  $k$ 
4:   ( $tidx, leaf$ )  $\leftarrow$  LEAFATLEVEL( $lv, k$ );
5:    $vers \leftarrow leaf.vers$ ;
6:    $C \leftarrow AM[(lv, tidx)].comm$ ;
7:    $amtpf \leftarrow$  Prove  $vers$  are the version numbers w.r.t. the commitment
    $C$ 
8:    $zeropf \leftarrow (amtpf, vers, sidx, C)$ ;
9:   while  $lv > 0$ 
10:     $tidx \leftarrow$  first bit to  $(k \cdot lv)$ -th bit of  $H(k)$ ;
11:     $commpfs[lv] \leftarrow$  PROVECOM( $lv, tidx$ )
12:     $lv \leftarrow lv - 1$ ;
13:     $L \leftarrow []$ ;
14:    for  $i \in [sidx - 1]$ 
15:       $keypf \leftarrow$  the first component of  $prove(leaf.keys[i])$ ;
16:       $L \leftarrow (leaf.keys[i], keypf) \cup L$ ;
17:    while  $lv > 0$ 
18:       $lv \leftarrow lv - 1$ ;
19:      ( $tidx, leaf$ )  $\leftarrow$  LEAFATLEVEL( $lv, k$ );
20:      for  $i \in [5]$ 
21:         $keypf \leftarrow$  the first component of  $prove(leaf.keys[i])$ ;
22:         $L \leftarrow (leaf.keys[i], keypf) \cup L$ ;
23:       $keypfs \leftarrow L$ ;
24:    return ( $zeropf, commpfs, keypfs$ );

```

## Abstract

Graphics Processing Units (GPUs) unlock emerging use cases like large language models and autonomous driving. They process a large amount of sensitive data, where security is of critical importance. GPU Trusted Execution Environments (TEEs) generally provide security to GPU applications with modest overheads. Recent proposals for GPU TEEs are promising, but many of them require hardware changes that have a long lead time to deploy in production environments.

This paper presents Honeycomb, a software-based, secure and efficient TEE for GPU applications. The key idea of Honeycomb is to leverage static analysis to validate the security of GPU applications at load time. Co-designing with the CPU TEE, as well as adding OS and driver support, Honeycomb is able to remove both the OS and the driver from the trusted computing base (TCB). Validation also ensures that all applications inside the system are secure, enabling a concise and secure approach to exchange data in plaintext via shared device memory on the GPU.

We have prototyped Honeycomb targeting the AMD RX6900XT GPU. Honeycomb is evaluated on five representative benchmarks and 23 applications in total, covering workloads of high performance computing, deep learning, and image processing. The results show that Honeycomb is both *practical* and *efficient* to secure real-world GPU applications. Validating applications to run on Honeycomb requires modest developer efforts. The TCB is  $18\times$  smaller than the Linux-based systems. Secure inter-process communication is up to  $529\times$  faster. Moreover, running large language model workloads like BERT and NanoGPT has  $\sim 2\%$  overheads.

## 1 Introduction

Innovations in hardware accelerators and deep neural networks continue to enable personalized experiences for our physical and digital presences, reshaping areas ranging from

smart homes [34], virtual reality [85], to personalized cancer medicines [22]. Offering such intimate experiences heavily relies on large amounts of valuable and sensitive user data, which requires high levels of security and privacy support on hardware accelerators such as GPUs.

Trusted Execution Environments (TEEs) [4] encapsulate applications into enclaves to enhance security. TEEs enforce strong isolation among enclaves and the untrusted host environments, so that applications inside the enclaves can process plaintext data securely at native speed. For each enclave, all traffic that crosses its boundaries is encrypted to maintain confidentiality and integrity. Recent prototypes [28, 44, 45, 83] realize GPU TEEs with modest overheads, via serializing secure access to the GPU [28], augmenting the GPU hardware [83], customizing the I/O bus [44], or leveraging the sharing capabilities in device drivers [45].

This paper explores an alternative approach – using static analysis to *validate* that mutually distrusted GPU applications are confined to their enclaves. Intuitively, a validator inspects the binary code of GPU kernel functions (GPU kernels for short) to show that all possible execution traces maintain the confidentiality and integrity of the system, therefore these applications can safely share the GPU. This approach offers three benefits. First, it can complement the hardware limitations of existing GPUs. For example, low-cost GPUs such as the VC4 used by Raspberry Pi allow arbitrary writes to memory due to the lack of corresponding MMUs [16]. A validator can detect insecure behaviors and thwart the attacks by running standard static analysis such as def-use analysis and range checks on the GPU kernels. Moreover, advanced static analysis [59] might mitigate new attacks [19, 21] much faster compared to deploying new hardware supports in production.

The second benefit is that it allows more efficient implementations of current GPU TEEs. Shifting the runtime checks to load time removes them from the critical paths. Moreover, validating that applications that always have disjoint contexts might save the TEE implementation from flushing architectural contexts, including TLBs and buffer queues during every context switch [28], thus improving performances.

\*Haohui Mai is also affiliated with Hengmoxing Technologies.

†Jiacheng Zhao is the corresponding author.

Finally, validating every application provides a system-wide security invariant asserting that all applications are “good citizens”. The security invariant enables secure and efficient communication among enclaves. Real-world applications such as autonomous driving [89] and video analytics [66, 70] process data in multiple-stage pipelines. Separating each stage of the pipeline into different enclaves and connecting them using Inter-Process Communication (IPC) not only increases modularity and robustness, but also enables assembling the pipelines using mutually distrusted components from multiple vendors [63, 74]. Current GPU TEEs focus on strengthening isolation, for example, enforcing exclusive ownerships of GPU device memory [83]. Therefore two mutually distrusted enclaves need to tunnel the data through an encrypted shared buffer on the host memory for IPC. The overheads are prohibitive for production applications. For example, the GPUs on an autonomous vehicle process up to 50 GB/s of uncompressed video streams to make timely driving decisions [69]. Copying 50 GB/s of data to the host already takes up 30~40% of the total memory bandwidth of a commodity, high-end AMD Zen3 server, let alone the overheads of encrypting/decrypting the data. The capability of exchanging plaintext data directly in GPU reduces the overheads drastically, thus enabling real-world applications to migrate towards a more modular and robust architecture.

This paper presents the design and implementation of Honeycomb, a software-based, secure and efficient TEE for GPU applications. Honeycomb runs multiple mutually distrusted applications on the same GPU, and facilitates efficient and secure data exchange between applications. It supports common GPU workloads from simulations of molecular dynamics to training and inference of neural networks. All these capabilities of Honeycomb are built upon the idea of using static analysis to confine the behaviors of GPU applications.

Honeycomb faces three challenges to realize the three benefits and to provide a complete, real-world solution for GPU TEEs. First, it must balance the trade-offs between the capabilities and the complexities of the validator. A validator equipped with theorem provers gains their power, but then Honeycomb must include the theorem provers in the TCB, which is complex (e.g., Z3 4.12.2 has ~525 K lines of code) and occasionally error-prone [77]. On the other hand, a naïve validator might be insufficient to validate common security checks at load time, requiring inserting extra runtime checks that sit squarely on the performance critical paths.

Second, Honeycomb must minimize the end-to-end TCB to provide high confidence in security. The software/hardware stack of GPU applications is quite complex. For example, the compiler toolchain and the driver for the AMD RX6900XT GPU each consist of two million lines of code. Defects and vulnerabilities in these components are inevitable [23, 25, 26], but they should not compromise the security of Honeycomb.

Finally, Honeycomb must provide system-level support for secure and efficient IPC. The aforementioned plaintext IPC

among GPU enclaves can only be securely implemented if the data copies are cautiously initialized by the Honeycomb system and from/to strictly protected memory regions.

Honeycomb addresses the above challenges with three key techniques. First, the validator of Honeycomb performs static analysis of GPU kernels directly on binaries. It decodes the instructions of the GPU kernels to reconstruct the control and data flows. It models the memory access patterns using scalar evolution [6] and polyhedral models [14]. Our evaluation shows that the approach is effective to validate that the majority of memory accesses in GPU kernels are safe, because real-world GPU kernels tend to be well-optimized, having highly regular control flow structures and memory access patterns. The few remaining cases can be handled by inserting runtime checks, whose latencies are also well tolerated by the GPU memory hierarchy (§5).

Second, Honeycomb leverages hardware isolation mechanisms, and uses security monitors [54, 79, 90] to validate interactions in the system, so that it can minimize the trust on the software/hardware stack. Honeycomb launches applications inside CPU TEEs powered by AMD SEV-SNP [4]. The validator directly parses the GPU binaries to remove the compiler toolchain from the TCB. To remove both the user-space and kernel-space GPU drivers from the TCB, Honeycomb uses two security monitors to intercept and regulate all traffic between the applications and the GPU: (1) a Secure VM Service Module (SVSM) [4] running inside the application enclave, which enforces security policies at the application level (e.g., the application only launches validated kernels), and (2) a security monitor running inside a sandboxing hypervisor of the GPU, which regulates the behaviors of the GPU driver (e.g., the driver should never map a private memory page into two applications). Additionally, Honeycomb secures the data transfer between the CPU and the GPU to protect the confidentiality and integrity of the data (§6).

For the final challenge, Honeycomb reserves dedicated regions of the virtual address space for secure IPC to exchange plaintext data. Particularly, Honeycomb divides the virtual address space of each application into four regions: protected, read-only, read-write, and private. The validator ensures that application GPU kernels can only modify the private region. Putting the metadata and the receiving buffers into the protected and read-only regions prevents user applications from tampering with the IPC, reducing IPC in Honeycomb to copying plaintext data within the device memory (§7).

We have ported five representative benchmark suites, including the SpecACCEL 1.2 benchmark suites [76], inference applications of the ResNet18 neural network model [37] and the BERT language model [29], an application that trains GPT language models [48], and an image processing application that performs Canny edge detection [20], i.e., 23 applications in total. We have evaluated them on a server equipped with two AMD EPYC 7443 24-core processors and an AMD RX6900XT GPU. The results are promising. The TCB is

18× smaller than the Linux-based systems. A concise validator is sufficient to statically verify the security of large parts of GPU applications. Validating inference workloads on neural networks like ResNet18 and BERT requires adding zero runtime checks into the GPU kernels. Large language model workloads like BERT and NanoGPT have ~2% runtime overheads. IPC in Honeycomb is up to 529× faster than exchanging data using an encrypted, shared buffer on the host.

This paper makes the following contributions:

- The use of static analysis on GPU kernels to confine the behaviors of GPU applications to improve security. Our evaluations on five representative benchmark suites show that the analysis is both practical and effective to determine whether real-world GPU kernels are safe at load time with minimal additional runtime checks.
- The design and the implementation of a lightweight, end-to-end secure execution environment for GPU applications based on static validation.
- An IPC primitive that enables secure and efficient communications between GPU applications. The co-design of static analysis and OS support leads to a highly concise implementation.

## 2 Background

To understand the design of Honeycomb, it is important to first review the architectures and the programming interfaces of GPUs, as well as the basic concepts of polyhedral analysis [14, 35] used in this paper.

*Architectures and programming interfaces of commodity GPUs.* Modern GPUs offer the single instruction, multiple thread (SIMT) programming model to the applications. To run a workload, an application submits a launch request to the command queue of the GPU. The request specifies the binary function (i.e., GPU kernel), its arguments, the number of threads, and optionally, the size of a user-controllable, on-die high-speed scratchpad (i.e., shared memory) to perform the workload. Threads are organized into grids and blocks uniformly. Each grid consists of the same number of blocks, and each block consists of the same number of threads. Each thread within the same block has its own vector registers but shares access to the shared memory. The programming model provides a conceptual view where each thread executes the same instruction based on the values of its own registers. To achieve parallelization, each thread loads the inputs into its own registers and computes the outputs in parallel. Figure 1 presents an example of filling a region of memory to a specific value under the SIMT model.

The hardware architecture of GPUs closely matches the SIMT model above. A typical GPU consists of thousands of processing elements (PE) that are grouped into a three-level

hierarchy. The lowest level is called a warp, consisting of 32 or 64 logical PEs executed in lock-step. The micro-architecture (e.g., AMD GCN) might introduce parallel scalar units to perform uniform computation within a warp, or pipeline the computations on physical PEs to hide execution latency. Warps are further grouped into Compute Units (CU). A CU consists of a pool of vector registers and shared memory. Finally, a single GPU packages multiple CUs on the same die.

The hardware scheduler multiplexes the hardware resources across applications. The minimal scheduling unit is a warp. It always schedules all warps of a block within the same CU, therefore all threads within a block divide the vector register pool and share the same allocated shared memory inside the CU. The scheduler continuously schedules all the blocks and grids until the execution is completed.

The GPU driver creates a virtual address space for each GPU application. It allocates buffers for arguments and command queues out of the Graphics Translation Table (GTT) memory from the host. The buffers are mapped into the virtual address space on the GPU, from which the GPU kernels read the arguments and the layouts of grids and blocks directly.

*AMD SEV-SNP.* AMD SEV-SNP [4] (Secure Encrypted Virtualization-Secure Nested Paging) offers enhanced security features at the hardware level for Virtual Machines (VMs) running on an untrusted cloud system hypervisor. Similar to other TEEs, SEV-SNP supports remote attestation as well as both data confidentiality and integrity guarantees for the application VMs against untrusted host hypervisors. A dedicated hardware engine in the memory controller encrypts data before sending them to the off-chip main memory. SEV-SNP also tracks the ownership of each physical page with a Reverse Map Table (RMP) so that only the owner can write to a memory region. It further validates the page mapping to prevent malicious remapping of a single page to multiple owners. In such ways, it is able to alleviate typical data corruption, replay, memory aliasing, and memory remapping attacks.

In addition, SEV-SNP enables tagging each physical page with Virtual Memory Privilege Levels (VMPLs). It is similar to Ring 0-3 in the x86 architecture but for TEE VMs. One use case of VMPL is to implement Secure VM Service Module (SVSM). SVSM runs at VMPL0 and the guest operating system runs at VMPL1. SVSM can intercept syscalls and memory operations and serve as a security monitor.

*Polyhedral model.* The polyhedral model has been widely used in automatic parallelization and optimization of GPU programs [8, 14, 92]. Conceptually it represents each memory access as an affine expression (i.e. a linear combination) over an ordered set of loop variables. Analyzing the effects of memory access, such as aliasing and ranges, reduces to solving inequalities of integer variables. The polyhedral model works well with GPU kernels because they implicitly loop over the grids and the blocks, and performant GPU kernels have regular memory access patterns.

More concretely, an iteration vector  $I = (i_0, i_1, \dots, i_n) \in \mathcal{D}^s$  records the values of loop variables  $i_0, \dots, i_n$  for an instruction  $s$ . The domain  $\mathcal{D}^s$  is called the iteration domain. Note that the iterator vector usually includes the grid index (`gid`) and the local thread index (`lid`) for instructions in GPU kernels. An access function  $\mathcal{A}^s$  (w.r.t. instruction  $s$ ) takes an iterator vector as input and outputs the actual memory address.

Note that when  $\mathcal{A}^s$  is an affine function and  $\mathcal{D}^s$  is an affine space, all loops in  $I$  have fixed steps. For simplicity, we denote an access function as a vector with each element representing the coefficients of the corresponding dimension of the iteration vector. The dot product of the access function and the iteration vector is the actual memory address. We also introduce an extra dimension which always has the value 1 at the end of the iteration vector so that the access function can represent constant offsets in a uniform way.

Figure 2 shows the access functions of the kernel in Figure 1, a kernel filling a range of memory with a value. Affine operations on the values directly translate to affine operations on the vector forms of the corresponding access functions (e.g.,  $\mathcal{A}^5 = \text{dim} \cdot \mathcal{A}^3 + \mathcal{A}^4$ ), provided that `dim` is a constant throughout the analysis. The GPU kernel actually loads `dim` from the memory, however. In this case, security invariants in Honeycomb ensure that the value `dim` remains constant throughout the executions so that the analysis remains valid.

### 3 Threat model

In this paper, we adopt a similar threat model to previous studies on secure execution environments for GPUs [44, 45, 83]. The adversary controls the entire software stack, including the compiler toolchains, the operating system, the hypervisor, and the device drivers. It also has physical access to the server hardware and may sniff the PCIe traffic. We assume that the host machine CPU features TEE capabilities such as AMD SEV-SNP or Intel TDX [43], and the GPU features a hardware random number generator or performance counters to collect entropy for cryptographic uses. We also assume that users have the specifications of the server hardware and how it is connected, such as which PCIe slot that the GPU is plugged in. Finally we assume that Honeycomb is able to establish a trusted MMIO path with the GPU. Our prototype uses AMD SEV-TIO [1] to establish it, but such a path can also be realized using other secure I/O buses [44, 65], or alternatively, equipping the server with tamper detection mechanisms [75] and establishing a trusted I/O path to the GPU using a hypervisor [94]. We defer the details to §8.

The adversary can launch applications in Honeycomb, alter the results of the compiler toolchains, and tamper with the physical memory of the server. Additionally, the adversary can tamper with the DMA buffers. However, we trust the device memory of the GPU, since modern GPUs usually integrate the device memory using 2.5D/3D silicon interposers inside the same package. We assume that the adversary cannot observe

or corrupt the data stored in it [83]. Supporting integrated GPUs is out of the scope of this paper.

Similar to previous GPU TEEs [44, 83], side-channel attacks [17, 40, 82, 86] on trusted hardware are out of the scope of this paper. Honeycomb relies on the rich set of orthogonal work to alleviate these problems [9, 80]. Availability and denial-of-service attacks are also out of scope.

Under this threat model, Honeycomb should ensure confidentiality and integrity for multiple mutually distrusted applications running on the same GPU. The adversary cannot tamper with the code, the data and the control flows of both the CPU and GPU parts of the applications.

## 4 Overview

Figure 1 describes the overall architecture of Honeycomb. Honeycomb offers unified TEEs that cover both the CPU and GPU parts of the application. Honeycomb starts an application inside an AMD SEV-SNP TEE VM. It first starts the Secure VM Service Module (SVSM) at VMPL0. The SVSM bootstraps the BIOS, the guest Linux kernel, and finally the user-space application at VMPL1. SVSM regulates all interactions between the applications and the GPU. Recall that in CPU TEEs data are stored as plaintext within the CPU package. They are only encrypted when leaving for the off-chip main memory. In Honeycomb data on the device memory are stored decrypted, and the SVSM encrypts them when they are sent to the host. The path of reading data is similar.

The application requests GTT memory from Honeycomb to interact with the GPU. A piece of GTT memory can serve as a staging buffer for memory copies, which is mapped into the user-level address space, or serve as backing buffers for command queues, which are only accessible by the SVSM. In both cases the SVSM inspects the access to regulate secure memory transfers between the GPU and the applications [83], and launches validated GPU kernels with proper parameters. Note that although the current implementation of Honeycomb is based on AMD SEV-SNP, our design is applicable to other VM TEEs such as Intel TDX.

Honeycomb isolates the GPU inside a sandbox VM. The security monitor (SM) inside the sandbox is a hypervisor running below the Linux kernel. The SM regulates all interactions between the driver and the GPU. It ensures that the GPU follows the expected initialization sequences, and keeps track of the ownerships of the device memory pages to prevent accidental sharing of device memory among applications.

To execute GPU kernels, an application first loads the GPU binary that contains the GPU kernels into the device memory. The validator in Honeycomb takes both the binary code of a GPU kernel and the accompanying preconditions as inputs. It validates that each memory instruction in the GPU kernel can only access certain regions of the virtual address space. Note that the actual target addresses sometimes cannot be determined until the application executes the kernel with

Figure 1: The overall architecture of Honeycomb. Left: Application VM and sandbox VM in their respective TEEs. Middle: Pre-conditions and source code of the GPU application kernel. Right: Layout of the virtual address spaces for two GPU applications. Long dashed arrows represent intercepted and validated requests by the validator (at load time) and the security monitors (at runtime). Dotted arrows represent physical memory page mappings.  $VA_{priv}$  is the topmost virtual address of the private region. Green boxes are components of the TCB.

$$\begin{aligned}
 \mathcal{D} &= \{(gid, lid) | 0 \leq gid < gridDim; 0 \leq lid < blockDim\} \\
 \mathcal{A}^3 &= (1, 0, 0) \\
 \mathcal{A}^4 &= (0, 1, 0) \\
 \mathcal{A}^5 &= dim \cdot \mathcal{A}^3 + \mathcal{A}^4 = (dim, 1, 0) \\
 \mathcal{A}^7 &= \mathcal{A}^5 + (0, 0, base) = (dim, 1, base)
 \end{aligned}$$

Figure 2: The iteration domain and the access functions (in the vector form) of the GPU kernel in Figure 1. The superscript denotes the corresponding statement. The parameter spaces of all access functions are  $(gid, lid, 1)$ .  $gridDim$  and  $blockDim$  describe the total number of grids and the number of threads in a block.

the concrete values of the arguments (e.g.,  $base$  in Figure 1). Therefore we introduce preconditions, which specify the constraints on the arguments so that the validator can analyze the bounds statically. Honeycomb checks the preconditions at runtime to ensure the attacker cannot subvert the analysis.

The validator decodes the instructions of the GPU kernel to reconstruct its control and data flows. It represents the target address of each memory instruction as a symbolic expression using scalar evolution and polyhedral models. It plugs in the preconditions to reason about the bounds of the target address, and ensures that the address stays within specified regions. The analysis is sound, meaning that once an access is proven, it is safe for all possible executions. For undecided cases like an indirect memory access  $a[b[i]]$ , Honeycomb requires the developer to annotate and add runtime checks to pass the validation. Our evaluation on real-world benchmark suites shows that the overheads of both development and runtime performance are modest – common production GPU kernels like matrix multiplications tend to have regular memory access patterns. The analysis is sufficient to capture the patterns, thus requiring few to none annotations.

The validator enforces access control that effectively divides the virtual address space of a GPU application into four regions: protected, read-only (RO), read-write (RW), and private, each of which has different access policies. For example, the application is prohibited to modify the RO region, but has full access to the private region. Honeycomb places the binary code and the arguments in the RO region so that a malicious kernel cannot modify the code on the fly after passing the validation. Furthermore, Honeycomb implements secure IPC through mapping the buffers into different regions. Honeycomb maps the IPC buffers into the sender’s protected and receiver’s RO region. The sender calls the trusted `send()` endpoint to copy the plaintext data to the IPC buffer, where both confidentiality and integrity are preserved.

## 5 Validator

The validator in Honeycomb checks the binary code for each GPU kernel of the application conforms with the following security invariants:

- *No dangling accesses.* A GPU kernel must never read uninitialized values from hardware registers.
- *All memory accesses reside in their regions.* All memory accesses to the memory regions conform with their access policies respectively.
- *Control flow integrity.* The execution must start at the designated entry point of the GPU kernel. The kernel can only transfer its control to the entry points of its basic blocks.

*Checking uninitialized uses of values.* The validator starts out parsing the binary code of the GPU kernel and building

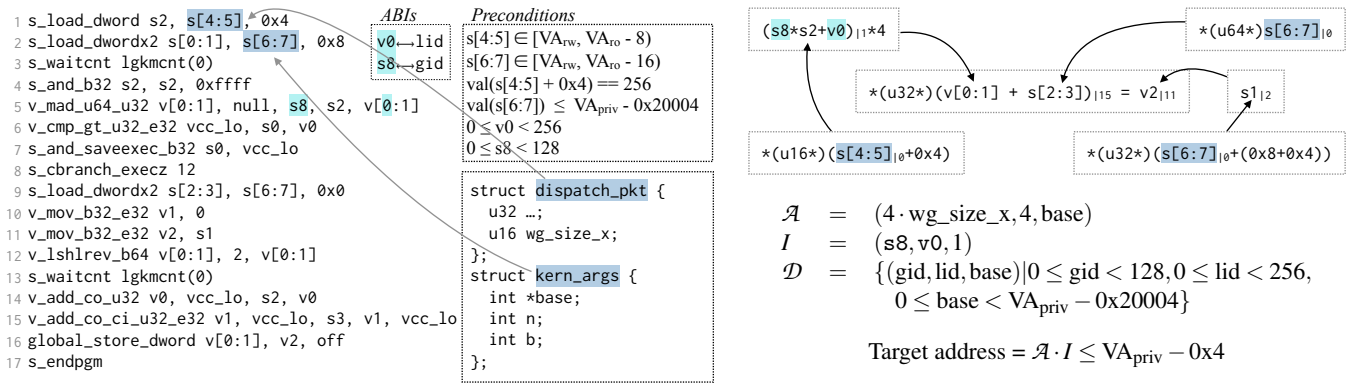

Figure 3: Workflow of validating the binary code generated from Figure 1. Left: the assembly, preconditions and the ABIs. Top right: the value chain of the symbolic expression that represents the target address of Line 16. Subscripts represent the line number on the left at which the value should be considered. Bottom right: the access function  $\mathcal{A}$ , the iteration vector  $I$  and the iteration domain  $\mathcal{D}$ .

the Static Single-Assignment (SSA) representation and the Control Flow Graph (CFG) for each kernel function. The validator checks dangling accesses by inspecting whether the SSA representation of the kernel function is valid.

*Checking memory accesses.* Figure 3 presents the overall workflow when validating the program described in Figure 1. For each memory instruction, the validator constructs a symbolic expression and derives the access function  $\mathcal{A}$  to represent the target address of each memory instruction. The algorithm combines scalar evolution analysis and polyhedral models, and is flow-sensitive and path-insensitive.

The validator further derives the iteration vector  $I$  and the iteration domain  $\mathcal{D}$  from the application binary interface (ABI) and the preconditions of the GPU kernel. Recall that the dot product  $\mathcal{A} \cdot I$  computes the value of the target address. It is sufficient to plug in  $\mathcal{D}$  to compute the range of the target address and to verify whether the memory access is inbound.

A closer look at Figure 3 shows that the validator must address practical complexities when analyzing the binary code. For example, the compiler promotes the load of `dispatch_pkt.wg_size_x` into a 32-bit load instruction (Lines 1 and 4). It also lowers a 64-bit addition into two instructions (Lines 14-15). The validator heuristically rediscovers their semantics when constructing the symbolic expressions. Additionally, the validator matches sequences of instructions to rediscover semantics of divisions, modulus, and min/max operators.

Another example is that conventional polyhedral models require all multipliers to be constants. The value of `s2` comes from a load instruction (Lines 1 and 4), breaking the subsequent analysis when constructing a polyhedral representation of the global ID (Line 5). The validator recognizes that the instruction is loading from the RO region and it is safe to treat it as a constant in the analysis. Such relaxation is essential to derive  $\mathcal{A}$  and eventually to validate that Line 16 is safe.

Aggressive compiler optimizations can create additional

burdens for analysis. For example, the definition and the usage of a value could be scattered in two basic blocks separated by other basic blocks in the CFG. They are guarded by the same condition so the program is valid at runtime but a path-insensitive algorithm fails to connect them. More powerful analysis or language-level support [30, 41, 60] will address the issue but we intentionally limit the capabilities of the validator to bound the size of TCB. Honeycomb requires the developer to alter the GPU kernel to pass the validation. Additionally, the validator requires the developer to add runtime checks for indirect memory accesses like `a[b[i]]` since it does not fully track the memory access of the heap.

We found that the simple algorithm is effective against commonly used production kernels such as matrix multiplications or element-wise transformations as the analysis perfectly captures the regular and predictable memory access patterns commonly seen in most GPU kernels.

*Enforcing control flow integrity.* It is relatively straightforward to decode GPU kernels since modern GPUs have RISC-style instruction sets. The validator simply validates that all branches jump to valid instructions. The validator does not support indirect branches. Although based on our experience they are rarely used in real-world GPU kernels, the developer can turn indirect branches to a series of branches that have explicit targets. The validator does not support self-modifying code to ensure the integrity of the analysis.

## 6 Security monitors

There are two types of security monitors in Honeycomb to regulate the interactions with the GPU. In Honeycomb every application runs inside its own TEE VM. The SVSM regulates the interactions between the application and the GPU. The security monitor (SM) in the sandbox VM regulates the interactions between the driver and the GPU. The SM also keeps track of the ownership of memory pages to prevent ac-

cidental sharing between applications. Together they are able to remove the OS kernel and the GPU driver from the TCB. Similar to existing GPU TEEs [83], Honeycomb implements the following functionalities.

*Initialization.* Honeycomb enforces the untrusted GPU driver to follow a correct sequence to initialize the GPU. However, to our best knowledge, no public specifications are available for our target device, the AMD RX6900XT GPU. We therefore collect the trace of an initialization sequence on the baseline platform and use it as the ground truth. We further inspect the source code of the driver to build state machines to model the initialization sequence. The SM intercepts all MMIO traffic to ensure that the GPU driver follows the transitions of the state machines. The SM directly passes the firmware to the GPU since the hardware will validate its integrity with cryptographic signatures.

Despite the fact that there is no specification, we were able to find five bugs in the AMDGPU driver that violate security. More specifically, there are two instances where the parameters of the hardware queues are initialized with incorrect values, two instances where the queues are prematurely enabled before all parameters are set, and one instance of out-of-bound access on the hardware buffer. All five bugs are confirmed by upstream developers, and their corresponding fixes have been deployed since Linux 5.19.

*Launching GPU kernels.* Applications call the same user-space APIs (e.g., the HIP APIs [2]) to launch GPU kernels on Honeycomb. First, applications call `hipModuleLoadData()` to load GPU binaries. The implementation of the API traps into the SVSM, where the SVSM validates the kernels, then copies the kernels into the protected region and records their preconditions given that they have passed the validations.

Applications call `hipLaunchKernel()` to launch a GPU kernel. Similarly, its implementation traps into the SVSM, where the SVSM confirms the preconditions are valid with respect to the actual arguments. It then updates the command queue to enqueue the launch if preconditions are satisfied.

*Isolating address spaces.* On the CPU side, Honeycomb leverages existing mechanisms in SEV-SNP TEE to enforce isolation between different applications. SEV-SNP ensures the integrity of VM data and protects against various vulnerabilities, including replay and remapping attacks (§2).

On the GPU side, the SM intercepts all traffic between the driver and the GPU to maintain a RMP table similar to Graviton [83] to track the ownership of the pages. The Linux driver allocates page tables inside the device memory and updates them through MMIO requests. The SM intercepts these requests and updates the RMP table. Additionally, the SM prevents applications from mapping the page tables into their address spaces to subvert the isolation.

*Securing data transfers.* Honeycomb implements secure data communication channels between the GPU and the host CPU, and coordinates all data transfers into and out of the GPU

device memory. All transfers between the host and the device memory must be done via a special trusted kernel in Honeycomb, with all transferred data encrypted and authenticated under an ephemeral encryption key. Honeycomb disallows the applications from mapping the host memory into their address spaces or directly creating DMA queues.

One practical issue is how to bootstrap and maintain the secure channel. Honeycomb uses the `s_memrealtime` instruction to get the value of the real-time counter on the AMD RX6900XT GPU. Honeycomb launches a kernel to perform reads, invalidating caches to generate entropy and extract them. The entropy is used to establish a shared security key using Diffie-Hellman key exchange [31]. Honeycomb stores the entropy in the protected region to prevent user applications from accessing it.

## 7 Secure and efficient IPC

Honeycomb enables two enclaves to securely exchange plaintext data within the device memory. To make an IPC, Honeycomb maps the IPC buffer to the sender's protected region and the receiver's RO region. The sender calls `send()` to initiate the IPC. `send()` is a trusted endpoint that simply copies the data into the protected region and updates the indices of the IPC buffers. The GPU kernels on the receiver side can read the RO region directly but need to update the indices via `recv()` provided by Honeycomb. The scheme is secure because no GPU kernels from the user applications can access the protected region nor write to the RO region.

For simplicity, the current prototype of Honeycomb maps all IPC buffers to the protected regions consistently across all applications so that it is possible to identify the endpoints using only the virtual addresses. Adding finer-grained access control through capabilities [33] is relatively straightforward.

To summarize, the ultimate simplicity comes from the guarantee that none of the user-provided GPU kernels inside Honeycomb is able to tamper with the data in the protected, RO and RW regions, making exchanging data between two enclave applications in Honeycomb as simple as copying a piece of memory.

## 8 Discussion

*Establishing a trusted I/O path to the GPU.* When the server does not have AMD SEV-TIO or other secure I/O buses, Honeycomb can leverage prior work [94] to establish a trusted I/O path to the GPU. On the high level, Honeycomb acquires exclusive control of the I/O paths at the beginning of the boot-up process, before any untrusted components can access the GPU. Particularly, the server first boots into the SM where the whole boot-up process is validated and attested via SecureBoot [55]. Second, the SM enumerates the PCIe buses to discover the MMIO regions of the GPU and all of its

upstream PCIe switches. Then it initializes the IOMMU to protect the MMIO regions from any unauthorized accesses by the hypervisor and other devices' DMA buffers. It further programs the PCIe Access Control Services (ACS) registers [5] to stop unauthorized peer-to-peer PCIe transactions. After these steps Honeycomb can continue the normal boot-up process. By correctly configuring the IOMMU and by disabling peer-to-peer PCIe accesses, the above initialization process is sufficient to isolate the MMIO regions of the GPU from the untrusted software components and other I/O devices inside the server [94]. Honeycomb relies on additional tamper detection mechanisms to detect and mitigate physical attacks.

In the alternative setup above, the TCB must include all components used in the boot-up process, such as the UEFI BIOS. The SM and the untrusted hypervisor must be adopted to support nested virtualization [11]. Legacy systems without tamper detection mechanisms have a weaker threat model as they are unable to defend against physical attacks.

*Remote attestations.* The user application needs to attest both its own SEV-SNP VM and the sandbox VM to validate the security of the execution environment. It follows the standard procedures to attest its own VM. The attestation also guarantees a valid execution context of the GPU since the SVSM is part of the attestation, and it regulates the GPU execution context. Note that the SM is part of the TCB. The SM maintains a public-private key pair for the attestation of the sandbox VM. The user application authenticates the SM using the key pair to validate the security of the sandbox VM.

## 9 Security analysis

*Attacking the software stack.* An attacker might try to launch a malicious GPU kernel by subverting the validation in Honeycomb. Some possible attacks include invalidating the preconditions with invalid arguments, subverting the data flows via manipulating the values of spilled registers, and modifying the code or the target addresses of a branch to hijack the control flows [18]. Recall that SEV-SNP ensures that the user application cannot tamper with the SVSM. The SVSM reevaluates the preconditions with the arguments before executing the GPU kernels to defend against the first attack. Honeycomb protects the code and the spilling regions in the RO and RW regions to defend against the second and third attacks. Particularly, the validator analyzes each global memory access in the GPU kernel to ensure that it cannot tamper with the reserved regions, maintaining the integrity of the validation.

An attacker might tamper with the system software stack, including the GPU driver, the host operating system, and the hypervisor, to subvert the security of Honeycomb. To gain access to the plaintext information residing in the device memory, they might execute code to craft malicious MMIO requests, to initiate unauthorized DMA requests, or to map the device memory from other applications to different address

spaces. This is ineffective because the SM in Honeycomb regulates all MMIO and DMA requests from the system software stack. By intercepting the MMIO requests, it enforces isolation on address spaces and prevents accidental sharing. It also enforces that data communication with the external world is all encrypted and authenticated.

The attacker might alter the GPU firmware or divert from the designated bootup sequences in order to control the GPU. This is ineffective because the GPU hardware verifies the integrity of the firmware [55], and the SM in Honeycomb validates the bootup sequences during GPU initialization.

*Attacking the hardware stack.* An attacker might interpose the host memory to try to alter the trusted components like the SVSM in Honeycomb. This is ineffective because SEV-SNP includes attestation procedures to verify the integrity of the trusted components. SEV-SNP also incorporates memory encryption and integrity to defend against the attack.

An attacker might interpose on the PCIe fabrics to insert MMIO or DMA requests, or tamper with existing requests to access the plaintext information residing in the device memory. Alternatively, they might map the MMIO regions of the GPU to another I/O device or initiate peer-to-peer PCIe transactions to interact with the GPU. Both types of attacks are ineffective when the GPU is attached to a secure I/O bus [1, 44, 65]. When using the alternative initialization process described in §8 to establish a trusted I/O path, Honeycomb detects and stops the first type of attacks using tamper detection mechanisms [75]. To defend against the second type of attacks, Honeycomb programs the IOMMU and PCIe ACS registers to acquire exclusive control on the MMIO regions of the GPU before starting any untrusted components. Additionally an attacker might write to the I/O ports that map to the registers in the PCIe configuration space, in the hope of relocating the MMIO regions of the GPU. Honeycomb is able to identify and stop potential attacks as the hardware topology uniquely determines the mappings [94]. An attacker might also initiate peer-to-peer PCIe transactions between an I/O device and the GPU bypassing the IOMMU. Honeycomb stops the attacks because it programs the PCIe ACS registers to prevent unauthorized peer-to-peer PCIe transactions.

Our threat model assumes that an attacker cannot snoop or tamper with the device memory of the discrete GPU. The attacker can also try to perform the row hammer attack [51], which can be mitigated by orthogonal research [7, 67, 87].

*Side-channel attacks.* An attacker might try to exploit various timing and power side channels. Defending them is out of the scope of this paper and can leverage orthogonal work [9, 80].

## 10 Implementation

We have implemented Honeycomb on top of Rust 1.64.0 nightly with about 32,000 lines of code. The current prototype supports the x64 architecture and the AMD RX6900XT GPU.

We use the AES256-GCM [32] to encrypt and decrypt traffic between the host and the GPU.

The validator understands the AMDGPU ELF binary format and disassembles the machine code of the GPU kernels of the AMD RDNA2 ISA. The structures of scalar evolution analysis and polyhedral representations closely resemble the corresponding parts in LLVM [53].

We have implemented both the SVSM and the SM in Rust. The SM is implemented as a Type I hypervisor. We have implemented the user-space runtime, including the corresponding bindings of HIP and OpenCL in C++, in around 8,500 lines of code. The user-space runtime is outside the TCB.

## 11 Evaluation

The evaluation of Honeycomb tries to answer the following questions both qualitatively and quantitatively:

- Does static validation in Honeycomb improve security?
- Is Honeycomb practical for real-world applications?
- Where do the overheads in Honeycomb come from?
- How efficient is the IPC in Honeycomb?
- How much effort is required to adopt Honeycomb for new applications?

### 11.1 Experiment setup

We evaluate Honeycomb on a server equipped with two 24-core 2.85 GHz AMD EPYC 7443 CPUs, 128 GB DDR4 memory, and a 480 GB SAMSUNG PM893 SSD. The server has an AMD RX6900XT GPU that has 16 GB of device memory. It connects to a gigabit Ethernet with the Broadcom BCM5720 Ethernet adapter. The machine runs a patched Linux 5.15.0 kernel to support SEV-SNP VMs. Both the sandbox and the application VM runs Linux 5.17.0 on top of QEMU 7.1.0. We have not yet enabled SEV-SNP for the sandbox VM due to complications of passing the AMD RX6900XT GPU directly into the VM. We use the ROCm 5.4.0 [3] GPU driver when running the baseline experiments. We pin all applications to the first CPU socket where the GPU is attached.

### 11.2 TCB

Honeycomb provides a secure and efficient execution environment for GPU applications. To quantitatively evaluate our efforts, we count the lines of code (LOC) in the TCB of both Honeycomb and the Linux platform using SCC [15]. The current prototype of Honeycomb only supports a limited set of hardware, thus we only count the lines of code for the x64 platform and the essential parts of the driver for AMD RX6900XT. Figure 4 presents the counts of LOC for the TCB of both Honeycomb and the Linux platform.

Honeycomb provides security guarantees with respect to the threat model in Section 3 with an order of magnitude smaller TCB compared to the normal Linux platform. The security of a GPU application running on Linux relies on the correctness of both the kernel space and the user space (ROCm) of the GPU driver. The result of the smaller TCB is consistent with other systems that adopt the design of security monitors [79, 90]. The SM and the validator in Honeycomb separate the concerns of enforcing security from implementing the required functionalities, removing the heavy-lifting portions (e.g., Linux) of the system out of the TCB.

| System                       | LOC         |
|------------------------------|-------------|
| <i>Honeycomb</i>             | 82,738      |
| SVSM                         | 9,839       |
| SM+Sandbox VM                | 9,376       |
| Validator                    | 12,299      |
| Rust runtime                 | 50,864      |
| <i>Linux 5.17</i>            | ~ 1,503,519 |
| Core functionalities for x86 | 844,993     |
| AMDGPU driver for AMD 6900XT | 607,689     |
| Kernel libraries (DRM & TTM) | 50,837      |
| ROCm 5.4.0                   | 397,151     |
| HIP Library                  | 188,995     |
| ROCR Runtime                 | 73,241      |
| ROCm Common Runtime          | 62,173      |
| ROCR Thunk interface         | 72,742      |

Figure 4: Estimated LOC for TCBs of Honeycomb and Linux. It also shows the LOC of some major components in the TCB.

### 11.3 End-to-end performance

We choose five representative benchmark suites to study how Honeycomb performs on real-world workloads:

*SpecACCEL*. SpecACCEL is a performance test suite that represents high-performance computing applications like simulations of computational fluid dynamics and molecular dynamics. We evaluate all 19 OpenCL applications in the SpecACCEL 1.2 benchmark suites. All benchmarks are evaluated against the default parameters and the reference input size.

*ResNet18*. ResNet18 is an 18-layer convolutional neural network model. It is a popular image classification model that is used on low-power edge devices. We implement a benchmark that classifies 10 images using the ResNet18 model. The model uses the single-precision, pre-trained weights (IMAGENET1K\_V1) from PyTorch 1.12.1 [64].

*BERT*. BERT is a large transformer model that powers various natural language processing tasks. We derive a benchmark from the NVIDIA FasterTransformer backend [62]. We use the BERT\_BASE configuration [29]. The model has 12 layers

Figure 5: Relative execution time for the five benchmark suites evaluated on Honeycomb.

Figure 6: The time spent on validating GPU kernels in wall clock vs. the size of the kernels.

and 110M parameters, preloaded with the single-precision, pre-trained weights called bert-base-uncased [38]. The benchmark reports the time of performing a single shot of inference on BERT.

*NanoGPT.* NanoGPT is a minimal implementation of training medium-size Generative Pre-trained Transformer (GPT) models. GPT models are often used to power chat bots or to generate human-like content. We implement a benchmark that fine-tunes the GPT2 model [68] using the tiny Shakespeare dataset in the NanoGPT repository. We preload the weights of its 124M parameters from [39]. The benchmark trains with a batch size of 4 and uses  $\sim 15$  GB out of the 16 GB of total device memory available.

*Canny.* Canny implements the Canny edge detection algorithm to detect edges in images. We implement a benchmark that detects edges on an image in the UHDSR4K dataset [91]. The resolution of the image is  $3840 \times 2160$ .

Figure 5 presents the relative execution time of all five benchmark applications. The relative execution time ranges from 0.89 (104.lbm) to 1.27 (Canny). Large language models in Honeycomb are particularly efficient: the relative slowdowns of BERT and NanoGPT are 2% and 0%. This is because their execution time is dominated by matrix multiplications, whose memory accesses can be efficiently reasoned about with scalar evolution analysis and polyhedral models. The validator requires no runtime checks to be inserted into the performance-critical, general matrix multiplication (GEMM) GPU kernels to pass validation. Honeycomb essentially launches the exact same GPU kernels compared to the baseline.

Figure 5 further breaks down the overheads into four categories: (1) Driver (slowdowns from an alternative driver), (2) SVSM (validating the requests in the command queues), (3) Mem (securing memory transfers) and (4) V (runtime checks). The characteristics of runtime overheads vary among applications. First, the alternative driver is simpler and faster in general but lacks the optimizations on large memory copies. Running Canny on the alternative driver is 18% slower (7.16s

vs. 6.11s) because it loads an 8MB image into the GPU before processing it. Second, to enforce security the SVSM must inspect each request of kernel launch. The overhead is more evident for applications that mostly consist of small, fast GPU kernels like ResNet.

The third source of overheads is secure memory transfer. For example, 117.bfs copies the frontier and the tail of the BFS queue back and forth between the host and the device in each iteration, transferring 400 bytes of data for 108,000 times. Enabling secure memory transfer results in a 42% slowdown (13.97s vs. 9.82s). 116.histo also has significant overheads because it uses memcpy() to zero out a piece of device memory at the beginning of each iteration. Changing it to memset() eliminates the overheads.

The final source of overheads comes from the runtime checks in GPU kernels that are inserted to facilitate validations. Runtime checks slow down 121.lavamnd by 19% (5.80s vs. 4.87s). However, most of the overhead can be attributed to one single runtime check. The GPU kernel writes to `a[b[i] + threadIdx.x * j]` in two-level nested loops. `i` and `j` are loop variables thus `b[i]` remains constant in the outer loop. Developer must insert a runtime check to aid the validation since `b[i]` is a value from the memory where the validator does not model. Note that the runtime check can be hoisted to the outer loop since checking the indices at the first and the last iterations of `j` is sufficient to guarantee safety. Hoisting the check effectively eliminates the overheads (both 4.87s for disabling runtime checks and hoisting the check to the outer loop). The case of 128.heartwall is similar. Extending the validation to understand hoisting is left to future work.

## 11.4 Overheads

The previous subsection has discussed the overheads on the runtime checks inside the GPU kernels. This section further studies other overheads introduced by the system design of Honeycomb, namely:

- Validating the GPU kernels at load time.

Figure 7: Round-trip bandwidth of data copies of various lengths between the host and the GPU, with and w/o secure memory transfers.

Figure 8: The achieved FLOPS in matrix multiplication on various sizes of the matrices. Both the x and y axes are on log scales.

Figure 9: Round-trip IPC bandwidth of the ping-pong application with different sizes of payloads.

- Securing memory transfers between the host and the GPU.
- Checking the preconditions against the arguments and launching the GPU kernels.

*Overheads of validating GPU kernels.* Figure 6 describes the time spent on validating the GPU kernels in all five benchmark suites we evaluate vs. the number of instructions they have. The time used by validation is roughly linear with respect to the size of the GPU kernel. Out of 149 GPU kernels we have evaluated, the largest one is a GEMM GPU kernel that has 11297 instructions coming from rocBLAS [49]. The longest time spent on validating an individual GPU kernel is around 30 ms (128.heartwall). At the application level, validating NanoGPT training takes the longest time in our evaluation. It consists of 73 GPU kernels, taking 162 ms in total to validate all of them. Note that the validation is a one-time overhead when loading the applications. Real-world GPU applications like training execute the kernels continuously for days. The evaluation shows that validating GPU kernels is efficient and has negligible overheads on overall application performance.

*Overheads of secure memory transfers.* We study the overheads of secure memory transfers using a benchmark that transfers data back and forth between the host and the GPU. A round trip of a secure memory transfer includes (1) encrypting the data on the host CPU, (2) copying the encrypted data to and from the GPU, and (3) decrypting the data. We warm up the benchmark for 5 seconds and report the average transfer bandwidth over a 30-second period for various sizes of transfers. Figure 7 presents the round-trip data bandwidth with and without secure memory transfers. The bandwidths of both ROCm and Honeycomb first increase linearly with the sizes of the payloads and then peak at 10.63 and 2.20 GB/s. The bandwidth is bounded by AES encryption/decryption throughput of a single CPU core.

*Overheads of checking preconditions and launching GPU kernels.* We study the performance impacts of checking preconditions in Honeycomb by measuring the performance of

multiplying two single-precision square matrices of various sizes in Honeycomb. We implement the benchmark using the GEMM GPU kernels from rocBLAS. The validator has verified that all global memory accesses in these GPU kernels are safe, thus there are no extra runtime checks inside the GPU kernels. We have further ported all checks on preconditions directly into the benchmark, making precondition checking the sole overhead in this benchmark.

Figure 8 presents the achieved FLOPS on both Linux and Honeycomb against various sizes of the square matrices (from  $2 \times 2$  to  $8192 \times 8192$ ), with or without checking the preconditions. Honeycomb performs 41 range checks on the kernel arguments to validate the preconditions on each launch, taking roughly  $0.04\mu\text{s}$  to complete. All GEMM GPU kernels in the benchmark have the identical function signature. Both the number of checks on preconditions and the performance are consistent.

Honeycomb is slightly slower than Linux when the size of the matrices is less than 1024, because SVSM must check each request to ensure that applications can only launch validated kernels. We observe that the overhead is  $\sim 8\mu\text{s}$  per launch of GPU kernels. To cross-validate the overheads, we compare the latency of launching a no-op kernel on Linux and on Honeycomb. The average latencies over a million launches on Linux and on Honeycomb are  $13.15\mu\text{s}$  and  $25.06\mu\text{s}$ . The overhead of checking preconditions is two orders of magnitude smaller than launching a no-op kernel.

## 11.5 IPC performance

We study the case of exchanging data between two TEE applications on the same host. We compare the bandwidth between exchanging the data via (1) an encrypted shared buffer on the host, and (2) the IPC mechanism in Honeycomb, where no encryption is needed. We have built two applications and evaluated their performance: (1) a ping-pong application that sends data back and forth, and (2) a two-stage image processing application that mimics the perception pipelines in autonomous vehicles. It ingests a video stream in an enclave

and performs edge detection in another one. The isolation not only increases modularity and robustness, but also simplifies the integrations with third-party vendor SDKs.

Figure 9 presents the effective bandwidth of the ping-pong application with different sizes of IPC payloads, along with a reference, insecure implementation that copies the payloads within the device memory using `hipMemcpyDtoD()`. IPC in Honeycomb is  $2\text{-}529\times$  faster compared to exchanging data via a shared encrypted memory buffer on the host. The effective bandwidth of round-trip IPCs peaks at  $\sim 233$  GB/s (89% of the reference insecure implementation) when sending payloads of 32 MB, where three buffers of such size utilize the shared L3 cache of the GPU (128 MB). In contrast, the bandwidth of using an encrypted shared buffer for IPC peaks at  $\sim 411$  MB/s. We attribute the inefficiency to the fact that GPU TEEs make secure memory transfers transparent to applications. Other GPU TEEs cannot give out the encryption keys to the applications without compromising the security, so the only way of sharing data securely is to re-encrypt the data before sharing them, where the performance is bounded by the CPU performance of encryption and decryption as shown in Figure 7.

We have assembled the Canny application into a two-stage image processing pipeline. The end-to-end latencies of processing a single frame of 4K image are  $679\ \mu\text{s}$  and  $18579\ \mu\text{s}$  when using direct IPC and an encrypted shared buffer on the host, where  $617\ \mu\text{s}$  is spent on actual computation.

## 11.6 Developer experience

Figure 10 presents the metrics on the kernels and development efforts of the five benchmark suites we have evaluated. It presents the number of GPU kernels, the number of memory instructions, the number of runtime checks inserted, and the number of preconditions written for each application. Neural network applications ResNet18, BERT, and NanoGPT are considerably bigger, where the GEMM kernels contribute to more than 70% of the total number of instructions. RocBLAS launches different GEMM kernels based on the sizes of matrices for optimal performances.

*Experience with neural network models and the Canny edge detector.* We have ported 109 GPU kernels in total for ResNet18, BERT, Nano and Canny. We are able to classify the GPU kernels used in neural network models into three categories: (1) element-wise operations, (2) matrix operations, including multiplication, transposition and convolution, and (3) special-purpose GPU kernels such as Im2d2col or radix sort. Note that developers do not directly write the GPU kernels. The GPU kernels either come from well-optimized libraries such as MIOpen [49] or are generated by PyTorch.

We found that GPU kernels in the first two categories have well-optimized, regular memory access patterns. Scalar evolution analysis and polyhedral models are sufficient to verify the safety of the memory accesses, meaning that no extra runtime

checks are required. However, it is important to extend the polyhedral models to treat the values of some kernel arguments as constants (§5) to complete the analysis. Many of these GPU kernels are generic library functions. They take the shape and the length of the data as arguments, which are often used in calculating addresses. GPU kernels used in the Canny edge detector also fall within the first two categories.

GPU kernels in the third category require case-by-base discussion. The class of Im2d2col GPU kernels used by ResNet18 essentially unrolls a matrix into a long vector under different configurations. The challenge of analyzing their memory access is that the GPU kernels use division and modulo operations to transform the basis of indices. For example, the statements `out_x = inner_lid % out_cols_wg;` `out_y = inner_lid / out_cols_wg;` repartition the index `inner_lid` based on the value of `out_cols_wg`. It is easy to see such accesses are inbound but neither the standard scalar evolutions nor polyhedral representations can model them. Such repartitions are often parts of the tight loops thus extra runtime checks can incur significant performance overheads. Fortunately, we found out that the compiler generates pretty stable code sequences for these statements. We have implemented a pattern matching algorithm to iterate over the instructions to uncover the semantics of repartitions, so that the validator can verify these Im2d2col GPU kernels without the need of runtime checks.

Radix sorts are introduced to speed up the training of neural networks on GPUs. Particularly, during the backward propagation pass the training application sorts the sparse gradients before propagating the values in order to improve locality and to save the precious memory bandwidth. While radix sorts are efficient on GPUs, they pose challenges for validation due to the presence of indirect memory references. It is a non-goal for the validator in Honeycomb to verify the safety of indirect memory references, so we have added runtime checks to the sorting kernels in the NanoGPT training application. The overall overheads are insignificant as radix sorts are accountable for less than 0.02% of the total running time. Replacing radix sort with an algorithm like merge sort that is more friendly to validation may be a good alternative.

Many preconditions are mechanical and usually straightforward (e.g., ensuring that the whole matrix is in the private region). Since GPU kernels take data shapes as inputs, all of which must be specified in the preconditions. For instance, each GEMM kernel requires 30 preconditions. Writing these preconditions is tedious, and we have developed a script to generate the preconditions automatically.

In short, it requires inserting zero runtime checks into ResNet18, BERT and Canny to pass validation in Honeycomb. We introduce runtime checks in the NanoGPT training application with negligible performance overheads. Developing preconditions for the GPU kernels requires modest effort. Patching frameworks like PyTorch to use the validated versions of the GPU kernels, however, turns out to be a big-

Figure 10: Metrics on the kernels and development efforts to validate GPU kernels in the five evaluated benchmark suites.

ger practical challenge. We eventually end up patching the userspace runtime to load the validated GPU kernels.

*Experience with the SpecACCEL benchmark suites.* We have ported all 19 benchmarks (40 kernels in total) in the SpecACCEL 1.2 benchmark suites to Honeycomb. We classify the required changes into three categories: (1) adding optimization, (2) undoing optimization, and (3) indirect heap references.

*Adding optimization.* The validator can benefit from optimizing the GPU kernel. For example, 110.fft has a division instruction in the kernel. The divisor is a power-of-2 constant. Propagating it into the GPU kernel reduces the division into bit shifts, simplifying the validation.

*Undoing optimization.* Aggressive optimization in compilers issue instruction sequences that are difficult to model in scalar expression. For example, the compiler compiles the expression  $-1-bx$  in 123.nw to a single instruction `s_not_b32 bx`. It is difficult for the validator to model such an instruction as a scalar expression. We have to rewrite the expression to undo the optimization so that the validator can recognize the expression.

*Indirect heap references.* There are 9 benchmarks that have indirect heap references in the code. Each instance of irregular heap access requires adding a runtime check which incurs runtime overheads. For example, 118.cutfp casts a float to the index of an array; other benchmarks like 112.spmv expose patterns like `a[b[i]]`. All these instances require adding runtime checks to pass the validations.

## 12 Related work

*TEE designs on GPUs.* GPU TEEs enforce isolation among mutually distrusted enclaves. Graviton [83] augmented the GPU hardware with RMP tables to isolate physical memory pages among enclaves. Telekine [42] was built upon Graviton to remove a side channel regarding the execution time of GPU kernels, enhancing the overall isolation confidence. HIX [44] and CRONUS [45] relied on the GPU driver’s isolation mechanisms to properly protect and isolate applications. However, modern GPU drivers are inherently complex, and even security features like isolation are prone to vulnerabilities [24, 27]. StrongBox [28] leveraged the secure IOMMU on the SoC to

isolate enclaves on integrated GPUs. It required updating the IOMMU and flushing the IOMMU TLB to switch between different execution environments.

HETEE [95] deployed a cluster of tamper-resistant servers with commodity GPUs. These servers accessed secure accelerator boxes through a centralized FPGA-based controller, achieving isolation through physical separation. Visor [66] focused on privacy-preserving video analytics in the cloud. It combined oblivious algorithms at the application level and a hybrid TEE at the system level to provide isolation.

Honeycomb enforces isolation via confining the behaviors of GPU applications with static analysis. Honeycomb’s approach complements the hardware limitations of existing GPUs, reduces overheads, and creates opportunities for optimizations like directly sharing data via IPC. Performing IPC in current GPU TEEs requires copying the data back and forth through an encrypted shared memory buffer on the host. Honeycomb combines confinements from static analysis and system-level designs to reduce IPC into copying plaintext within the device memory. IPC in Honeycomb is up to two orders of magnitude faster than conventional methods, enabling real-world applications to adopt a more modular architecture with modest overheads.

GPU TEEs also enforce isolation between enclaves and the untrusted host environment. They need to establish secure communication channels between the application running inside the CPU TEE and the GPU. Prior work implemented end-to-end secure communication channels in the GPU hardware [83], in the PCIe fabrics [44], or leveraging the secure IOMMU inside the SoC [28, 45]. Honeycomb leverages existing work on secure I/O bus [1, 44, 65] or software-based solutions [94] to establish secure communication channels.

*Crypto-based secure computing on GPUs.* Recent advances in modern cryptography offer theoretically provable solutions for privacy-preserving computing, such as Multi-Party Computation (MPC), Garbled Circuit (GC) and Homomorphic Encryption (HE). These algorithms have been used to realize secure GPU computations for machine learning and data analytics. On top of GAZELLE [47], Delphi [56] used GPU to accelerate the HE-based linear operations, and also selectively replace the expensive GC-based nonlinear ReLU opera-

tors with polynomial approximations. CryptGPU [78] further implemented both linear and nonlinear operations in MPC-based protocols on GPUs. It embedded the secret-shared value computations into floating-point operations, effectively utilizing GPU hardware units. GForce [61] instead focused on inference and addressed the high latency of non-linear operators by applying new quantization approaches and employing GPU-friendly protocols. Finally, Piranha [84] was a general and modular framework for accelerating secret-sharing-based MPC protocols on GPUs, leveraging optimized integer-based GPU kernels and memory-efficient in-place computations.

The cryptographic solutions do not keep the plaintext values in the untrusted platforms, so they are more resistant to side-channel vulnerabilities. However, their substantially higher computational cost causes huge slowdown compared to native processing. Specialized hardware [50, 71, 72] and trusted hardware units [93] have been proposed to accelerate HE and MPC, but all require non-trivial hardware changes.

Slalom [81] took a different approach. It used a CPU TEE to compute the non-linear parts, and offloaded encrypted data to the untrusted GPU to process linear operations. Both confidentiality and integrity are guaranteed. DarKnight [36] further optimized the flow with a better encryption method that greatly reduced the communication cost between CPU and GPU as well as the computations involved in the CPU TEE.

*Secure operating systems.* There is fruitful research on improving the security of operating systems, including explicitizing the security policies [73, 90], applying safe languages in the OS kernel [13, 41], and proving properties via formal verifications [52, 54]. Honeycomb utilizes techniques including security monitors and virtualization [10, 79] to remove the Linux kernel and the device driver out of the TCB.

*Software fault isolation (SFI).* Lightweight fault isolations [46, 57, 88] have been proven effective on the x86 architecture. Essentially, validation in Honeycomb is a form of SFI for GPU kernels. Honeycomb, however, combines the SFI with an alternative memory layout and other system-level supports to extend the fault isolation to a secure execution environment.

*Polyhedral analysis.* There is rich literature on utilizing polyhedral representations for loop analysis and transformations [8, 14, 35, 58]. Researchers have extended the approaches to more general cases [12]. Honeycomb uses the polyhedral analysis to model the effects of GPU memory access and to ensure that the memory access conforms with the security policy.

## 13 Conclusion

Honeycomb demonstrates that static analysis (validation) is a practical and flexible technique to enforce security for GPU applications. Combining with hardware and OS support, Honeycomb's validation guarantees powerful system-wide invariants like every memory access in the applications conforms

with the security policies. As a result, Honeycomb has reduced the size of TCB by  $18\times$ , and provided a secure IPC primitive that is  $529\times$  faster than conventional approaches.

The evaluation of Honeycomb on five representative benchmark suites, 23 applications in total, shows that Honeycomb is practical and efficient to provide secure GPU TEEs for real-world applications. It requires inserting few or none runtime checks into the GPU kernels to validate them, thus the runtime overhead is minimal. Large language model workloads like BERT and NanoGPT have  $\sim 2\%$  runtime overheads on Honeycomb.

The boom of GPU applications today requires continuous innovations in GPU software/hardware stack. Our experience on Honeycomb shows that static analysis has a lot of potential to help explore novel designs in the full software/hardware stack and to speed up innovations.

# An Extensible Orchestration and Protection Framework for Confidential Cloud Computing

Adil Ahmad<sup>†</sup>, Alex Shultz<sup>†</sup>, Byoungyoung Lee<sup>\*</sup>, Pedro Fonseca<sup>§</sup>

<sup>†</sup>Arizona State University <sup>\*</sup>Seoul National University <sup>§</sup>Purdue University

## Abstract

Confidential computing solutions are crucial to address the cloud privacy concerns. Although SGX has witnessed significant adoption in the cloud, the reliance on hardware implementation is restrictive for cloud providers in terms of orchestrating deployments and providing stronger security to their clients' enclaves. eOPF addresses this limitation by providing a comprehensive, secure hypervisor-level instrumentation framework with the ability to monitor all enclave-OS interactions and implement protected services. eOPF overcomes several challenges including bridging the semantic gap between the hypervisor and SGX and attesting the co-location of the framework with enclaves. Using eOPF, we implement two protected services that provide platform resource orchestration and complementary enclave side-channel defense. Our evaluation shows that eOPF incurs very low performance overhead (<2%) in its default state and only modest overhead (geometric mean of 17% on SPEC) when strong, complementary side-channel defenses are enabled, making eOPF an efficient and practical solution for the cloud.

## 1 Introduction

The previous two decades have shown a substantial growth in internet services enabled by the cloud. Unfortunately, using cloud services requires users to outsource sensitive code, data, or both to cloud infrastructures shared by untrusted individuals. Moreover, the rise in cyber-attacks and corresponding increasing governmental regulations on sensitive information management (e.g., CCPA, GDPR) have made cloud privacy a first-order concern for many cloud providers and users. Thus, the cloud model success increasingly depends on providing strong privacy guarantees.

Cloud providers have been trying to accommodate the user demand for privacy using confidential computing solutions. Such solutions allow secure computation on cloud machines without trusting the machine's huge and vulnerable software codebase like the operating system (OS). Among several ap-

proaches, the hardware-protected Intel Software Guard eXtensions (SGX) *enclaves* have turned out to be the most popular key building block. In particular, SGX is already deployed by major cloud providers (e.g., Microsoft Azure [24], IBM Cloud [55]), thanks in no small part due to the extensive software ecosystem (e.g., development kits and library OSs) that aids the development of new SGX programs and porting existing codebases [17, 25, 76, 83].

Despite the strong security properties of SGX, its inflexible hardware implementation poses pragmatic challenges for cloud providers and users. For instance, modern cloud services aim to be elastic, which often comes with a pay-as-you-go model that requires detailed fine-grained resource usage accounting. Unfortunately, SGX only provides detailed enclave-usage data to the OS, which is untrusted even when cloud providers run containerized instances since the OS' large codebase is susceptible to attacks from untrusted users on the machine. Moreover, since SGX's inception, many attacks have been discovered against enclaves, which are currently difficult for cloud providers to mitigate. In particular, hardware updates for several attacks (e.g., digital side-channels) were never implemented by Intel, eroding user trust in the security capabilities of SGX and exposing users to attacks.

This paper proposes eOPF, a framework designed to provide a privileged trusted software environment for cloud providers to deploy secure services on enclave-running platforms. eOPF leverages virtualization extensions to enable trustworthy and complete interposition between enclaves and the OS. By virtue of such interposition, eOPF allows cloud providers to build protected services that enhance enclaves. In particular, this paper shows how eOPF can be used to (a) securely orchestrate enclaves (e.g., control and monitor enclave resource usage) and (b) add complementary enclave side-channel defenses.

Leveraging a framework like eOPF to enable services for enclaves poses several technical challenges. First, to enable protection and resource monitoring, the framework should interpose between the OS and enclave and mediate all OS-enclave interactions. Unfortunately, this capability is not na-

tively available to the virtualization layer. Second, for remote users to trust that their enclaves are protected, they should determine that their enclaves are co-located with the framework. Unfortunately, there is currently no mechanism to guarantee such co-location. Third, even if previous challenges are solved, it is necessary to show how to securely implement orchestration and protection services using the framework.

eOPF achieves complete interposition of all enclave-OS interactions through a combination of hardware-enabled interception features and several indirect mechanisms (§4.1). In particular, Intel CPUs allow a virtualization-based framework to intercept all SGX supervisor instructions, which are used to manage enclave creation and destruction. To reliably trap on all events during enclave execution (e.g., enclave start and stop events), eOPF carefully leverages a combination of memory protection (namely extended page tables), the x86 single-step mode, and interrupt-interception mechanisms.

We address the co-location challenge by designing, to our knowledge, the first platform-enclave co-attestation protocol allowing enclave users to trust that their enclaves are protected (§4.2). Instead of naively leveraging the virtualization framework for enclave installation, which does not prove co-location to a remote user, eOPF leverages a combination of the cloud provider’s initial provisioning, intercepted enclave installation, and SGX remote attestation to achieve co-location guarantees for cloud users.

In its current form, eOPF includes a library of functions to allow cloud providers and users to enable several orchestration and protection services (§5). For instance, eOPF implements a library of side-channel defenses that users can select during runtime. The defense capabilities are implemented at a resource-level (e.g., page tables, caches) in a principled manner to isolate resources responsible for side-channel and ensure full protection. Additional services can be flexibly implemented through further software libraries.

We implemented a proof-of-concept eOPF framework with services on the Bareflank extensible framework [3]. In addition, we analyze the end-to-end security of the system and show that eOPF is effective at preventing diverse attacks against its interposition, co-attestation, and implemented services. Furthermore, we demonstrate eOPF’s performance (§8) using benchmarks and real-world programs—the SPEC CPU 2006 integer suite [13], Redis [12], and Lighttpd [9]. Our results indicate that the base framework (without side-channel defenses) incurs less than 2% performance impact to enclaves, and when all side-channel defenses are enabled, it incurs a geometric mean performance overhead of 17%, hence suitable for diverse use-cases in today’s clouds.

## 2 Confidential Cloud Computing

This section describes the confidential cloud computing system model, threat model, and research goal of eOPF. Fig. 1 provides an overview of the system model.

Figure 1: Our confidential computing model.

### 2.1 System Model

We assume that users want to run sensitive computations on the cloud (e.g., healthcare analytics on genetic information of several individuals [16]). They trust the cloud provider (like other confidential computing approaches [2, 47, 48]) but do not trust other users on the machine. The cloud provider does not trust users and aims to protect users from each other, since some may be malicious.

The cloud provider leverages SGX to enable users to securely run computations in enclaves, without trusting the bulk of the software stack or other users. SGX has several advantages over other approaches. First, SGX provides strong confidentiality and integrity guarantees against a wide-range of attacks [33]. Second, SGX is now widely-available in Intel server machines [4], a sizeable portion of all servers in the market today. Third, there are mature software development kits (SDKs) allowing users to port their programs to SGX enclaves [17] and library operating systems [76, 83] that allow users to easily run legacy programs inside enclaves.

Our model also assumes that the cloud provider runs a type-1 hypervisor on the machine (e.g., AWS Nitro [2], protected KVM [54]) and provisions containerized instances for users. Type-1 hypervisors provide better security guarantees due to a thin software codebase running at the virtualization layer (i.e., Intel VMX [52]). Containerized instances increase resource efficiency and simplify resource provisioning; hence, containerized instances underlay increasingly popular cloud models, such as microservices and serverless computing [1, 11, 72]. Moreover, since users run their sensitive computations inside SGX enclaves, the traditional isolation limitations of container instances do not apply. Nevertheless, our model also directly applies to scenarios where the cloud provider provisions virtual machines (VMs) (§9).

Since the cloud machine runs enclaves of different users, the cloud provider needs to deploy a *flexible, protected* layer to easily manage enclave instances, including managing resource oversubscription (e.g., AWS burstable instances [6]) to maximize resource efficiency. Furthermore, the cloud provider wants to use this layer to offer *enhanced, complementary protection* for enclaves against attacks that SGX does not protect, potentially by charging a higher cost.

## 2.2 Threat Model and Assumptions

The cloud provider and honest users assume that a dishonest user (or other third-parties) may compromise the machine's operating system, by leveraging a kernel vulnerability or mis-configuration. After OS compromise, they assume that an attacker will launch attacks to (a) steal sensitive information from enclaves using digital side-channels [40, 43, 60, 84, 88] or (b) launch attacks against the platform or other users using enclaves (e.g., to prevent malware introspection [74]).

**Assumptions.** This heading describes our assumptions about the security of the SGX processor and hypervisor, as well as the availability of a trusted key management service.

*SGX processor.* We trust that the processor is correctly implemented. In particular, it correctly prevents direct access of enclaves from external software and implements all cryptographic and remote attestation primitives.

*Hypervisor.* We trust the hypervisor is correct and securely initialized on the cloud machine by the trusted cloud provider. A cloud provider can securely initialize a hypervisor by leveraging UEFI secure boot [87] or verified late launch (e.g., Intel TXT [52, 63]). Leveraging a trusted platform module (TPM) [23], the provider can also attest the correct initialization remotely. Note that although we trust the hypervisor, its compromise cannot harm existing SGX guarantees since enclaves are protected from hypervisors. Please refer to §7.3 for a hypervisor TCB discussion.

*Key management service.* We assume the availability of a trusted local or remote key management service (KMS). A trusted local key management service can be designed using a TPM. In either scenario, we assume that our system has secure access to the KMS (e.g., using an isolated channel to a local device [89] or authenticated encrypted channel).

**Out-of-scope.** We do not consider attacks through micro-architectural defects, software vulnerabilities inside enclave programs, system calls, and physical attacks. We also exclude attacks through micro-architectural defects (e.g., speculative execution attacks [29, 56, 85]). Defenses enabled by our system (§5.2) for side-channels also prevent the exploitation of micro-architectural defects [27, 56] in SGX enclaves through these channels. However, the root cause of micro-architectural defects are hardware bugs, and as such they are already routinely addressed by Intel through microcode or hardware updates [7, 51]. Existing schemes [57, 75, 76] can prevent vulnerability exploitation in buggy enclave programs and protect enclaves from malicious system call results [25, 49]. Finally, physical attacks that infer DRAM access patterns and electromagnetic analysis are very expensive [58].

## 2.3 Research Goal

Given the mistrust of the OS, this paper's research goal is to design a hypervisor-level instrumentation framework that

allows cloud providers to enable protected services on enclave platforms. The framework is designed to be flexible and support two use-case classes: (a) secure enclave orchestration (e.g., preventing dishonest users from running enclaves, monitoring enclave resource usage) and (b) complementary side-channel defense for enclaves (e.g., by isolating resources).

Combining a hypervisor-level framework with SGX is favorable for cloud providers and users. From a cloud provider's perspective, hypervisor-only approaches [47, 48] offer more control but they require significant investment to design in-house full enclave abstractions and implement the corresponding SDKs. From a user's perspective, hypervisor-only approaches offer flexible functionality (e.g., resource isolation) but they have a single point-of-failure (i.e., the cloud hypervisor) in terms of data protection. Our approach solves both problems by leveraging SGX with its robust software ecosystem [17, 76, 83] and complementary data protection guarantees in the event of a cloud hypervisor compromise. Hence, co-leveraging SGX and a hypervisor is a *best-of-both-worlds* scenario for cloud providers and users.

## 3 Background on Intel SGX

Intel SGX [64] allows a process to create protected execution contexts called *enclaves*. This section describes memory protection, lifecycle, and remote attestation aspects of SGX since they are relevant to eOPF.

**Enclave page cache (EPC).** This is a reserved physical memory region where enclaves reside. SGX relies on the operating system to over-subscribe the EPC using *demand paging* (i.e., securely retrieving pages from an encrypted backing store using page faults and updating page tables).

**Enclave lifecycle.** An enclave is created by the OS using SGX supervisor leaf instructions (ENCLS). During enclave execution, the untrusted and enclave parts of the process execute SGX user leaf instructions (ENCLU) for a world switch.

*Enclave Creation.* The OS executes ECREATE to create an enclave context. After context creation, the OS invokes EADD to copy initial code and data, provided by the user, from non-enclave to enclave pages. Then, the OS executes EEXTEND to measure the copied page (explained in the next section). Finally, the OS executes EINIT to finalize the enclave.

*Enclave Entry/Exit/Resumption.* The untrusted part of the process can transition to the enclave mode using EENTER. Afterward, the enclave executes EEXIT to transition back to the untrusted mode, for two reasons: (a) synchronous exits (i.e., to perform a system-call or shutdown the enclave) and (b) asynchronous exits (i.e., to handle page faults, interrupts, and exceptions). After handling the reason for an exit, the process executes ERESUME to resume the enclave.

**Remote attestation.** SGX enables remote users to assert that their code and initial data is correctly loaded into an enclave

by sending them the enclave measurement (MRENCLAVE or  $M_e$ ) signed using the SGX CPU’s attestation key.

The enclave measurement process is entirely deterministic [30]. The measurement algorithm has an initialization, update, and finalization stage. During initialization (ECREATE), the CPU creates an initial SHA-256 hash using the OS-provided SGX Enclave Control Structure (SECS), which contains the enclave’s metadata (e.g., base address and size). In the update stages, the CPU updates the hash using each page added into the enclave (at EADD) alongside an OS-provided security information (SECINFO) block. The SECINFO block contains information about the page’s metadata (e.g., offset and permissions). In the same stage, the CPU measures each added page in 512-bit blocks (at EEXTEND). Lastly, in the finalization stage, the enclave’s measurement is hashed one last time with the total count of bits that are updated in the MRENCLAVE (at EINIT).

In formal terms, assuming an enclave of  $N$  pages ( $P^1$  to  $P^N$ ) with  $Z$  total bits, the entire enclave measurement is:

$$M_e = H_{fin}(H_{upd}(\dots H_{upd}(H_{upd}(IV, SECS), P^1) \dots, P^N), Z)$$

In this equation,  $IV$  are the initialization vectors. Additionally, for simplicity, we assume that  $H_{upd}(state, P)$  also includes a hash of the SECINFO of page  $P$ .

## 4 eOPF Design

eOPF provides a privileged trusted software environment for cloud providers to build protected services on their SGX-compatible confidential computing platforms. eOPF leverages hypervisor-level instrumentation to enable trustworthy and complete interposition between enclaves and the OS. This interposition allows users to run protected services that augment enclave security and improve resource management (e.g., measure enclave execution time).

Hypervisor-level or virtual machine extensions (VMX) [52] allow eOPF to monitor and control the execution of the OS, e.g., observe and manipulate page tables. In particular, by leveraging VMX, eOPF can intercept supervisor instructions executed by the OS and exceptions raised by the machine. Moreover, eOPF can also leverage VMX features to protect its TCB from the OS and external devices.

Designing a secure hypervisor-level instrumentation framework for enclaves poses several challenges that we address:

**C1: Semantic VMX-SGX gap.** Complete and reliable interposition of enclave interactions is needed to build protected services. While VMX framework can natively trap on SGX supervisor instructions for enclave management, it cannot natively trap SGX user instructions that determine when an enclave starts or stops. These latter events are typically junctions of information exchange between enclaves and the OS; hence, interposition is critical to augment enclave security.

**C2: Co-location attestation hurdle.** SGX’s remote attestation allows a remote user to know that their programs are

(a) EPT-based enclave entry and resume monitor

(b) Single-step-based synchronous enclave exit monitor

Figure 2: eOPF’s interposition on enclave entries and synchronous enclave exits.

running inside an enclave, but provides no guarantees that this enclave is running on the cloud provider’s machine. Without such guarantees, users cannot tell that their enclaves are protected by eOPF.

**C3: Practical service libraries.** It is necessary to show how to leverage the enclave instrumentation framework to build protected services. To help users easily build such services, it is necessary to design and implement easy-to-use libraries with core functions (e.g., transparently augment enclave protections against classes of attacks).

### 4.1 Enclave Life-Cycle Interposition

eOPF achieves complete interposition over all interactions between an enclave and the OS using native x86 features and new indirect interposition mechanisms.

**Enclave management monitor.** eOPF leverages the native capabilities of x86 virtualization to trap all SGX supervisor instructions (ENCLS), which are used for enclave creation, deletion, and other management tasks. In particular, eOPF sets the ENCLS-interception bit and its corresponding instruction bitmap in the x86 Virtual Machine Control Structure (VMCS) [52] to trap ENCLS instructions. On a trap, eOPF undertakes three sequential steps. First, eOPF implements service-specific operations needed for the instruction (refer to §4.2 and §5.1). Second, eOPF executes the trapped instruction using its trusted code and parameters provided by the

OS. Third, eOPF resumes the OS' execution from after the instruction by updating the processor's program counter.

**EPT-enforced enclave entry and resume monitor.** eOPF tracks enclave entry and resume events using the extended page tables (EPT). EPT allows a virtualization framework to protect regions of the physical memory from unauthorized read, write, and execute operations. By removing execute permissions from the enclave page cache (EPC) region, eOPF can ensure that every time enclave code is executed it raises a trap. The challenge, however, is that the trap is raised as an enclave exit, and there is no guarantee that the OS will resume the enclave after eOPF resolves the trap.

eOPF addresses the challenge by creating a trusted resume pointer (TRP), a reserved location within the process' address space that is guaranteed to execute `ERESUME`. eOPF inserts the TRP at a location where it does not significantly impact the OS' process memory management (i.e., only shares top-level page table with the remaining addresses). The OS is notified through a shared memory channel and kernel module (§6) to reserve the TRP region. eOPF write-protects the TRP and page tables that address this location using EPT, ensuring the TRP cannot be modified by the OS.

Fig. 2-(a) illustrates the EPT-based enclave entry and resume scheme employed by eOPF. On every processor core, eOPF leverages the EPT to disable execute permissions for all enclave page cache (EPC) regions (1). Hence, when a process transitions into the enclave region (i.e., using `EENTER` or `ERESUME`) (2), the CPU traps the operation with an EPT violation (3). eOPF resolves the violation by enabling execution permissions (4) and redirecting the program counter (`rip`) to the TRP (5). Finally, the enclave resumes (6).

**Dual enclave exit monitors.** eOPF uses the x86 single step mode and interrupt interception features to track synchronous and asynchronous enclave exits, respectively.

*Single-step-based synchronous exit monitor.* eOPF leverages the x86 single step mode to trap synchronous exits (e.g., for an exit-based system call). In particular, since system software is not allowed to intercept enclave execution apart from debug mode, the execution (from `EENTER` to `EEXIT`) within an enclave is considered a single step [32].

Fig. 2-(b) illustrates the synchronous exit monitor process during an exit-based enclave system call. eOPF enables the single-step mode by setting the MTF in the current processor's VMCS (1) before entering the enclave (2). Hence, the processor's execution traps to eOPF's monitor when the enclave executes `EEXIT` (3~4). eOPF disables this trap allowing the exit to be processed by the system. This process is repeated at the next enclave entry.

*Interrupt-based asynchronous exit monitor.* Apart from synchronous exits, the enclave performs asynchronous exits in order to service interrupts (e.g., raised by the timer hardware). eOPF ensures that all interrupts are trapped by setting the interrupt-interception bit inside the VMCS.

Figure 3: The platform-enclave co-attestation protocol.

## 4.2 Platform-Enclave Co-Attestation

SGX's attestation does not tell a user that their enclaves are running on their cloud provider's machine. In particular, the attestation report only contains information about the platform's security version (microcode) [53]. This is a significant challenge that motivates eOPF's co-attestation protocol.

Without a guarantee of co-location between enclaves and eOPF, an attacker (e.g., a malicious user) who has compromised a cloud machine's operating system could trick users into sending data to enclaves unprotected by eOPF. In particular, the attacker could exfiltrate a user's code from a cloud machine, send it to their own SGX-capable machine, and install it inside an unprotected enclave. Afterwards, the attacker could route all network traffic from the cloud machine to their own machine, and trick the user into sending their confidential data to the unprotected enclave. This potential attack would not require collusion with the VMM, since VMMs must allow network traffic to a cloud user's machine.

A naive approach to prevent this attack would be to leverage eOPF's interposition (last section) and design an entirely new in-house SGX attestation approach. Unfortunately, that is a significant undertaking that would require complex attestation functionality to be redundantly re-implemented and make enclave security completely reliant on eOPF, instead of complementary to SGX protections.

eOPF implements a more secure, novel co-attestation protocol that leverages both eOPF's interposition and SGX remote attestation. The key insight of our approach is that eOPF's interposition allows it to bind an *infeasible-to-guess* secret (as a watermark) to a user's enclave created on its machine, which will be transmitted and validated through SGX remote attestation to the remote user.

The eOPF co-attestation protocol has three stages. First, with the help of the trusted cloud provider, a remote user establishes a secure communication channel with an eOPF instance. Through this channel, the user sends a secret to this eOPF instance. Second, during enclave creation, the eOPF

instance securely and transparently inserts that secret into initial enclave memory. Third, the remote user leverages SGX attestation to verify the initial enclave contents and validate that co-attestation secret is valid, thereby confirming that the enclave is co-located with a cloud provider eOPF instance. In all these steps, eOPF uses a side-channel resistant cryptographic library (e.g., EverCrypt [69]) to protect secret keys. Fig. 3 illustrates our co-attestation protocol.

**eOPF-user channel establishment.** With the provider’s help, an eOPF instance on a cloud machine and a user of the machine establish a secure communication channel. In particular, during initial platform provisioning, the cloud provider installs the eOPF framework on the machine with a signed digital attestation certificate (①). This certificate and the corresponding private key is securely stored by eOPF using a trusted key management service (e.g., protected storage device or a trusted platform module) (§2.2).

When a remote user wants to run enclaves on the machine, the user will first establish a secure communication channel with the eOPF framework (②–④). In particular, the user asks the framework to authenticate itself (②) and the framework responds with its signed certificate (③). If the certificate signature is valid—based on the cloud provider’s off-the-band provided public key ( $PubK_C$ )—the remote user and the eOPF instance establish a shared secret key ( $K_{FO}$ ) (④). Note that eOPF does not require direct access to the network. In particular, all eOPF-user communication can be routed through the operating system. This approach is safe since all communication after shared channel establishment is end-to-end encrypted (using  $K_{FO}$ ) and is similar to how enclaves use the operating system as an untrusted network transport.

**Identifier-provisioned enclave installation.** Once a secure channel between the user and an eOPF instance is established, the eOPF instance installs a secret identifier into a user-specified enclave during enclave creation. We explain this process in the next paragraphs.

The user compiles a special enclave binary with one empty reserved memory page (4KB) at the end using a custom linker script and sends it to the OS. The reserved memory page will be used to hold a random 4KB secret (called  $eid$ ). The user also creates a *premeasurement* ( $pM_e$ ) of this enclave binary. The  $pM_e$  is a hash of all enclave binary pages using SGX’s enclave measurement algorithm (described in §3) except the last reserved page. In formal terms, assuming the enclave has  $N$  pages ( $P^1$  to  $P^N$ ), the  $pM_e$  is calculated as follows:

$$pM_e = H_{upd}(\dots H_{upd}(H_{upd}(IV, SECS), P^1), \dots, P^{N-1})$$

The user sends the enclave binary to the OS (⑤). Simultaneously, the user sends the  $pM_e$  and  $eid$  to eOPF using their secure communication channel (⑥).

During enclave creation, eOPF recreates  $pM_e$  to attest that the correct user enclave is being initialized on the machine (⑦). In particular, on enclave creation (§4.1), eOPF recreates the hash using an internal SHA-256 library config-

ured with the OS-provided parameters to `ECREATE` and `EADD` instructions (i.e., `SECS`, `SECINFO`, and page contents). If the premeasurement matches  $pM_e$ , eOPF transparently modifies the last enclave page to include the  $eid$  (⑧). This requires trapping `EADD` and replacing the contents inside the physical page being added to the enclave.

There are three requirements for the above operations to securely happen. First, the OS should not modify an enclave page while it is being measured by eOPF. Second, the OS should not read the  $eid$  while it is being copied into the enclave. Third, after copying  $eid$ , there should be no additional pages added to the enclave. eOPF fulfills the first two requirements using EPT. In particular, eOPF write-protects the `SECINFO` and page contents of the enclave page before the premeasurement process. Similarly, while adding  $eid$  to the reserved page, eOPF removes all permissions from the page before executing `EADD`. These protections are only disabled after `EADD` executes (§4.1). Finally, eOPF does not allow any `EADD` operation on the enclave after adding  $eid$ , ensuring that it really is the user’s enclave, and not a malicious enclave designed by the OS to steal  $eid$ .

Please refer to §9 for a discussion on how this co-attestation step can be potentially achieved without premeasurement.

**Attestation-based co-location check.** Once the enclave is securely provisioned with a secret identifier ( $eid$ ) that is only known to the eOPF instance, a remote user can leverage SGX remote attestation (§3) to check whether their enclave contains that identifier or not (⑨~⑪). In formal terms, assuming a correct enclave page with  $eid$  is  $P^{eid}$  and  $Z$  total bits, the correct enclave measurement should be as follows:

$$M_e = H_{fin}(H_{upd}(pM_e, P^{eid}), Z)$$

Since  $eid$  is a 4KB identifier, there is an infinitesimally small chance for an attacker to randomly guess ( $2^{-32768}$ ); hence, this measurement can only hold if the enclave memory contains  $eid$  provisioned by eOPF, proving co-location.

## 5 eOPF Protected Services

eOPF allows cloud providers to implement protected services in an extensible manner. This section demonstrates eOPF’s value by presenting the design of two services that help cloud providers manage resources and augment enclave security.

### 5.1 Secure Enclave Orchestration

The secure enclave orchestration service gives cloud providers the ability to control what enclaves run on their platform, detect when enclaves are used for malicious purposes, and obtain detailed enclave-related resource usage for accountability and billing. This section describes how eOPF allows cloud providers to achieve such orchestration.

**Protected launch control.** eOPF ensures that only users approved by the cloud provider are allowed to run enclaves on

cloud machines. In modern SGX machines, cloud providers leverage flexible launch control (FLC) [53] to provision a platform and provide launch tokens to their customers without relying on Intel’s provisioning service. Unfortunately, flexible launch is controlled by the untrusted OS using MSR, IA32\_SGXLEPUBKEYHASH{0–3} and the attacker can exploit this feature to launch arbitrary enclaves. eOPF leverages virtualization features to trap all writes to MSRs (i.e., WRMSR) and disallows modifications to launch control MSRs. Hence, all valid changes to the FLC feature must come from the cloud provider directly to eOPF.

**Malware scanning.** An attacker may try to hide malware on the cloud machine using shielded environments like enclaves [39, 74]. For instance, research shows that attackers can use TPMs to hide attack targets from forensic analysts [39]. A typical approach to detect malware on a machine is by scanning binaries and signature matching against a database of known malware. Although a simple approach, this is effective in practice (e.g., one study shows 59% of known malware can be detected by signature matching tools [81]).

eOPF enables secure scanning of enclave contents within its framework during enclave creation. In particular, during enclave creation, as each page is being added to the enclave (§4.1), eOPF compares the hash of contents against known malware hashes. eOPF also provides the ability to prevent the attacker from installing a barebones enclave and leveraging it to insert malware (e.g., by enabling execute permissions on data pages). This is achieved by intercepting and rejecting `EMODPE`, an `ENCLS` leaf instruction leveraged for changing existing enclave page permission changes and adding additional pages.

One concern with enclave content scanning is user privacy especially in scenarios where enclave code is an intellectual property (e.g., services like 23andMe [16] with proprietary healthcare analysis algorithms). Such concerns can be mitigated if the cloud provider runs their scanning tool inside an enclave and makes the source code of the scanner publicly-available for enclave attestation by remote users. If a proprietary scanner is used, the provider can employ SGX sandbox enforcement mechanisms [19, 49]. With these, users can trust that the proprietary scanning tool will be unable to leak sensitive information from the scanning enclave.

**Resource usage statistics.** Once an allowed enclave is running on the machine, eOPF collects detailed statistics about the enclave’s machine resource usage and periodically sends it to a system administrator.

By default, eOPF collects information about two resources: CPU time and memory. In particular, eOPF collects how much time (in cycles using `RDTSCP`) is dedicated to the user’s enclaves by implementing timers at enclave entries and exits. To prevent the OS from modifying CPU timer information, eOPF disallows all changes to timer-related MSRs [52]. eOPF also collects how much memory is allocated to the en-

clave. This is achieved by monitoring enclave page addition (`EADD`) and enclave page removal (`EWB`) instructions.

If a user enables complementary enclave side-channel defense, enclaves use additional resources (§5.2). eOPF also collects statistics of such usage for reporting purposes. In particular, eOPF tracks whether hyperthreading is disabled on a CPU core to defeat per-core side-channels. If the user selects static memory allocation for paging side-channel defense, this information is also collected. Finally, eOPF reports whether the enclave is using an isolated last-level cache or not, and how many partitions within the LLC are reserved for the user.

## 5.2 Complementary Side-Channel Defense

This service allows users to enable complementary principled defenses against digital side-channels. Digital side-channel attacks allow untrusted software on a machine (e.g., the OS) to observe the interactions of trusted software and the hardware platform [70]. Observation allow attackers to infer memory access patterns of an enclave program, which has been shown to leak sensitive enclave data (e.g., cryptographic keys) because many programs have data-dependent pathways [26].

To reason about defeating side-channels, we divide hardware resources based on how they can be observed (hence, exploited) into cross-core and per-core resources. For instance, last-level cache is shared by all processor cores, hence it can be observed by attacker on any core, while the L1/L2 caches are private to each processor core and can only be observed if the attacker runs code within the same core.

Using our classification and by integrating techniques from literature [60, 61, 66, 67], this service offers principled side-channel defense that can be flexibly enabled by users with minimal effort. In particular, the service isolates cross-core resources, ensuring an attacker cannot simultaneously observe enclave access onto the resource from any other core. Moreover, the service invalidates or deactivates per-core resources to ensure an attacker is unable to observe enclave access semantic when they run sequentially on a processor core after an enclave, or parrallely on an enclave-running core.

### 5.2.1 Cross-Core Resource Isolation

**Page tables.** The page table is created and maintained by the untrusted OS. The OS can infer page-granular (4KB for SGX enclaves) access patterns of an enclave through an enclave’s page tables. In particular, the OS can modify the enclave’s page tables to induce page faults [88] or stealthily observe the access bits of the enclave’s page table entries [84]. To avoid these attacks, eOPF allows the OS to create and delete the page tables, at enclave creation and deletion, respectively. However, eOPF prevents modifications to the page tables during enclave execution. Therefore, eOPF employs *temporal isolation* to protect the page tables.

After enclave creation, eOPF write-protects an enclave’s page tables using EPT. During each enclave entry, eOPF also checks the CR3 value to ensure that the OS did not try to create duplicated enclave page tables. Hence, eOPF ensures that the attacker cannot induce enclave page faults during execution. Furthermore, eOPF scans the enclave’s page tables and sets the access bit of each entry, ensuring that the attacker cannot leak information through access bits. At enclave shutdown, eOPF disables write-protection to let the OS handle page table deallocation. Please refer to §9 as to how this defense can be extended to support oblivious page swapping.

**Last-level cache (LLC).** The LLC contains cache lines from all programs executing on all processor cores. Hence, the LLC is vulnerable to cache attacks [26, 74]. To defeat these attacks, eOPF partitions the LLC such that an enclave’s cache lines are *spatially isolated* from untrusted programs.

Cache Allocation Technology (CAT) allows isolating cache lines of different CPU processors across different partitions in the LLC. Leveraging CAT, eOPF divides the LLC into enclave and non-enclave partitions. At enclave entries and resumes, eOPF switches the processor to the enclave partition, while the untrusted software (on other processors) use the non-enclave partition. On enclave exits, eOPF reverts the processor back to the non-enclave partition. While each partition can support unlimited enclaves, CAT can only support 15 distrusting partitions concurrently at this time. In particular, the latest CAT implementation has 16 domains [52] and 1 partition must remain reserved for untrusted software. In the future, if additional domains are implemented, eOPF can support additional distrusting partitions.

eOPF creates new LLC partitions using CAT-related MSRs, IA32\_L3\_MASK\_N. A processor follows the partition specified in its register IA32\_PQR\_ASSOC. Whenever a partition is changed, all cache-lines must be invalidated to enforce the change. eOPF achieves this using WBINVD. Furthermore, eOPF prevents modifications to CAT MSRs during enclave execution to ensure full control over CAT.

## 5.2.2 Per-Core Resource Invalidation and Deactivation

**Intra-core computational units (ICUs).** Such units include Arithmetic Logic Units (ALUs) and Translation-Lookaside Buffer (TLBs). An attacker can abuse hyper-threading, a hardware feature that allows concurrent execution of two threads on the same processor core, to infer an enclave’s access semantics onto ICUs [21, 44]. To defeat these attacks, eOPF ensures that hyper-threading is *deactivated* on the processor core that is running an enclave.

eOPF notifies the OS using its shared memory channel (§6) that a certain enclave should execute without hyper-threading. The OS can disable hyper-threading in software (e.g., OpenBSD does this by default [10]) by programming the x86 Local APIC [52]. In particular, once hyper-threading is disabled on a processor, it does not raise hardware interrupts.

Hence, eOPF monitors each core for hardware interrupts and if it observes hardware interrupts on enclave-running (hyper-threaded) processor cores, it terminates the enclave. On each enclave exit, ICUs are automatically flushed by the SGX processor, leaving no observable intermediate effect.

**L1 and L2 cache.** Enclave and untrusted programs that run sequentially or in parallel (using hyper-threading) on a processor core share cache lines across the L1 and L2 caches. An attacker can exploit this sharing to leak enclave contents through cache attacks [26, 43]. eOPF *deactivates* hyper-threading (previous section) to prevent parallel attacks. To protect against sequential attacks, eOPF *invalidates* the L1/L2 cache (using WBINVD) at enclave exits. Hence, all enclave contents are flushed back to memory and the attacker observes an empty cache state on each attack.

**Branch predictor units (BPUs).** Branch predictor units like the branch target buffer (BTB) and pattern history table (PHT) predict the control-flow of a computation in an out-of-order CPU. Attackers can use them to infer an enclave’s control-flow by observing whether a particular branch was taken or not [40, 60]. Unfortunately, the SGX CPU does not provide native mechanisms to invalidate these units. Nevertheless, eOPF deactivates the components critical for their side-channel exploits and designs software invalidation.

Prior work has shown that reliable attacks on the BTB require specialized units such as the Last Branch Record (LBR) or Intel Processor Trace (PT) [60], particularly because of the BTB’s small size in comparison to other predictors. The LBR and PT are performance tools that cannot be used by enclaves. Hence, eOPF deactivates the LBR and PT by setting MSRs, IA32\_DEBUGCTLA and IA32\_RTIT\_CTL, respectively, and denying all modifications to these MSRs.

eOPF uses knowledge of the PHT’s structure to implement a software invalidation technique, ensuring the attacker is unable to observe intermediate enclave artifacts on the PHT. In particular, the PHT contains 16,384 entries and is indexed by the lowest  $\log_2 N$  bits of a conditional branch instruction’s address [40]. Each PHT entry is a 2-bit Finite State Machine with 4 states: (a) Strongly Not-Taken, (b) Weakly Not-Taken, (c) Weakly-Taken, and (d) Strongly-Taken. An entry is updated each time the processor takes (or does not take) a branch. Using this knowledge, eOPF generates conditional branches aligned to each PHT entry. For each branch, the code performs an always-true arithmetic comparison and takes the branch. Therefore, each PHT entry moves towards the Strongly-Taken state. eOPF runs the code thrice to ensure that the final state of each PHT entry is Strongly-Taken. Hence, the attacker always observes a uniform state of the PHT.

## 6 Implementation

We built a prototype of eOPF using the Bareflank extensible framework [3]. However, in practice, eOPF can be built using

any VMX framework or type-1 hypervisor (§2.1). By default, eOPF enables EPT protections, traps all enclave events and critical processor-related events (e.g., WRMSR), and enables the enclave orchestration service (refer to §4.1 and §5.1). Apart from bootstrapping and VMX-specific code, the base framework includes a SHA-256 hash generator [65] for co-attestation and kernel module for eOPF-OS communication. Furthermore, we implemented three eOPF modules: a *paging module* (PM) for page table protections, a *caching module* (CM) for L1/L2 and last-level cache protections, and a *branching module* (BM) for BPU protections.

Our prototype does not currently implement communication with the user. Such communication is a one-time cost at enclave creation; hence, it does not impact runtime results. Also, Bareflank does not currently support IOMMU to protect the framework against device-based attacks. Nevertheless, IOMMU should be enabled by default in cloud machines and it is not an additional slowdown factor incurred by eOPF.

## 7 Security Analysis

This section provides a security analysis of eOPF and protected services by discussing several attacks and implemented defenses (Fig. 4). It concludes with a brief TCB discussion.

### 7.1 Analyzing Framework Security

**Preventing attacks against interposition.** eOPF requires secure interposition of enclave and important system events. To prevent this interposition, the attacker can try to overwrite the VMCS, a data structure that contains the ENCLS-interception bitmap, the monitor trap flag (MTF), and is responsible for enabling other important interception functionality (e.g., WRMSR traps). Moreover, the attacker can try to modify the TRP and trick eOPF into thinking the enclave resumed. eOPF prevents all aforementioned attacks (§4.1).

The VMCS and its extended instruction bitmaps are located in protected eOPF memory and the attacker is unable to modify these structures to disable ENCLS or other system functionality interposition. The protected memory is created from virtualization extensions. In particular, eOPF uses EPT protections to prevent software access and IOMMU protections to prevent device access [89]. The critical data structures (or tables) of EPT and IOMMU are also stored within the protected memory; hence, the OS cannot access them. Finally, the TRP is located in a reserved region of the enclave process' address space, it cannot be overwritten due to memory protections, and its page tables are also write-protected.

**Preventing attacks against co-attestation.** The attacker can attempt to circumvent co-attestation by trying to leak secret eOPF keys provisioned in the machine or the enclave unique ID (*eid*), trying to guess *eid*, and replaying communication. eOPF prevents all such attacks (§4.2).

| Potential attacks                           | eOPF defense                                                            |
|---------------------------------------------|-------------------------------------------------------------------------|
| <b>Against interposition (§4.1)</b>         |                                                                         |
| Modify VMCS                                 | Prevent software and device access using EPT and IOMMU, resp.           |
| Disable mem. protections                    | Access-protect EPT/IOMMU structures                                     |
| Modify TRP                                  | Write-protect TRP and its PTs                                           |
| <b>Against co-attestation (§4.2)</b>        |                                                                         |
| Leak eOPF secrets                           | Store in protected memory/storage and use SC-resistant crypto libraries |
| Steal <i>eid</i> using enclave              | Only install to pre-measured enclave                                    |
| Guess <i>eid</i>                            | Use very large number                                                   |
| Replay communication                        | Use Random nonces                                                       |
| <b>Against enclave orchestration (§5.1)</b> |                                                                         |
| Modify LC MSRs                              | Trap writes to MSRs                                                     |
| Hide resource usage                         | Trap EADD; prevent TSC MSR changes                                      |
| Hide malware in enclaves                    | Scan initial content and disable changes                                |
| <b>Against side-channel defense (§5.2)</b>  |                                                                         |
| Write to page tables                        | Write-protect using EPT                                                 |
| Disable/modify CAT                          | Trap writes to MSRs                                                     |
| Enable hyper-threading                      | Monitor interrupts on signalled cores                                   |
| Enable LBR/PT                               | Trap corresponding MSRs                                                 |

Figure 4: Table illustrates how eOPF defends against several attacks directed at its framework and protected services.

The platform is securely provisioned by the trusted cloud provider and all secret keys established during provisioning are securely maintained within the system's protected key management system (e.g., a persistent dedicated storage). Every subsequent cryptographic operation is also securely performed in a side-channel resistant manner ensuring the attacker cannot leak keys while they are being used. Moreover, during enclave installation, the *eid* is directly received by eOPF through a secure communication channel with a remote user and securely kept in protected memory. The possibility of the attacker being able to guess the correct *eid* is infinitesimally small ( $2^{-32768}$ ). This is harder than guessing an RSA cryptographic key. Finally, even though the OS can record and replay network packets, all network communication is secured using random nonces to prevent replay attacks.

### 7.2 Analyzing Services Security

**Preventing attacks against enclave orchestration.** After compromising the OS, the attacker can attempt to run arbitrary enclaves by modifying launch control MSRs or hide their enclave resource usage from the cloud provider. Additionally, an attacker might try to hide malware inside enclaves. eOPF prevents all aforementioned attacks.

eOPF ensures that SGX flexible launch control features can only be configured by the cloud provider by intercepting all writes to the launch control MSRs. Hence, even a user that has compromised the OS cannot run enclaves on a machine without obtaining a launch token from the cloud provider. Since eOPF interposes all enclave supervisor and user interactions, it can trivially measure how the enclave is using resources. In particular, it uses RDTSCP to measure CPU

time on enclave entries and traps all instructions that insert or remove enclave pages. To prevent the attacker from keeping malware inside enclaves, eOPF scans enclave contents at load time and prevents subsequent code changes.

**Preventing attacks against side-channel defense.** The attacker can attempt to disable side-channel defenses by modifying entries inside enclave page tables (e.g., reset access bit), modify CAT configuration to disable last-level cache isolation, resume hyper-threading to leverage per-core side-channels, and re-enable LBR/PT to exploit BTB-related side-channels. eOPF protects against all aforementioned attacks (§5.2).

Access and dirty bits are set in enclave page table entries, and the tables are write-protected (using EPT) to prevent additional modifications. To modify CAT partitions, the OS would need to write to CAT-related MSR (using `WRMSR`) and such a write is trapped by eOPF. If the attacker re-enables hyper-threading, they will be caught since the processor core will raise an interrupt that will be intercepted by eOPF. Finally, LBR and PT configurations can only be changed by writing to MSR, and any such attempt is caught by eOPF.

### 7.3 Analyzing eOPF’s TCB

This section analyzes eOPF’s TCB followed by a brief discussion on the impact of attacks on eOPF to a user.

eOPF allows the OS to handle most functionality and only interposes on sensitive interactions (e.g., MSR writes). Hence, from a cloud machine’s perspective, eOPF only marginally increases the TCB, which can be rigorously tested.

On a virtualized cloud machine, eOPF’s complete TCB includes the hypervisor. We find this acceptable for several reasons. In particular, even though hypervisors can be large, the attacker-exploitable interface is typically significantly narrower than monolithic OSs, resulting in fewer discovered vulnerabilities in hypervisor codebases [28, 77]. The exploit of these vulnerabilities can be made significantly more challenging by using memory lockdown and compiler instrumentation to ensure hypervisor code integrity and control-flow integrity, respectively, with a small performance impact [86]. Moreover, eOPF’s TCB can be reduced using hypervisor compartmentalization [77]. In such scenarios, eOPF can execute alongside a tiny security monitor and enforce security invariants while remaining isolated from the large cloud hypervisor.

Finally, since eOPF is external to the enclave and the microcode, it cannot access enclave contents and, during its operation, it is not exposed to enclave secrets. Hence, attacks against eOPF cannot harm the existing SGX guarantees.

## 8 Performance Evaluation

This section describes eOPF’s performance through custom benchmarks and diverse real-world programs.

**Setup.** We evaluated eOPF using SGX desktop and server machines (Fig. 5). Although SGX is deprecated on desktops,

|                   | Desktop         | Server          |
|-------------------|-----------------|-----------------|
| <b>Hardware</b>   |                 |                 |
| CPU model         | i7-8700         | Xeon Gold 6348  |

Figure 5: Machine platforms used for evaluation.

we used the desktop because we observed a large number of enclave exits on it. In particular, the desktop has a smaller EPC which leads to frequent page faults (which cause exits) when running large enclaves [68]. Many of eOPF’s side-channel defenses incur extra costs at exits; hence, the desktop machine allows us to better observe worst-case overheads.

We leveraged two software optimizations to reduce enclave exits, both of which are well-supported by modern systems. First, unless noted otherwise, we used the *exitless* (or *switchless*) system call setting for all experiments. This setting is now widely-supported (e.g., even the relatively basic SGX SDK supports it [17]) and is known to improve performance by avoiding expensive enclave exits using background request handling threads and system call batching. Other work also evaluates SGX enclaves using this option [22, 68]. Second, we configured both machine kernels as *tickless* [15] to reduce enclave exits due to frequent timer interrupts [66].

**Terminology.** eOPF refers to the base framework with all interposition and cloud orchestration features but no runtime side-channel defense. eOPF+PM refers to the system with the paging module enabled for paging side-channel defense. eOPF+CM refers to caching module enabled on a system to prevent cache attacks, while eOPF+BM refer to the system enabled with BPU defenses. Hyper-threading in enclave-running cores is disabled for both CM and BM. When all side-channel defenses are enabled, we refer to the system as eOPF+PM+CM+BM. Our baseline in all experiments was a non-virtualized system.

### 8.1 Microbenchmarks

This section describes our experiments to find the raw cost of eOPF’s enclave interposition and side-channel protection at different events through two benchmarks.

**Enclave event interposition benchmark.** We created a test program that executes 100k barebones enclave entry and exit tests. In the entry test, the application enters the enclave while providing current (pre-entry) time as argument. The enclave measures the time it took to enter and returns to the appli-

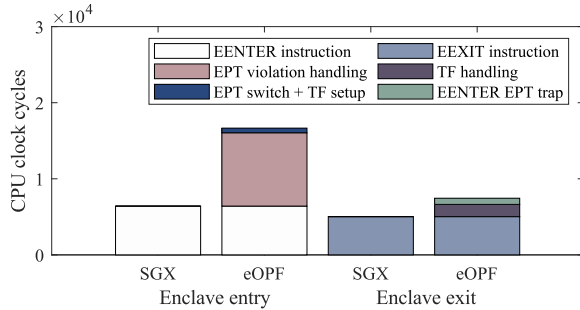

Figure 6: Overheads at enclave entry and exit for eOPF on our server machine. TF means *trap flag*. SGX’s EENTER and EEXIT instruction cost was comparable to existing work [68].

ation. In the exit test, the same set of operations occur but from enclave to the application. To get a detailed picture, we also measured the time to perform eOPF-specific tasks (e.g., switch EPT during entry) from inside the framework. The time was measured everywhere using RDTSCP. Finally, we disabled *exitless* mode for this experiment to get the full cost of exits. Fig. 6 shows the performance overhead incurred in our experiment with native SGX and eOPF.

*eOPF overhead.* eOPF adds 59% overhead to enclave entries, while it adds 71% overhead to enclave exits.

On each entry, eOPF incurs a virtual machine exit to handle the EPT violation, which takes 9639 cycles on our machine. We believe some of this cost is because eOPF is implemented on Bareflank, which is designed for modularity instead of performance; hence, it can be further optimized. Once the violation is handled, eOPF sets the trap flag to trap subsequent exits and switches the EPT to allow enclave execution. These tasks take 1067 cycles.

On each enclave exit, eOPF incurs a virtual machine exit for the trap flag, which only takes 1608 cycles on our machine. Afterwards, eOPF switches the EPT to trap subsequent enclave entries which takes 812 cycles on our machine.

**Side-channel protection benchmark.** We ran a benchmark enclave program that continuously writes to a large 256 MB buffer on both machines. We ran the enclave continuously for 60 seconds and measured incurred performance overheads (using RDTSCP) while enabling different side-channel protection modules. Since the resources affected by the caching and branching modules (CM and BM) have different sizes on each of our test machines, we ran their experiments on each machine. Fig. 7 shows the runtime performance overhead.

*eOPF+PM overhead.* Paging defenses introduce a one-time cost, during the enclave’s lifetime, at enclave creation. The paging module performs the following steps: (a) maps guest page tables to eOPF’s address space, (b) scans entire page tables (including non-enclave entries) to find the enclave regions and sets access/dirty bits, and (c) write-protects enclave page table entries. On the server machine, these steps adds an

| Invalidation     | Time (kcycles) |       | Time (ms) |      |
|------------------|----------------|-------|-----------|------|
|                  | Min            | Max   | Min       | Max  |
| <b>Desktop</b>   |                |       |           |      |
| CM (L1/L2 + LLC) | 247            | 10560 | 0.08      | 3.35 |
| BM (PHT)         | 120            | 844   | 0.04      | 0.30 |
| Total            | 367            | 11404 | 0.12      | 3.65 |
| <b>Server</b>    |                |       |           |      |
| CM (L1/L2 + LLC) | 3240           | 19454 | 1.25      | 7.48 |
| BM (PHT)         | 373            | 494   | 0.14      | 0.19 |
| Total            | 3613           | 19947 | 1.39      | 7.67 |

Figure 7: Overheads due to resource invalidation at enclave exits for CM and BM.

additional  $\sim 1.9$  seconds to our enclave’s creation. We expect this cost is negligible for longer-running enclaves.

*eOPF+CM overhead.* At enclave exits, eOPF’s cache defenses (§5.2.1 and §5.2.2) require (a) partitioning the last-level cache (LLC) and switching partitions during enclave execution and (b) writing back and invalidating the caches at enclave exits. Please refer to §8.2 for the runtime overhead.

Partitioning the LLC and switching partitions is fast: it takes  $\sim 200$  cycles to update a model-specific register (using WRMSR). Cache write-back and invalidation time depends on the state and size of the cache. On the desktop machine, we noticed that it took up to 3.35 ms, whereas its lower bound (through consecutive invalidations) was 0.08 ms. Cache invalidation took from 1.25 ms to 7.48 ms on the server.

Despite a smaller cache, invalidation on the desktop is not that much faster than the server. The reason is that, unlike server machines where SGX does not implement hardware memory integrity [41], the desktop enforces integrity using a Merkle tree. This tree is updated on each cache-line that is flushed to DRAM [46], incurring 6 additional memory accesses per-cache-line. Notably, invalidating non-enclave memory on the desktop machine took only up to 0.81 ms.

*eOPF+BM overhead.* We executed our custom branch predictor flush to invalidate the PHT (§5.2.2). The lower bound for invalidation was 0.04 and we saw an upper bound of 0.30 milliseconds. Since typically branch misprediction adds a 5 nanoseconds latency [36], our evaluation results indicate that all branches were being mispredicted.

**Benchmark result summary.** eOPF interposition and side-channel protection cost is only incurred at enclave entry or exits. Although the cost can be high, these events are only a small fraction of the program’s execution and can be significantly reduced with widely-available optimizations like switchless enclaves and tickless kernels (§8). For instance, in our experiments with SGX SDK’s switchless benchmark [14], we noticed only 3k exits for 2 million enclave calls. Hence, as the next section will demonstrate, eOPF’s overhead on real-world programs using software optimizations is typically modest, even with all side-channel protections enabled.

## 8.2 Real-world Enclave Programs

**Common settings and results.** While partitioning sensitive functionality of a program to run inside an enclave was the initial SGX intent, it has evolved over the years to run entire programs inside enclaves using Library OSs [25, 76, 80, 83], particularly for convenience reasons. In fact, even Intel has officially adopted (and continuously supports) the Gramine Library OS (formerly Graphene [83]) as an SDK for running Linux programs inside SGX [5]. Hence, we also used the Occlum and Gramine Library OSs [76, 83] to run Linux programs inside enclaves for evaluation.

Unless noted otherwise, we ran programs on the server machine using an enclave partition size of  $1/12 \cdot \text{LLC}$ , the smallest allowed CAT-based partition on the server machine. This setting allows the machine to be shared amongst the most number of users, highly desirable in cloud machines. We ran each program 10 times and report the average.

Since eOPF+PM only incurs a one-time performance overhead during enclave creation, in our long-running programs, its performance impact was negligible. Hence, we do not illustrate its overhead in Fig. 8 and Fig. 9

We also evaluated the overhead incurred by the base framework alone (i.e., no side-channel modules were enabled) during each real-world program's execution inside enclaves. The base framework must interpose all enclave events, which increases the runtime cost (§8.1). However, our evaluation shows that this cost is very small during execution. On the server machine, the framework's cost is less than 2% on average during execution of each real-world program described in this section, primarily because exits are low and CPU virtualization (required by the framework) is lightweight.

**Assorted (SPEC).** SPEC is a collection of well-known CPU and memory-intensive programs that are useful to assess real-world system performance. It has been used for evaluation by the Occlum LibOS (which we used for this experiment) and includes real-world programs (e.g., compiler toolchains and compression libraries) that are evaluation targets for other SGX systems [75]. The Occlum LibOS is designed to support SPEC 2006 integer benchmarks out-of-the-box, unlike the latest SPEC 2017. Hence, we decided to evaluate our system with SPEC 2006 integer benchmarks.

Fig. 8 illustrates eOPF's performance across SPEC using reference datasets on the server machine. Encouragingly, even with all protections enabled, most programs incurred a modest performance overhead—7 out of 11 incurred less than 20% slowdown, and the geometric mean slowdown was 17%. Across all programs, the biggest slowdown factor was cache protections. Since our experiments used switchless system calls and tickless kernels (§8), most programs incurred very few enclave exits and showed modest performance overhead. Nevertheless, the smaller enclave LLC partition had a considerable effect (e.g., 311%) on the performance of highly memory-intensive programs like gcc and omnetpp.

We also ran SPEC programs on the desktop machine using test datasets to estimate performance in worst-case scenarios with many enclave exits. Since reference workloads require significant memory, it is infeasible to run them on the desktop machine. Fig. 9 illustrates eOPF's performance on the desktop using  $1/8 \cdot \text{LLC}$ , the closest to fair sharing for each core. With both CM and BM enabled, the geometric mean overhead was 34% on the desktop machine. Since the desktop machine only has a 128 MB EPC, demand paging was inevitable. Thus, the programs incurred many more enclave exits because of page faults and performance was (expectedly) lower than the server machine. We noticed two programs, mcf and sjeng, incurred a very high overhead. We found that their test datasets required up to 1 GB of memory, hence their enclaves incurred the most exits (due to page faults) per-second.

**Key-value store (Redis).** Key-value stores like Redis [12] are widely used in cloud environments. We evaluated Redis using default settings and its official redis-benchmark, which tests 20 different key-value store operations including GET, SET, MSET, and POP. We ran each operation for 100,000 iterations using the default settings of 50 parallel clients. In its default state, Redis only keeps the key-value store *in-memory* for performance and does not write to disk. Additionally, note that while Redis ran inside an enclave, client network socket connections were received by user-space code outside the enclave, since enclaves cannot receive network packets directly. This code then sent the packets to the Redis enclave. In typical scenarios, client request in the packets would be protected using TLS that terminates inside the enclave, but redis-benchmark does not support TLS. Hence, requests were unencrypted and we used this for benchmarking purposes.

In our experiments, eOPF+CM+BM reduced throughput by 4–21% (geometric mean was 11%) across these operations. We only observed 27 enclave exits per-second during the benchmark's 119s execution. These exits were few due to switchless optimizations (§8). Given a low number of enclave exits and the fact that Redis is highly memory-intensive, the major factor behind its throughput reduction was the program executing on a restricted LLC partition.

**Web server (Lighttpd).** Webservers like Lighttpd [8], handle sensitive queries to fetch webpages, and hence are a good fit for SGX. We ran Lighttpd with 8 worker threads because this setting maximized throughput. From a separate server machine (average latency between machines was 0.09 ms), we used ApacheBench to send 10,000 HTTP requests for a 10 KB file from up to 256 concurrent clients. We sent HTTP requests like prior research [76] for stress benchmarking. In real-world cases, HTTPS ensures a request is end-to-end protected with TLS connections terminating inside the enclave.

In our experiments, eOPF+CM+BM's geometric mean throughput reduction across the test was only 5%. Interestingly, requests from a single client incurred a 65% throughput reduction, while requests from 256 concurrent clients incurred only 1% reduction. The reason is that the worker threads go

Figure 8: SPEC CPU 2006 performance with eOPF using the reference dataset on the server machine. The enclave partition was  $1/12 * \text{LLC}$ . For this test, the enclave exits per-second were: 3, 105, 4, 3, 3, 2, 2, 1, 11, 1, 8, from left to right.

Figure 9: SPEC CPU 2006 performance with eOPF using the test dataset on the desktop machine. The enclave partition was  $1/8 * \text{LLC}$ . For this test, the enclave exits per-second were 29, 2184, 3071, 965, 25, 3444, 417, 298, 60, 22, 91, from left to right.

to sleep when there are no requests and they are awakened through inter-processor-interrupts, hence they incur additional enclave exits. With greater concurrency, the workers are always busy handling requests, thus they do not go to sleep.

### 8.3 Key takeaways

**T1.** The base eOPF (which enables secure enclave orchestration) incurs a low performance overhead ( $< 2\%$ ) on real-world programs because (a) it leverages lightweight techniques and (b) its overhead is incurred at infrequent enclave exits.

**T2.** While eOPF’s overhead expectedly increases with principled side-channel defenses, especially for highly memory-intensive programs (e.g., 311% for gcc on the server machine), it remains modest for the vast majority of programs (e.g., 17% geomean for SPEC programs on the server machine).

**T3.** eOPF’s side-channel defense overhead is comparable to defenses that detect attacks using heuristics (e.g., Varys [66] incurs 15% overhead). However, through invalidation and isolation, eOPF provides strong protection akin to cryptographic techniques that obfuscate *all* side-channel leakage with high costs (e.g., Raccoon [70] incurs  $21.8\times$  overhead).

**T4.** Given the modest defense cost and the fact that eOPF allows users to flexibly decide when defenses are applied, eOPF can be practically adopted in today’s cloud machines.

## 9 Discussion

**Virtual machine support.** In addition to containers, eOPF can orchestrate and protect enclaves running in different vir-

tual machines (VMs) without a design change. This is because eOPF executes at the hypervisor layer, where it has the ability to distinguish between enclaves in different VMs [50, 52] during enclave lifecycle interposition (§4.1). In particular, when the hypervisor starts or resumes a VM, eOPF tracks this using the virtual machine control structure (VMCS). Subsequently, at any exit to the VMM during enclave creation or asynchronous enclave exits, eOPF determines which VM encountered this event by checking the VMCS again. Finally, eOPF interposes on (a) enclave entries using the per-VM EPT and (b) synchronous enclave exits using the single-step interception bit, which is also set in the per-VM VMCS.

**Co-attestation without premeasurement.** While provisioning an enclave with a secret identifier (*eid*) during co-attestation, the requirement is that *eid* is not disclosed to an attacker-controlled enclave (§4.2). In principle, this can be achieved without premeasurement if eOPF (a) installs the *eid* in any recently-created enclave and (b) restricts *eid* enclave page permissions using EPT to prevent the enclave from accessing it, unless SGX measurement is called at which time the user will verify. We leave the study of alternate co-attestation primitives for eOPF to future work.

**Supported enclave count.** By default, eOPF is a thin orchestration layer that collects statistics and enforces properties for cloud providers; hence, it supports as many enclaves as the platform originally can. If *all* side-channel protections are enforced (§5.2), eOPF can support (a) as many enclaves as can be kept resident in the EPC (i.e., within 512 GB in modern systems [41]) and (b) as many *distrusting* containers (each with unlimited enclaves) as CAT partitions allow (currently

15 partitions). The first limit can be removed using oblivious page swapping mechanisms (discussed in the *future eOPF extensions* paragraph in this section). The second limit can be addressed if future hardware iterations increase the number of isolated cache partitions (e.g., using recent proposals [37]). eOPF can be easily extended to leverage new functionality when it is made available by developers or hardware vendors.

**Future eOPF extensions.** eOPF is designed to be an extensible framework that flexibly provides several guarantees to cloud providers and enclave users. One possible extension would be to support *oblivious swapping* of enclave pages at page faults [67]. In particular, when a page fault happens during enclave execution, eOPF can clear the CR2 register to shield the faulting page from the OS. Instead, eOPF can provide a list of candidate pages for the OS to bring into the EPC. To create a secure candidate list, eOPF can rely on a cryptographically-secure algorithm like the Oblivious RAM (ORAM) [82]. eOPF can also enable the use of efficient per-thread hardware memory protection (using MPK) for enclaves and enable memory protection use-cases [49]. In particular, currently enclaves cannot securely use MPK since it requires setting protection keys in page tables [20], which are controlled by the OS. Instead of relying on the OS, the enclave can rely on eOPF to set correct protection keys.

## 10 Related Work

**Privileged software monitors for TEEs.** A lot of research has been done to design software security monitors that are more privileged than the OS and leverage them to create protected process contexts with strong isolation guarantees. Many systems [31, 47, 48, 62] rely on hardware memory protection capabilities (e.g., EPT) of virtualization layers (e.g., VMX) for such security monitors. Other systems [35, 38] rely on compiler instrumentation (e.g., software fault isolation) to deprive the OS and execute a security monitor at ring-0. On non-x86 systems, several designs [34, 41, 42, 59] leverage architectural privileged layers like ARM TrustZone or RISC-V machine mode and their protection features (e.g., physical memory protection). While our design of eOPF takes inspiration from all these systems, eOPF remains unique for several reasons. First, eOPF only offers complementary protection to enclaves, ensuring that even if its monitor is compromised, user computations retain SGX protections. Second, by leveraging SGX and its extensive industry support, eOPF can be readily-adopted by cloud providers without hardware changes or designing extensive software development kits.

**SGX digital side-channel defenses.** Researchers have proposed both software and hardware solutions to address digital side-channels in enclaves. Software solutions implemented inside enclaves cannot prevent memory access patterns from being disclosed since that is a hardware limitation. Therefore, many software protection schemes rely on cryptographic

protocols like ORAM [18, 70, 71] to obfuscate all memory access patterns (i.e., make all access patterns indistinguishable). However, since ORAM is expensive, these defenses incur significant slowdown (e.g.,  $21.8\times$  [70]). Other software solutions [45, 66, 78, 79] leverage heuristics to detect certain attack vectors. On the hardware front, Autarky [67] implements strong and efficient protection against page table attacks. One of Autarky’s ideas is to set all access and dirty bits for enclave page table entries, which is also adopted by eOPF’s page table defense. In contrast to these defenses, eOPF offers a more comprehensive protection against several side-channels with low performance impact and minimal user effort.

**Running programs inside enclaves.** Haven [25] runs Microsoft Windows programs in enclaves with minimal changes. Graphene [83] and Panoply [80] implement library OSs to run Linux applications inside enclaves, while VC3 [73] allows developers to protect data analytics. Ryoan [49] provides trusted client-server application processing in SGX and Scone [22] enables SGX-protected containers. Eleos [68] designs user-level paging to reduce enclave exits and improve performance. eOPF is orthogonal to this line of research and can improve the security guarantees provided by these systems.

**Enclave and platform attestation.** Windows 11 machines leverage the TPM [23] for secure boot and platform attestation. SGX’s remote enclave attestation is also inspired by the TPM. Recently, MAGE [30] demonstrated how to extend SGX enclave to attest mutually-trusted enclaves together by leveraging a *premeasurement* of enclave memory regions. eOPF’s use of premeasurement ( $pM_e$ ) is inspired by MAGE, but eOPF uses it to enable platform-enclave co-attestation.

## 11 Conclusion

eOPF provides a trusted privileged environment for cloud providers to enable protected services on their SGX-capable confidential computing platform. In this paper, we overcome several challenges to design eOPF, implement secure cloud orchestration and complementary side-channel defense as services enabled by eOPF, and provide a detailed security and performance analysis of the framework. Our results indicate that eOPF provides strong protection with very low performance impact on average ( $<2\%$  for the framework alone) and it can be readily-adopted in today’s clouds.

## 12 Acknowledgment

We would like to thank the anonymous reviewers and our shepherd, Bryan Parno, for their insightful reviews which significantly improved the paper’s evaluation and presentation. This work was partly supported by the National Science Foundation (NSF) under grants CNS-2145888 and the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. RS-2023-00209093).

## Abstract

This paper introduces Nimble, a cloud service that helps applications running in trusted execution environments (TEEs) to detect rollback attacks (i.e., detect whether a data item retrieved from persistent storage is the latest version). To achieve this, Nimble realizes an append-only ledger service by employing a simple state machine running in a TEE in conjunction with a crash fault-tolerant storage service. Nimble then replicates this trusted state machine to ensure the system is available even if a minority of state machines crash. A salient aspect of Nimble is a new reconfiguration protocol that allows a cloud provider to replace the set of nodes running the trusted state machine whenever it wishes—*without* affecting safety. We have formally verified Nimble’s core protocol in Dafny, and have implemented Nimble such that its trusted state machine runs in multiple TEE platforms (Intel SGX and AMD SNP-SEV). Our results show that a deployment of Nimble on machines running in different availability zones can achieve from tens of thousands of requests/sec with an end-to-end latency of under 3.2 ms (based on an in-memory key-value store) to several thousands of requests/sec with a latency of 30ms (based on Azure Table).

## 1 Introduction

Cloud providers today offer *confidential computing* services where VMs support *trusted execution environments* (TEEs) in which a customer’s code is isolated from other code (including the hypervisor). The promise of TEEs is that customers’ applications enjoy security properties even if the provider is compromised, such as confidentiality of the application’s memory, and the integrity of the application’s execution.

Unfortunately, TEEs do not provide persistent state. If a TEE crashes or is maliciously restarted, its volatile state is lost. Applications running in TEEs must therefore explicitly address this. A common approach is for applications to persist their state in cloud storage services and to use cryptographic primitives such as authenticated encryption to protect that state so that it remains confidential and is not modified by a compromised storage service or OS. But encryption alone does not prevent *rollback attacks*. In such attacks, the provider restarts a customer’s TEE; when the application then attempts to recover its volatile state from persistent storage, the provider intercepts the request and returns old data.

Rollback attacks can be terribly harmful. For instance, con-

sider Signal’s “secure value recovery”, which is a service that runs inside TEEs in a public cloud and allows Signal’s users to back up cryptographic keys or other secret data under a short PIN [6]. Users can establish a TLS session with the service in the TEE, provide their PIN, and recover their key. To prevent an attacker from brute forcing a PIN, Signal enforces a quota on the number of times a wrong PIN can be entered by persisting a counter that tracks the number of attempts made so far. But a compromised cloud provider who wishes to brute force the PIN could simply make some guesses, crash the application, rollback the value of the counter, and retry. This example is far from unique; other types of situations where rollback attacks are problematic include financial transactions, revocation of certificates, access control changes, etc.

Given the significance of rollback attacks, we ask: *how can a cloud provider deploy a service that customers’ confidential computing applications can use to detect rollback attacks?* Importantly, since this will be a core service that runs within a cloud provider, it is paramount that any solution be simple to understand and implement, and that the *trusted computing base* (TCB) be small and easy for customers to audit.

**Prior solutions and their limitations.** One can use a replication protocol to address rollback attacks. For example, the client could keep the latest version of their data replicated across a set of machines, and, assuming a threshold number of these machines are honest, the client can obtain the latest state. In confidential computing, a cloud provider can offer a cloud service that runs a BFT protocol inside TEEs. For many prior works [13, 21, 26, 35, 39, 52], this requires only a small amount of trusted code inside TEEs (typically code to manipulate a counter or a log) and they guarantee safety as long as the trusted code is correct. The drawback is that, to our knowledge, these works do not support *reconfigurations* where the set of TEEs changes over time. Meanwhile, reconfiguration is an absolute necessity: a cloud provider needs the ability to replace failed nodes or migrate healthy nodes whenever it wishes to perform maintenance and updates.

An alternate approach pursued by several proposals [6, 41, 49] is to run *an entire replication protocol* inside TEEs. If the original replication protocol supports reconfigurations, then it stands to reason that the resulting system inside TEEs might do so as well. The drawback is that this significantly increases the complexity and size of the TCB. Meanwhile, for a cloud

service, it is crucial that customers be able to audit the code in the TCB, which is not possible given the complexity and nuance of replication protocols.

**Our solution.** In order to simultaneously support efficient and safe reconfigurations while maintaining a small TCB, we depart significantly from prior works with two key observations. First, state machine replication (SMR) protocols are complex because they must guarantee both *safety* (for rollback resistance this means that any value a client reads is the latest value that had been written) and *liveness* (that a client's request is eventually processed). However, we can separate these two concerns and focus the efforts of the TCB on guaranteeing safety. Liveness can be done outside of the TCB. Such a design is acceptable because, in a cloud setting, a compromised provider can trivially violate liveness anyway (by simply refusing to run the client's code in the first place); liveness, therefore, is a property that an *honest* provider implements for its own sake to ensure that its service is good and highly available.

Second, we observe that a lot of the complexity with SMR is already implemented by existing storage services so one should not reinvent or reimplement the wheel. Instead, we should leverage existing services as much as possible to achieve liveness without significant engineering effort.

By leveraging the above observations, we design *Nimble*, a new SMR protocol that features a small and simple TCB for guaranteeing safety *even in the presence of arbitrary reconfigurations*, and a simple untrusted protocol that reuses existing infrastructure to tolerate faults and to keep the system live. Indeed, owing to Nimble's small TCB, we have formally proven the safety of Nimble's core protocol using the IronFleet [27] methodology with the Dafny program verifier [31].

Nimble is architected as a traditional cloud service built on top of a crash fault-tolerant cloud storage service, providing the interface of a highly-available append-only ledger service. When clients write data to Nimble, Nimble appends this data to their ledger. To ensure that the ledger service provides safety even when the provider is *Byzantine*, Nimble runs a small amount of trusted code that we refer to as an *endorser* inside a TEE. The job of the endorser is very simple: it holds the tail of the ledger in its protected volatile memory. When a client asks for the most recent block written to a ledger, the client provides a *nonce* (a cryptographically random value) to the service. The service forwards this nonce to the endorser who then returns a signature of the current ledger's tail and the nonce. The service then gives the client the data in the ledger in addition to the signature from the endorser that establishes the freshness of said data. Nimble cannot rollback a ledger protected by an endorser because endorsers have no API to rollback their state!

Of course, an endorser can crash and lose its volatile state, so Nimble relies on a set of endorsers. Nimble ensures safety by requiring that there be a quorum of signatures for the nonce and the tail. Nimble ensures liveness (under an honest

provider) by instantiating multiple endorsers. A crucial aspect of Nimble's design is that, since the fault-tolerant storage service already establishes a total order of operations, endorsers do not need to run a replication protocol among themselves.

A remaining challenge is that Nimble needs a mechanism to add, replace, or remove endorsers. This protocol must ensure safety even when the provider is fully untrusted, and must not impede progress when the provider is honest. To address this, Nimble includes a novel reconfiguration protocol that preserves these desirable properties.

To demonstrate the simplicity and applicability of Nimble, we have implemented Nimble on top of both Intel SGX and AMD SEV-SNP, as well as several storage services: an in-memory key-value store, a local disk filestore, MongoDB, and Azure Tables. Our implementation of Nimble with the in-memory key-value store can process 50K requests/sec with an end-to-end latency of under 3 ms. Our geo-replicated Azure tables implementation can also process 50K reads/sec with under 3 ms of median latency; write throughput is more modest, at around 3K writes/sec (without any batching), with an end-to-end latency of 30 ms.

We also demonstrate how to port a significant application to use Nimble by equipping the Hadoop distributed file system (HDFS) with rollback protection. With Nimble-HDFS, data analytics applications running in confidential computing can be certain that the data they read from it is the latest version and has not been rolled back.

**Limitations.** One of the key design tenets behind Nimble is simplicity: both from the perspective of customers that must audit the trusted parts of the system but also from the perspective of engineering teams that must implement and deploy Nimble. This is why we chose to reuse existing storage services rather than implementing our own. As a result, Nimble's implementation inherits the performance of existing systems and may in some cases be more costly than alternatives that do not use storage as a black box. For example, a co-design of Nimble's endorser and the fault-tolerant storage system could save a network round trip, but at great engineering expense.

## 2 Context and rollback attacks

This section provides context, and introduces rollback attacks and their effect on various applications.

### 2.1 Context: Confidential computing

Cloud providers such as Google and Microsoft offer *confidential computing* services where customers' applications run on *trusted execution environments* (TEEs) provided by hardware (e.g., Intel's SGX, AMD SEV-SNP). TEEs encrypt and integrity protect the memory of an application or a whole VM. Additionally, when a cloud provider launches a TEE, through a mechanism known as *remote attestation* (discussed below), a customer can verify that their binary is the one executing in the TEE. Confidential computing promises to help customers run high-assurance applications in the cloud, which,

for example, operate on sensitive data that they wish to keep hidden from the cloud provider. Some proposed and deployed applications for confidential computing are key vaults [6], data analytics [1], machine learning [5], data aggregation [7], auctions [8], and contact discovery for messaging apps [37].

**Remote attestation.** A major component in confidential computing is remote attestation, where a client can confirm that the code running in a TEE is indeed the expected code. Details are elsewhere [19], but at a high level, the TEE produces a *quote* (which contains, among other things, the hash of the binary that was loaded into memory) and signs it with an attestation key that is part of the hardware. A client can verify this quote through a variety of ways, including checking a certificate chain or contacting an attestation service.

**Persistent state.** In practice, applications need to persist data in a storage service (e.g., S3, DynamoDB, Cosmos DB) that lives outside of the TEE’s memory for later retrieval (e.g., in case they restart). To preserve the data’s confidentiality and integrity, TEEs can use *authenticated encryption* prior to externalizing any state. Specifically, a TEE can store data encrypted in a database or on disk, and retrieve it at a later time—and check that it is a valid ciphertext to ensure the data has not been modified. In addition to authenticated encryption, TEEs can use other cryptographic techniques such as oblivious RAM [25] to ensure that their data access patterns are additionally kept private.

**Physical attacks.** Modern TEEs such as the latest version of Intel SGX, Intel TDX, AMD SEV-SNP, and AWS’s Nitro cannot protect against attackers who have physical access to the TEE (they give up memory integrity properties in favor of higher performance). However, existing confidential computing applications already accept this threat model, as otherwise they would not be running inside the TEEs of cloud providers. As a result, a solution to rollback attacks need not defend against physical attacks either.

**Side channel attacks.** There is a large literature [15, 17, 30, 38, 47, 48, 51] that has identified software attacks that can extract information kept in TEE’s memory or violate the integrity guarantees provided by TEEs. Nevertheless, hardware vendors have in the past promptly patched vulnerabilities when discovered and reported by researchers, and there are academic hardware designs that are provably safe from many types of side channels [20]. We believe that TEEs will be more robust to these types of attacks over time.

In this work, we consider these attacks to be out of scope. As we discuss next, rollback attacks are challenging enough even in the absence of these other orthogonal issues.

**Rollback attacks.** While authenticated encryption provides ciphertext integrity and plaintext confidentiality, it does not ensure that the data is *fresh*. In particular, a malicious storage service could provide a valid ciphertext (encrypted and signed by the TEE), that is not the latest version. In Section 1 we discuss Signal’s “secure value recovery” and showcase how

it can be subverted by an attacker who rolls back the application’s state. This same class of attacks can be performed against a banking application (e.g., rolling back a payment), a confidential VM (rolling back to an older version of the OS that has a vulnerability), etc. It is therefore imperative that confidential computing environments have a way for applications to detect such attacks.

### 3 Rollback protection

This section describes a solution for applications running inside TEEs to detect rollback attacks.

**Characterizing rollback attacks.** An application running inside a TEE experiences a rollback attack when one of the following events happens: (1) *stale responses*, where a malicious storage service provider returns a prior version of data instead of the latest (i.e., lack of freshness), possibly because the malicious storage service forks the views of its clients [33]; (2) *synthesized requests*, where a malicious provider synthesizes requests on its own (i.e., they were never issued by the application) and applies them to the storage (thereby affecting future reads); or (3) *replay*, where a malicious provider uses valid requests that were previously sent by the application and applies them to the storage again.

#### 3.1 Our solution

**Addressing stale responses.** It is well known that *linearizability* [28], a widely studied correctness criterion, captures freshness. Informally, a system satisfies linearizability if every operation on an object in the system appears to take place atomically, in an order that is consistent with the real-time ordering of the operations themselves. For example, if an operation  $W$  completes before another operation  $R$  begins, then  $R$  must observe the effects of  $W$  and complete after it.

Our solution to address stale responses is to rely on an append-only ledger service that guarantees linearizability [28] even when the provider is compromised (in Sections 4 and 5, we describe a novel instantiation of such a ledger service, with high performance and a small TCB). In particular, whenever the application wishes to update its persistent state, it stores its updated state in a *block* and appends the block to the ledger; whenever the application wishes to read back its persistent state, it reads the block found at the ledger’s tail.

**Addressing synthesized requests.** We require an application running in a TEE to hold a signing key in a signature scheme that is known only to the application. When the application stores its state in the aforementioned ledger, the application first signs the state with its signing key and then stores the state and the signature in a block. When reading its state from a ledger, the application verifies that there is a valid signature.

**Addressing replay.** To prevent a malicious provider from replaying prior appends, we make the following modification to the solution described thus far: the signature stored in an appended block covers not only the application’s state, but also

the position of the block in the ledger. When reading its state from a ledger, an application verifies that the returned position of the tail matches the position covered by the signature.

Assume that the application's configuration includes a label of the ledger (we denote this as  $\ell$ ). Let  $(sk, vk)$  denote the application's signing and verification keys in a signature scheme, with `Sign` and `Verify` methods. The application maintains a counter, which we denote with  $c$  (when the application is launched for the first time, it can execute the read protocol to set  $c$ ).

**Update protocol.** When an application wishes to update its persistent state from  $S$  to  $S'$ , it does the following:

- Issue `append( $\ell, B, c + 1$ )` and get `receipt`, where  $B = (S', \sigma)$ , and  $\sigma = \text{Sign}(sk, (\ell, S', c + 1))$ .
- If the `append` succeeds and `receipt` is valid, update  $c \leftarrow c + 1$ , else follow the steps in the read protocol.

**Read protocol.** When an application wishes to retrieve persistent state, it does the following:

- $nonce \leftarrow \text{random}()$  // e.g., 128 bits
- $(i, B, receipt) \leftarrow \text{read\_latest}(\ell, nonce)$
- Parse  $B$  as  $(S, \sigma)$ .
- If `Verify( $vk, (\ell, S, i), \sigma$ )` passes and `receipt` is valid with respect to `nonce`, set  $c$  to  $i$  and use  $S$  as the state. If not, abort with `Err("rollback detected")`.

**Putting things together.** We require an append-only ledger service with the following intuitive APIs. We provide a concrete instantiation of such a service in Sections 4 and 5.

- `new_ledger(label) → (ack/nack, receipt)`
- `append(label, block, exp_index) → (ack/nack, receipt)`
- `read_latest(label, nonce) → (index, block, receipt)`

A receipt is a cryptographic object that the client uses to verify that the operation was executed correctly. The nonce in `read_latest` is a random value that prevents the service from caching and returning old receipts, since each receipt must cover the nonce. With these checks, a client obtains linearizability [28] from the ledger service.

The expected index (`exp_index`) in `append` is a directive provided by the application to the ledger service. Its purpose is to help the *honest* ledger service determine whether it can store a particular block in the current tail or whether it must reject the request and notify the application (an honest ledger service just needs to maintain for each ledger how many entries are already appended to support these semantics). In other words, it acts as a type of concurrency control. This is important when the application is concurrent and one of its threads has already stored a block at that position in the ledger. Given the signature in the block, the ledger service cannot append a block anywhere different than its expected index, as the client would detect the inconsistency when it

verifies the signature.

Observe that in the read protocol, if the client's check passes, the service could not have rolled back state. By assumption, a receipt is valid for a random nonce if and only if the service is linearizable. So, it cannot lie about the index  $i$  in the response (i.e., the number of entries in the ledger). Furthermore, in the update protocol, the client embeds crucial metadata (including the expected index of the tail) and signs it with its private key. Since the service provider cannot forge signatures, it cannot return data that was not previously stored at that index by the client.

### 3.2 Storing state in an existing storage service

While the ledger service can be used to append arbitrary data, it has a very limited API. Therefore, it is often better for an application to store their state in some existing (untrusted) storage service better suited to its needs. For example, use a storage service that has better performance for large data, or one that supports things like random access reads and writes, scans, search, stored procedures, etc. We now extend the solution from the prior subsection to support this.

In a nutshell, for updates, the application proceeds in two steps: (1) it persists its state in an existing storage service and then (2) stores a cryptographic digest of that state in the ledger service using the Update procedure described above. Similarly for reads, the application reads state from the storage service and a digest from the ledger service, and in addition to the checks described thus far, it checks that the digest of the state retrieved from the storage service equals the digest from the ledger service. There is one key issue that does not affect safety, but affects liveness: the application may fail after it performs step (1) but before step (2), during updates.

We address this as follows. During update, instead of only storing  $S'$  in the storage service, the application stores  $(S', c + 1, \sigma)$ . This ensures that, by design, the storage service holds a counter that is at most one higher than the counter stored on the ledger service (the storage service cannot tamper with  $S'$  or  $c + 1$  since they are protected by  $\sigma$ ). When an application restarts, it can check if the counter in the ledger service is one lower than the counter in the storage service. If so, this implies a failure after the application updated the storage service but before it updated the ledger service. Therefore, the application uses  $S', c + 1$ , and  $\sigma$  from the storage service to complete its pending append to the ledger service.

Note that the above mechanism will not lead to the corruption of the state in the ledger even if the client mistakenly performs the update more than once. For example, suppose that the client first issues its update operation to the ledger and then fails. When the client restarts, the ledger has not yet processed the update operation (perhaps it is sitting in a queue somewhere) so the client receives the old counter ( $c$ ) from the ledger. If the client re-issues the update, at most one of the two requests (the one in the queue or the freshly issued one) will be applied since they have the same expected index.

FIGURE 1—Nimble’s architecture (see text for details).

**Concurrency.** If the application has multiple processes that operate on the same persistent state, then we require the storage service used by the application to be linearizable. Furthermore, the application must be able to deal with the failure of its processes and achieve exactly-once semantics [42, 54].

## 4 An overview of Nimble

This section describes Nimble, an append-only ledger service that fills the key role in our rollback protection method (§3).

**Design goals.** To support its target application of rollback protection for confidential services, a key guarantee that we desire from Nimble is linearizability [28]. Unfortunately, an untrusted service can trivially violate linearizability by returning stale responses or by presenting different views of a ledger to different clients [33, 36]. As we discuss below, Nimble will make such violations detectable by relying on certain operations being performed correctly inside TEEs.

Given Nimble’s reliance on TEEs, our second design goal is to naturally ensure that this trusted code is as small as possible and simple enough that it can be audited by customers.

If the cloud infrastructure on which Nimble is hosted is malicious, it can trivially violate liveness (by literally not running the client’s application in the first place), so our third goal is to ensure that if an honest provider runs Nimble as specified, the service will be live.

Finally, we wish to avoid reimplementing complex replication protocols: optimizing them, and ensuring that they are correct and comply with a plethora of business and technology standards for deployment within a public cloud is hard and time consuming. So, we wish to leverage existing services.

**Threat model and assumptions.** Nimble assumes that TEEs work as intended: they protect the memory and the execution of any application running within it from attacks (§2). Nimble’s code running outside TEEs is untrusted by clients, and may behave arbitrarily. Nimble makes standard cryptographic hardness assumptions for its safety guarantee. Nimble ensures liveness during sufficiently long periods of synchrony and when the service follows its prescribed protocol.

As we discuss below, providing safety requires Nimble

to run a trusted state machine, called an endorser, inside a TEE. Since TEEs can crash and lose their state, Nimble runs a collection of endorsers. Unfortunately, if Nimble loses a majority of its endorsers, it must either give up safety or liveness. We discuss this further in Section 9.1. Additionally, for now, we assume that an endorser’s code does not change over time. We discuss possible solutions to this in Section 9.2.

**Design and architecture.** Figure 1 depicts Nimble’s architecture, which is analogous to that of a traditional cloud service. Nimble employs a collection of worker processes, which we refer to as *coordinators*. They are stateless and untrusted, and their job is to process requests from *clients* (i.e., customer applications running in TEEs). For each ledger, Nimble maintains a *hash chain* (a linked list where each node contains data and a cryptographic hash of the previous node) and stores that hash chain in an existing untrusted cloud storage service (e.g., Azure Table). Note that this storage service is completely separate from (and may even be different from) the storage service used by clients to store their data (§3.2).

To guarantee linearizability despite using an untrusted cloud storage, Nimble runs a trusted state machine inside a TEE, which we refer to as an *endorser*. An endorser stores, for each ledger, the tail of the associated hash chain in its memory. An endorser’s code is public, and when launched inside a TEE, it produces a fresh key pair for a signature scheme such that the TEE platform can prove (via remote attestation) that the public key belongs to a legitimate endorser. An endorser uses its secret key to sign its response to any append or read operation. Since an endorser’s state is volatile, Nimble runs a collection of endorsers to achieve fault tolerance. When Nimble boots up, it produces a unique and static identifier that is derived by hashing the public keys of the endorsers. We assume that this identifier is public knowledge.

For each request issued, a client expects a response and a receipt. A receipt contains a list of public keys and signatures that cover the response and the public identifier. The client first verifies that the public keys in the receipt belong to legitimate endorsers based on remote attestation.<sup>1</sup> The client then verifies that there is a quorum of valid signatures from the public keys in the list (in Nimble, a quorum is a majority of endorsers). This is analogous to *witness cosigning* [46]. Additionally, for *read\_latest*, a client sends a nonce and checks that the endorsers’ signed message includes the nonce. This prevents a malicious service from replaying a stale receipt.

To support *reconfigurations* (i.e., addition and/or removal of endorsers), an endorser maintains additional bookkeeping and performs additional checks when the set of endorsers changes. Similarly, a coordinator maintains additional state in the cloud storage service and implements an untrusted distributed protocol. Details are in the next section.

<sup>1</sup>Clients can cache public keys to avoid verifying that they belong to legitimate endorsers. So, clients only need to do remote attestation when the endorser set changes or they lose their local state.

**Small TCB.** Nimble achieves a small TCB because endorsers contain only safety-critical aspects of a replication protocol. For example, to process appends and reads, endorsers maintain tails of hash chains and provide signed responses to requests. To support reconfigurations, they maintain additional state and perform checks but that code is only concerned with safety but not liveness.

## 5 Design details and correctness

This section describes the details of Nimble’s design. We begin with a core protocol that does not support reconfigurations and then describe modifications to support reconfigurations.

### 5.1 Core protocol

Nimble is a replicated state machine with a new architecture where its APIs (see Section 3) are first built on top of an existing crash fault-tolerant storage service, which we refer to as the *untrusted state machine*. A stateless coordinator process can use the untrusted state machine as a black box to implement Nimble’s APIs. To obtain linearizability in the presence of malicious behavior, Nimble uses a collection of endorsers running another state machine, which we refer to as the *endorser state machine*, inside a TEE (a minority of endorsers in the collection can crash).

We first describe the state machine run by endorsers and the untrusted state machine, and then describe how they are invoked in the end-to-end protocol.

**Endorser’s state machine.** Let  $(\text{KeyGen}, \text{Sign}, \text{Verify})$  denote a signature scheme and  $\mathfrak{H}$  a collision-resistant hash function. In our implementation, each state transition of an endorser is atomic (achieved via synchronization primitives) and an endorser state machine provides linearizability.

#### Endorser’s state

- $sk$ , a secret key in a digital signature scheme.
- $\text{status} \in \{\text{“uninitialized”}, \text{“active”}\}$ .
- $id$ , the identity of a particular instance of Nimble.
- $M$ , a label-value map, where a label is a byte vector and a value is tuple  $(t, h)$  in which  $t$  is the tail node of a hash chain and  $h$  is an unsigned integer specifying the number of entries in the hash chain.

**Untrusted state machine.** As noted earlier, Nimble relies on a crash fault-tolerant storage service. In particular, Nimble uses this storage service to realize the untrusted state machine. It does so by storing all the necessary state in the storage service, and using its standard APIs (e.g., put, get, insert, conditional update, atomic batch update) to carefully mutate the state to achieve the desired semantics.

The untrusted state machine is same as the endorser’s state machine, with two key differences. First, it does not generate a key pair nor does it provide a TEE attestation (naturally, it does not sign any of its responses). Second, it stores all entries

appended to a ledger not just the tail entry and provides an API to access ledger entries by their index (as we see below, this is useful for providing liveness in certain cases).

#### Endorser’s state transitions

```

1: fn bootstrap
2:    $(sk, pk) \leftarrow \text{KeyGen}(1^\lambda)$ 
3:    $\text{status} \leftarrow \text{“uninitialized”}$ 
4:   return  $(pk, a)$  //  $a$  is a TEE attestation proving that  $pk$  belongs to a legitimate endorser running inside a TEE.

5: fn initialize( $c$ )
6:   if  $\text{status} \neq \text{“uninitialized”}$  then return  $\text{Err}(\text{AlreadyInit})$ 
7:   if  $pk \notin c$  then return  $\text{Err}(\text{NotInConfig})$ 
8:    $id \leftarrow \mathfrak{H}(c), M \leftarrow \perp, \text{status} \leftarrow \text{“active”}$ 

9: fn new_ledger( $\ell$ )
10:  if  $\text{status} \neq \text{“active”}$  then return  $\text{Err}(\text{NotInit})$ 
11:  if  $\ell \in M$  then return  $\text{Err}(\text{LedgerExists})$ 
12:   $M.\text{insert}(\ell, (0, 0))$ 
13:  return  $\text{Sign}(sk, (\text{“new\_ledger”}, id, \ell, 0, 0))$ 

14: fn append( $\ell, b, \text{exp\_index}$ )
15:  if  $\text{status} \neq \text{“active”}$  then return  $\text{Err}(\text{NotInit})$ 
16:  if  $\ell \notin M$  then return  $\text{Err}(\text{LedgerDoesNotExist})$ 
17:   $(t_{\text{prev}}, h_{\text{prev}}) \leftarrow M.\text{get}(\ell)$ 
18:  if  $\text{exp\_index} \neq h_{\text{prev}} + 1$  then
19:    return  $\text{Err}(\text{OutOfOrder}, h_{\text{prev}})$ 
20:   $t_{\text{curr}} \leftarrow (\mathfrak{H}(t_{\text{prev}}), b); h_{\text{curr}} \leftarrow h_{\text{prev}} + 1$ 
21:   $M.\text{update}(\ell, (t_{\text{curr}}, h_{\text{curr}}))$ 
22:  return  $\text{Sign}(sk, (\text{“append”}, id, \ell, t_{\text{curr}}, h_{\text{curr}}))$ 

23: fn read_latest( $\ell, n$ )
24:  if  $\text{status} \neq \text{“active”}$  then return  $\text{Err}(\text{NotInit})$ 
25:  if  $\ell \notin M$  then return  $\text{Err}(\text{LedgerDoesNotExist})$ 
26:   $(t_{\text{curr}}, h_{\text{curr}}) \leftarrow M.\text{get}(\ell)$ 
27:  return  $\text{Sign}(sk, (\text{“read\_latest”}, id, \ell, t_{\text{curr}}, h_{\text{curr}}, n))$ 

28: fn append_with_read_latest( $\ell, b, \text{exp\_index}, n$ )
29:  return  $(\text{append}(\ell, b, \text{exp\_index}), \text{read\_latest}(\ell, n))$ 

```

**Coordinator’s workflow.** A coordinator invokes the APIs provided by the endorser state machine and the untrusted state machine to provide the APIs we describe in Section 3.

To initialize a Nimble instance, a coordinator process calls bootstrap on a configurable number of endorsers (denote it as  $n$ ) to obtain their public keys. Let  $c$  denotes the list of public keys and the public identity of the instance is  $\mathfrak{H}(c)$ . The coordinator then calls initialize( $c$ ) on the untrusted state machine and when that succeeds, it calls initialize( $c$ ) on the endorser state machine, waiting for  $\lfloor n/2 \rfloor + 1$  out of  $n$  endorsers to respond. At this point, the system is setup to process requests.

When a client issues a request (e.g., new\_ledger, append, or read\_latest), the coordinator uses the provided argument to call the corresponding API on the untrusted state machine and when that returns, it calls the same API on the endorser state machine with the same argument, waiting for  $\lfloor n/2 \rfloor + 1$  out of  $n$  endorsers to respond. The coordinator collects a quorum of those responses and sends it to the client.

The coordinator retries its workflow to account for network failures (e.g., reordered or dropped messages). Furthermore, a coordinator uses the “OutOfOrder” error returned by an endorser to detect if the endorser is “lagging behind”, and if so, it issues appends to roll forward the endorser’s state using blocks in the untrusted state machine.

**Achieving liveness.** For liveness, we require certain extensions to ensure that a coordinator can eventually produce a valid receipt for each request it successfully executes. Recall that Nimble’s liveness holds only when the provider is honest, so the discussion below is limited to that case.

**new\_ledger and append.** An endorser may execute a request (e.g., an append), but when it responds with its signed message to a coordinator, the network may drop the message. To address this, an untrusted process colocated with the endorser stores the signatures generated by an endorser and provides APIs for a coordinator to retrieve them (ensuring that a coordinator that repeatedly retries can obtain signed messages that were generated). Since this mechanism is needed only for liveness, it does not affect the endorser state machine.

Furthermore, when a coordinator assembles a receipt (recall from Section 4 that a receipt is a quorum of signatures), it persists the receipt in the untrusted state machine alongside an appropriate ledger entry. Once a receipt is persisted, the coordinator calls an API on the untrusted process colocated with the endorser to garbage collect the associated signed message. In this way, even if a coordinator crashes or the message from Nimble to a client is dropped, a client can eventually retrieve a receipt for a new\_ledger or an append request from Nimble.

**read\_latest.** There are cases where a coordinator may not succeed in obtaining a valid receipt for a read\_latest request. Specifically, the coordinator may struggle to obtain a quorum of matching responses as each endorser may be in a slightly different state. This can occur during periods of concurrent appends when one append has been applied in one endorser but not yet in another. Nimble addresses this as follows.

Suppose that a coordinator thread (say “read thread”, for ease of reference) is unable to obtain a valid receipt for a read\_latest request. After a configurable number of retries, the “read thread” persists the pending read\_latest request in the untrusted state machine. Furthermore, we modify the coordinator’s workflow so that when a coordinator’s thread receives an append (call it an “append thread”), if there is a pending read\_latest, it invokes the **append\_with\_read\_latest** API of endorsers to execute both the append and the pending read\_latest as an atomic operation. The “append thread” also persists receipts from the endorsers in the untrusted state machine, including the receipt of the pending read\_latest. Meanwhile, the “read thread” retries invoking read\_latest on endorsers and polls the untrusted state machine to see if a concurrent thread produced a receipt via the **append\_with\_read\_latest** API; one of these code paths will eventually succeed.

**Safety and liveness guarantees.** We have a formal specification and a proof of safety in Dafny [31] (our proof uses

IronFleet’s state machine refinement technique [27]). A challenge in our context is that we must account for arbitrary responses from a coordinator and the storage service whereas IronFleet only considers crash faults.

**Lemma 5.1.** *Assuming the integrity and confidentiality guarantees provided by TEEs for executing the specified endorser state machine and standard cryptographic hardness assumptions, whenever Nimble produces a valid receipt for a request, Nimble respects linearizability.*

*Proof (sketch).* By design and implementation, and the stated assumptions, each endorser’s state machine is linearizable. Now suppose that Nimble produces valid receipts for two requests  $R_1$  and  $R_2$ . Suppose that the quorum of endorsers that produce a valid receipt for  $R_1$  and  $R_2$  are respectively  $Q_1$  and  $Q_2$ . In Nimble, a quorum size is a majority, so  $Q_1 \cap Q_2$  must have at least one endorser. Let  $e \in Q_1 \cap Q_2$ . Given that  $e$ ’s state machine is linearizable, then it follows that it processed requests  $R_1$  and  $R_2$  such that it respects linearizability. Since a valid receipt requires that a quorum of endorsers sign the same response, Nimble’s response must equal  $e$ ’s response. This implies that Nimble is linearizable.  $\square$

**Lemma 5.2.** *When the service is honest and during sufficiently long periods of synchrony, and when clients submit requests that can be successfully executed, a coordinator process can eventually generate valid receipts.*

*Proof (sketch).* The claim holds for new\_ledger and append requests because they are first performed on the untrusted state machine and the same operation is applied on a quorum of endorsers in the same order. Even if coordinators are subject to crash failures, or the network drops or reorders packets, the untrusted state machine is linearizable and internally fault tolerant by design and implementation. Since the endorser’s append API takes an additional hint, expected\_index argument, this allows an honest coordinator to apply appends in an endorser in the same order as it is applied in the untrusted state machine. Furthermore, if the network drops signed messages from an endorser to the coordinator, the coordinator can eventually retrieve them. Thus, a coordinator can eventually obtain a valid receipt for new\_ledger and append requests.

For read\_latest requests, there are two cases: (1) no concurrent appends, and (2) concurrent appends. In the first case, a coordinator eventually succeeds in obtaining a quorum of signed messages on the same value (if an endorser is lagging behind, the coordinator can provide missing appends from the untrusted state machine to bring them up to date). In the second case, a coordinator uses append\_with\_read\_latest to combine the read\_latest request with a concurrent append request to obtain a valid receipt.  $\square$

## 5.2 A safe and live replacement of endorsers

Nimble’s core protocol is restricted to a static collection of endorsers. Unfortunately, this restriction is unrealistic: once

an endorser fails, the system loses its initial level of fault-tolerance. Furthermore, once a majority of endorsers fail, the system is permanently unavailable as it cannot process requests nor produce valid receipts ever again.

Nimble includes mechanisms to introduce new endorsers, and to retire existing endorsers, thereby enabling it to proactively maintain a sufficient number of endorsers and avoid the aforementioned issues.

A core challenge is that a proactive replacement of endorsers must not allow untrusted components in the system (e.g., a coordinator) to abuse it to violate linearizability. Another challenge is that the system should not enter a deadlock state if a coordinator process performing such a replacement fails at an inopportune time. In our context, there is another challenge: to achieve high performance, there is no total ordering of all operations. That is, in Nimble’s core protocol, operations on different ledgers proceed in parallel and they only need to be processed by a majority of endorsers (i.e., not all endorsers). Thus, at any point in time, the state of endorsers might not be identical.

Unfortunately, existing solutions are a poor fit in our context. If Nimble were to adopt the folklore solution of keeping membership (i.e., the identity of “current” endorsers) as part of state that is replicated, the system will necessarily have to impose a total order on all operations. This adversely affects performance. Alternatively, each ledger could maintain its own membership state (i.e., each ledger has the list of endorsers that are responsible for endorsing operations on that ledger). However, to change endorsers, the system will need to invoke  $N$  instances of the view-change protocol, where  $N$  is the number of ledgers. In practice,  $N$  can be millions or more, so it is not practical.

Below, we describe how Nimble addresses these challenges *without* bloating the TCB. In a nutshell, Nimble’s solution can be viewed as a way to resolve the tension between the two existing solutions described above.

**Nimble’s reconfiguration protocol.** We introduce a new safe and live protocol, orchestrated by a coordinator, to proactively replace endorsers. At a high level, Nimble proceeds in a sequence of configurations, where in each configuration, a particular set of endorsers, identified by their public keys, are responsible for producing receipts. Nimble’s endorsers keep track of the current configuration as well as the immediately preceding configuration (we denote these with  $C_{curr}$  and  $C_{prev}$  in the endorser’s state machine). Furthermore, when an endorser joins a configuration it “takes over” a previously generated public identity of a Nimble instance only when it can confirm that a quorum of endorsers of the prior configuration have “renounced” it. Moreover, every response signed by an endorser covers, in addition to the public identity, their value of  $C_{curr}$ . This ensures that responses produced by an endorser are tied to a particular configuration and clients can

use it to discover which public keys and quorum size they need to use to verify the responses produced by Nimble.

To switch from one configuration to the next, Nimble’s coordinator proceeds in three phases (this protocol can be invoked at any time). Before we describe these three phases, we provide some preliminaries.

Let  $\mathcal{E}$  and  $\mathcal{N}$  denote sets of existing and new endorsers respectively. In Nimble,  $\mathcal{E} \cap \mathcal{N}$  is an empty set (this simplifies the protocol and proofs, as we discuss in [11, Appendix A]). A coordinator launches endorsers in the set  $\mathcal{N}$ , calls their bootstrap method to obtain their public keys. Let  $C_{\mathcal{E}}$  and  $C_{\mathcal{N}}$  respectively denote the sequence of public keys of endorsers in  $\mathcal{E}$  and  $\mathcal{N}$ . Let  $id$  denote the identity of the Nimble instance (the hash of the list of public keys of the first set of endorsers that bootstrapped the system and that the provider advertises).

At every step in the protocol below, the coordinator reliably persists responses it has received in the untrusted state machine, and by design every step is idempotent. A convenient way to log this information is to use an append-only ledger in the untrusted state machine (an endorser is not explicitly aware of this ledger). Before starting the protocol below, the coordinator appends  $C_{\mathcal{N}}$  to this ledger. Furthermore, all messages logged by the coordinator during the protocol are stored alongside  $C_{\mathcal{N}}$ . As a result, if a coordinator fails or is slow at any point in the protocol, another coordinator can safely take over and complete the remaining steps.

The additional state and transitions needed to support Nimble’s reconfiguration protocol are given below.

#### Endorser’s additional state

- status  $\in$  {“uninitialized”, “initialized”, “active”, “finalized”}.
- $C_{prev}$ , endorsers’ public keys of the previous configuration.
- $C_{curr}$ , endorsers’ public keys of the current configuration.
- $C_{next}$ , endorsers’ public keys of the next configuration.
- $\sigma$ , a signature on the finalized state and other metadata

#### Endorser’s updated initialize function

```

1: fn initialize( $i, m, C_{prev}, C_{curr}$ )
2:   if status = “initialized” then
3:     return Sign( $sk, \langle$ “initialize”,  $id, C_{prev}, C_{curr}, M\rangle$ )
4:   if status  $\neq$  “uninitialized” then return Err(AlreadyInit)
5:   if SecretToPublic( $sk$ )  $\notin$   $C_{curr}$  then
6:     return Err(NotInConfig)
7:   if  $i = H(C_{curr})$  and ( $m \neq \perp$  or  $C_{prev} \neq \perp$ ) then
8:     return Err(InvalidInit)
9:   else if  $i \neq H(C_{curr})$  and ( $m = \perp$  or  $C_{prev} = \perp$ ) then
10:    return Err(InvalidReconf)
11:   $id \leftarrow i, M \leftarrow m, C_{prev} \leftarrow C_{prev}, C_{curr} \leftarrow C_{curr}$ 
12:  status  $\leftarrow$  “initialized”
13:  return Sign( $sk, \langle$ “initialize”,  $id, C_{prev}, C_{curr}, M\rangle$ )

```

### Endorser's additional state transitions

```

1: fn finalize( $C_{next}$ )
2:   if status = "finalized" then return ( $M, \sigma$ )
3:   if status  $\neq$  "active" then return Err(NotActive)
4:    $C_{next} \leftarrow C_{next}, \text{status} \leftarrow \text{"finalized"}$ 
5:    $\sigma \leftarrow \text{Sign}(sk, \langle \text{"finalize"}, id, C_{curr}, C_{next}, M \rangle)$ 
6:    $sk \leftarrow \perp$  // erase the endorser's signing key
7:   return ( $M, \sigma$ )

8: fn activate( $R_{exist}, A, R_{next}$ )
9:   if status  $\neq$  "initialized" then return Err(NotInit)
10:   $q \leftarrow \lfloor |C_{prev}|/2 \rfloor + 1, \kappa \leftarrow \lfloor |C_{curr}|/2 \rfloor + 1$ 
11:  if  $|R_{exist}| < q$  or  $|R_{next}| < \kappa$  then
12:    return Err(InsufficientQuorum)
13:  // Parse  $R_{exist}$  and  $R_{next}$ 
14:   $[(p_1, M_1, \sigma_1, a_1), \dots, (p_q, M_q, \sigma_q, a_q)] \leftarrow R_{exist}$ 
15:   $[(\rho_1, \eta_1, \alpha_1), \dots, (\rho_\kappa, \eta_\kappa, \alpha_\kappa)] \leftarrow R_{next}$ 
16:  for all  $i \in [q]$  do
17:    if  $a_i$  does not attest to  $p_i$  then
18:      return Err(InvalidAttestation)
19:    if  $\neg \text{Verify}(p_i, \sigma_i, \langle \text{"finalize"}, id, C_{prev}, C_{curr}, M_i \rangle)$  then
20:      return Err(InvalidFinalize)
21:  for all  $i \in [\kappa]$  do
22:    if  $\alpha_i$  does not attest to  $\rho_i$  then
23:      return Err(InvalidAttestation)
24:    if  $\neg \text{Verify}(\rho_i, \eta_i, \langle \text{"initialize"}, id, C_{prev}, C_{curr}, M \rangle)$  then
25:      return Err(InvalidInitialize)
26:  if  $\neg \text{verify\_state}((M_1, \dots, M_q), M, A)$  then
27:    return Err(InvalidState)
28:  status  $\leftarrow$  "active"

29: fn verify_state( $[M_1, \dots, M_q], M, A$ )
30:   $[A_1, \dots, A_q] \leftarrow A$ 
31:  for all  $i \in [1, \dots, q]$  do
32:     $M'_i \leftarrow M_i$ 
33:    for all  $\ell \in M_i$  do
34:      for all  $a \in A_i[\ell]$  do
35:         $M'_i[\ell].tail \leftarrow (H(M'_i[\ell].tail), a)$ 
36:         $M'_i[\ell].index \leftarrow M'_i[\ell].index + 1$ 
37:    if  $M'_i \neq M$  then return false
38:  return true

```

**(1) Finalize existing endorsers.** A coordinator interacts with endorsers in  $\mathcal{E}$  to “finalize” their state. In particular, a coordinator invokes a new API supported by an endorser, called **finalize**. It takes as input the new configuration’s public keys  $C_{\mathcal{N}}$  and it outputs  $(M_i, \sigma_i)$ , where  $M_i$  is the endorser’s state and  $\sigma_i$  is a signature on the message  $\langle \text{"finalize"}, id, C_{\mathcal{E}}, C_{\mathcal{N}}, M_i \rangle$  (an endorser signs over  $C_{\mathcal{N}}$  because it is intended to be consumed by endorsers in  $\mathcal{N}$ ). A coordinator waits for a quorum of endorsers in  $\mathcal{E}$  to finalize their state and persists their responses in the untrusted state machine. We refer to the aggregated response as  $R_{exist}$ .

Once an endorser provides a response to finalize, it enters a “finalized” mode where it erases its signing key, and hence it *cannot* process any further requests.<sup>2</sup> It however continues

<sup>2</sup>Nimble’s threat model (Section 4) assumes that active endorsers are not vulnerable (e.g., they do not leak their keys). By erasing a signing key in finalize, Nimble ensures that if an adversary can break the TEE’s guarantees in the future, they cannot recover finalized endorsers’ signing keys.

to respond with its finalized state and the signature on the finalized state, to ensure liveness.

**(2) Initialize new endorsers.** We modify the **initialize** method of the endorser’s state machine described in Section 5.1 to support transferring state (including an existing public identity) to the new endorsers ( $\mathcal{N}$ ). As before, if the coordinator supplies an empty state and an empty prior configuration (i.e.,  $M$  and  $C_{\mathcal{E}}$  are both  $\perp$ ), then this means that this is a new instance of Nimble and the public identity is the hash of the current configuration ( $H(C_{\mathcal{N}})$ ). What is new is that the coordinator could instead supply *any* state ( $M$ ), prior configuration ( $C_{\mathcal{E}}$ ), and public identity ( $i$ ) that it wishes, and the endorsers simply accept that information. The endorsers check that this information is actually safe to use before they start processing requests during the activate function, which we describe next. The initialize function outputs a signature  $\eta_i$  on the message  $\langle \text{"initialize"}, id, C_{\mathcal{E}}, C_{\mathcal{N}}, M \rangle$ .

A coordinator waits for a quorum of endorsers in  $\mathcal{N}$  to initialize their state and persists their responses in the untrusted state machine. We refer to the aggregated response as  $R_{next}$ .

**(3) Activate new endorsers.** We add a new API called **activate** that allows a coordinator to convince an initialized endorser in  $\mathcal{N}$  to start processing requests. The coordinator must provide evidence that it is safe for the endorser to “take over” the initialized identity. An endorser performs a sequence of checks: (1) it checks that a quorum of existing endorsers in  $\mathcal{E}$  have been finalized; (2) it checks that a quorum of new endorsers in  $\mathcal{N}$  have been initialized with the same state; and (3) the state of a quorum of new endorsers is derived from the state of a quorum of existing endorsers by picking ledger tails with the highest positions seen in the quorum.

To prove (1) and (2), the coordinator provides  $R_{exist}$  and  $R_{next}$  respectively. To prove (3), the coordinator provides additional blocks ( $A$ ) that can be appended to the tail of each of the ledgers that were supplied by existing endorsers when they called finalize ( $M_i$ ) such that the resulting state equals  $M$ . This check is in the **verify\_state** function. An honest coordinator can find these blocks in the untrusted state machine.

**Verifying receipts in the presence of reconfigurations.** Suppose that a client goes offline and Nimble executes several reconfigurations. We now discuss how such a client can verify receipts produced by Nimble. Recall that a client retains the public identity of Nimble ( $id$ ).

Observe that Nimble’s reconfiguration protocol ensures that endorsers in a Nimble instance *always* use the same public identity  $id$ . Furthermore, an endorser’s signature covers, in addition to its response, both the public identity  $id$  and the public keys of endorsers in its own configuration (i.e.,  $C_{curr}$ ). We extend the coordinator’s APIs so a client can use them to retrieve  $C_{curr}$  and each endorser’s attestation report. This allows a client to (lazily) learn the public keys of endorsers in the latest configuration as well as verify that those public keys belong to legitimate endorsers. Finally, a client does the following checks to verify a receipt: (1) public keys in the

| Component   | Trusted? | Language | SLoC |
|-------------|----------|----------|------|
| Coordinator | No       | Rust     | 3564 |
| Endorser    | Yes      | Rust     | 1843 |
| Endorser    | Yes      | C++      | 559  |
| Endpoint    | Yes      | Rust     | 517  |

FIGURE 2—Implementation of Nimble (SLoC) (excluding existing libraries and crates used by Nimble)

receipt are in  $C_{curr}$ ; (2) signatures are valid when verified with the known  $id$  and  $C_{curr}$  (as well as other information specific to a request); (3) there is a quorum of valid signatures based on the number of public keys in  $C_{curr}$ .

**Lemma 5.3.** *Assuming the integrity and confidentiality guarantees provided by TEEs for executing the specified endorser state machine and standard cryptographic hardness assumptions, at any point in time, if Nimble produces a valid receipt for an append operation  $O$  using endorsers in  $\mathcal{E}$ , and if a coordinator activates a majority of endorsers in  $\mathcal{N}$  with state  $M$ , then  $M$  must contain the effects of executing  $O$ .*

*Proof (sketch).* Consider an append request  $O$  for which Nimble produces a valid receipt using endorsers in  $\mathcal{E}$ . This means that a majority of endorsers in  $\mathcal{E}$  applied  $O$  and provided a signature on the same response (let  $Q$  denote that majority). Furthermore, any majority of endorsers in  $\mathcal{E}$  must contain at least one endorser from the set  $Q$ .

Now, by the premise, the coordinator successfully activates a majority of endorsers in  $\mathcal{N}$ . This means that the coordinator must have called their initialize and activate methods such that all checks in the activate method pass. By assumptions about TEEs and cryptography, this means that a majority of endorsers in  $\mathcal{N}$  must have been given with  $(R_{exist}, A, R_{next})$  such that all checks in the activate method pass. Again, by the aforementioned assumptions, the only feasible way to achieve this is by calling finalize on a majority of endorsers in  $\mathcal{E}$  to obtain a valid  $R_{exist}$ . From the aforementioned reasoning, at least one of states retrieved from a majority of endorsers in  $\mathcal{E}$  must contain the effects of applying  $O$ . Thus,  $M$  provided to a majority of endorsers in  $\mathcal{N}$  contains the effects of applying  $O$ . Finally, by design, once an endorser in  $\mathcal{E}$  returns a response to the finalize method, it *cannot* process any request, as a result, once  $R_{exist}$  is generated, no valid receipt can be generated by using a majority of endorsers in  $\mathcal{E}$ .  $\square$

**Lemma 5.4.** *When the service is honest and during sufficiently long periods of synchrony, if a majority of endorsers in  $\mathcal{E}$  and  $\mathcal{N}$  are live, then a coordinator that can be subject to crash failures can eventually obtain a majority of endorsers in  $\mathcal{N}$  to start processing requests.*

*Proof (sketch).* We first argue that the claim holds when a coordinator does not experience crashes. We then argue that a coordinator that restarts can still complete the protocol by using state persisted in the untrusted state machine.

We need to establish that the coordinator *can* provide inputs that pass checks in the activate method of the endorser state machine. By inspection, if the coordinator follows its prescribed protocol, one can see that nearly all of the checks in the invoked activate method pass on an endorser state machine that holds a signing key where the corresponding public key is in the sequence  $C_{curr}$ . We now argue that `verify_state` check passes too. Suppose that the coordinator computes  $M$  as specified in the protocol. When the service is honest, for every append request processed by the service, it is first applied on the untrusted state machine (which is linearizable and crash fault-tolerant) and then applied on each endorser in the same order (endorser’s state machine is also linearizable). However, for any given ledger, some endorsers may be “lagging behind” others since Nimble requires only a majority of endorsers to process an append. This implies that an honest coordinator can retrieve blocks from the untrusted state machine, and construct  $A$  such that `verify_state` $((M_1, \dots, M_q), M, A) = \text{true}$ .

Now, consider the case where a coordinator may crash. Observe that each step persists state in the untrusted state machine. When a coordinator restarts, it can examine the state in the untrusted state machine to identify the step in which it failed and repeatedly retry steps in the specified reconfiguration protocol. Furthermore, by design, all APIs of an endorser (e.g., initialize, finalize) are idempotent. Even if a coordinator finished a step but failed before logging state into the untrusted state machine, a new coordinator can safely retry the step. As a result, a coordinator that repeatedly retries eventually activates a quorum of endorsers in  $\mathcal{N}$ , which then can produce valid receipts for clients’ requests.  $\square$

## 6 Implementation

Nimble is available as an open-source project [3]. Nimble’s implementation is in Rust. In addition to the Rust-based endorser, we implement an endorser in C++ using the Open Enclave SDK [4]. The Rust endorser runs inside a confidential VM supported by AMD SEV-SNP, and the OpenEnclave-based endorser runs inside Intel SGX. Both a coordinator and an endorser run as microservices, each exposing an RPC interface. To ease the adoption of Nimble, we implement an *endpoint* that exposes a REST API. The endpoint implements the client-side verification logic (Section 5.2) and runs inside a confidential VM (i.e., a client essentially outsources all of its verification tasks to the endpoint). With an endpoint, a client only needs to perform remote attestation to ensure that the right code runs, and establish a secure channel with it.

For cryptographic primitives, endorsers use SHA-256 for hash functions and ECDSA with P-256 for signatures, both implemented by OpenSSL.

Figure 2 shows the lines of code for each component in Nimble. The Rust-based endorser implements the full protocol described in Section 5, while the C++ implements only the core protocol (no reconfiguration).

We implement several optimizations. First, a coordinator waits only for a quorum of endorsers to provide a matching

response (this helps reduce latency, especially when a minority of endorsers is deployed in a remote region, is slow, or is disconnected). Second, an endorser stores a copy of the tail node (rather than its hash), so for read operations, this allows a coordinator to avoid a round trip with the storage service.

Nimble’s implementation supports reconfigurations to replace failed endorsers. However, the coordinator microservice does not proactively invoke the reconfiguration protocol. Instead, it exposes additional *control* APIs that allow a monitoring process to trigger the addition or removal of endorsers. In a full deployment of Nimble, we expect to make use of a monitoring infrastructure to invoke these control APIs.

## 7 Evaluation

This section answers the following evaluation questions:

- What is the latency and throughput of Nimble operations, and how do they depend on the underlying storage or TEE technology used by Nimble?
- How does Nimble’s TCB compare to alternative solutions?
- What is the cost of a reconfiguration, and how does it scale with the number of ledgers in Nimble?
- How difficult is it to port a real application to use Nimble and what overheads does Nimble introduce?

### 7.1 Experimental setup

We run all of our experiments on Azure. We run endorsers on three different machines, each on a different availability zone to ensure that a server, rack, or even an entire data center failure does not cause a loss of a quorum of endorsers. When we run endorsers in Intel SGX, we use Azure DC32s v3 instances; when we run endorsers in AMD SEV-SNP, we use Azure DC32as v5 instances. The coordinator runs in Azure D48ads v5 instances, as does our client (a workload generator). Finally, we deploy several endpoints that run inside AMD SEV-SNP and execute verification logic. We use an Azure load balancer to route requests among the endpoints, and direct all client requests to this load balancer.

Given that Nimble inherits the performance of its underlying storage, we evaluate two configurations:

- *An in-memory key-value store*: An unreplicated in-memory key-value store that does not tolerate failures. This key-value store has low access latency and high throughput. It serves as a best-case scenario for Nimble. In a real deployment of Nimble, this store could be replaced with existing replicated in-memory key-value stores that provide high throughput and low latency [23, 43, 44].
- *Azure table with geo-replication*: Azure storage with the strongest replication guarantees enabled (RA-GZRS). It has lower throughput and higher latency than our in-memory key-value store, and suffers from high tail latency since it is a multi-tenant cloud service with no SLAs.

### 7.2 Latency and throughput of Nimble

We start by conducting a series of microbenchmarks on Nimble. To generate workloads, we use *wrk2* [50], a popular constant-load open-loop workload generator. The resulting workload is sent to our Azure load balancer which is then split across our REST endpoints. We measure the median and 90-th percentile latencies, as well as the throughput achieved by Nimble on its different configurations.

Figure 3 depicts the results. Figure 3a shows the performance of Nimble when using AMD SEV-SNP endorsers and our in-memory key-value store. In this configuration, the median latency of all operations is under 2.5ms, and the 90-th percentile latency is under 3.2 ms. This latency is possible due to the fast communication between machines inside Azure data centers, even if the endorsers and coordinator are in different availability zones. Append and read throughput both peak at around 50K req/sec, which is quite significant given that Nimble’s endorsers process and sign *individual* requests; we do not do any batching in this experiment. The bottleneck is indeed computational and comes from the cryptographic operations performed by the endorsers.

Figure 3b shows the performance of Nimble when using AMD SEV-SNP endorsers and Azure table storage. In this configuration we observe two things: (1) the higher storage latency plays a key role for append operations, leading to median latencies of around 30–40 ms. More significantly, tail latencies are very high (sometimes up to 2 seconds), owing to the fact that we use a shared service without guaranteed SLAs. The append throughput performance is significantly worse than our in-memory counterpart, reaching around 2,600 reqs/sec. Here the bottleneck is no longer computational and is instead Azure storage which has an account-wide throughput limit of 20K entities/sec; in Nimble, every append accesses multiple rows (entities) in Azure Table to provide the required untrusted state machine semantics (Section 5.1), which hits this limit. Reads are not impacted by these salient properties of storage because of our fast-reads optimization (Section 6).

Figure 3c shows the performance of Nimble when using Intel SGX endorsers and our in-memory key-value store. The performance is lower than AMD SEV-SNP endorsers because our SGX endorsers must continuously cross between the untrusted host that runs the networking stack and the enclave, in addition to the hardware being completely different. Finally, we omit the SGX endorsers and Azure Table configuration because the performance is very similar to that of Figure 3b, owing to Azure storage being the bottleneck.

### 7.3 Comparison of TCB size

A key component of Nimble is its relative simplicity. We therefore ask how Nimble compares to similar proposals. Figure 2 gives the breakdown of the complexity of Nimble’s different components (we use TCB as a proxy for it), and Figure 4 compares it to other works. The key take away is that the

FIGURE 3—Microbenchmark of the different operations supported by Nimble. Time is measured end-to-end from the perspective of the client and includes the time needed for the endpoint to verify the signatures provided by Nimble on behalf of the client.

| System             | TCB   | restarts?        | reconfig? |
|--------------------|-------|------------------|-----------|
| ROTE [35]          | 1.1K  | No               | No        |
| Narrator [39]      | 5.1K  | Yes              | No        |
| TEEMS [22]         | 11.0K | Yes              | No        |
| CCF [41]           | 55.5K | Yes <sup>†</sup> | Yes       |
| Nimble (this work) | 2.3K  | Yes <sup>†</sup> | Yes       |

FIGURE 4—Source lines of code (SLoC) comparison of Nimble to other works that provide a fault-tolerant rollback detection service, and whether they can support a replica that restarts (fails and then comes back), as well as replacing the set of replicas. For ROTE, Narrator, and TEEMS we use the numbers from the papers. For CCF we use numbers provided by the authors. Note that this table should be treated *qualitatively* since these systems are implemented in different languages with different coding styles, libraries, etc. The takeaway is that ROTE, Narrator, and Nimble are “simple”; TEEMS is moderately complex as it implements an entire replication protocol within the TCB; and CCF is more complex since it implements a replication protocol in addition to logic that handles blockchain smart contracts. <sup>†</sup>CCF and Nimble can handle replica restarts by treating them as new replicas and engaging reconfiguration.

| # of ledgers | median reconf. time | total communication |
|--------------|---------------------|---------------------|
| 100K         | 805 ms              | 175.59 MB           |
| 200K         | 1.53 sec            | 337.65 MB           |
| 500K         | 3.72 sec            | 881.62 MB           |
| 1M           | 7.14 sec            | 1.68 GB             |

FIGURE 5—Total reconfiguration time (median across 10 runs) and the total amount of communication between the coordinator and the old and new endorsers (measured with `tcpdump`).

complexity of Nimble’s TCB is similar to that of ROTE [35] and Narrator [39], despite the fact that Nimble supports reconfiguration and these prior systems do not. When compared to TEEMS [22] or CCF [41], Nimble is significantly simpler. Indeed, it is precisely this simplicity that allowed us to formally prove the safety of the core protocol of Nimble using the Ironfleet methodology [27] and the Dafny program verifier [31]. Doing the same for these other works that include an entire consensus protocol in their TCB is a daunting task.

#### 7.4 Cost of reconfiguration

One of the key innovations in Nimble is the ability to securely reconfigure from one set of endorsers to another. As

we explain in Section 5.2, this process requires “finalizing” existing endorsers, which effectively stops request processing while the reconfiguration takes place. Hence, reconfiguration time impacts the availability of Nimble. There are two factors that affect this time: (1) the number of ledgers in the system, and (2) the difference between the number of ledger entries processed by the endorsers. We find that (1) is the dominating factor given that the fast network and endorsers running on similar hardware in our experimental setup lead to small differences in which ledger entries they have processed.

To measure the impact of (1), we conduct an experiment where we populate the system with a varying number of ledgers and then induce a reconfiguration to replace an existing set of three endorsers to a brand new set of three endorsers running on different machines (also on three different availability zones). Figure 5 depicts the results for both total time and network communication. We observe a near-linear cost increase in reconfiguration time in terms of the number of ledgers. This cost comes from a variety of factors: (i) hashing of the state at existing endorsers; (ii) determining which state to initialize the new endorsers and transferring that state; and (iii) hashing and verification of the provided state at the new endorsers (e.g., the `verify_state` method).

**Balancing costs.** Given that Nimble’s cost of reconfiguration is high when the system supports many ledgers, and such cost translates directly to service unavailability, one possibility is to partition the ledger space so that disjoint sets of endorsers are responsible for different sets of ledgers. In this manner, if an endorser in one of the partitions fails, the provider can perform a reconfiguration that changes only the ledgers within this partition—without needing to touch the other partitions. Of course, disaster scenarios such as an entire availability zone going down could still require endorsers in all partitions to be swapped, but this is a rarer event.

#### 7.5 Integrating applications with Nimble

One important consideration with a system like Nimble is how would existing applications use it. To answer this question, modify the Hadoop Distributed File System (HDFS). We choose HDFS because (1) it has a lot of state at many different components and (2) any cloud customer who runs a data analytics application that uses HDFS is vulnerable to rollback

FIGURE 6—Results of NNThroughputBenchmark on an HDFS deployment (Baseline) and a deployment of Nimble-HDFS.

FIGURE 7—Results of Intel’s HiBench with a dataset scale set to “large” on a MapReduce deployment running on top of standard HDFS (Baseline) and a Nimble-HDFS backed by Azure Table.

attacks today—even if HDFS and their application runs on confidential computing servers. Hence, a rollback-resistant HDFS would provide significant benefit.

We spent three person months modifying HDFS to integrate with Nimble, for a total of 1,689 lines of Java. We discuss the specifics in [11, Appendix B]. At a high level, we observe that HDFS logs data and metadata in order to recover from crash failures. These logs are committed to disk either synchronously or periodically in batches (in which case the system might lose the latest uncommitted state during a failure). While these logs are in memory, we can protect them by running HDFS’s namenode and datanode inside TEEs. However, as soon as they are written to disk, they are vulnerable to rollback attacks. We identified all such events in HDFS and replaced them with the approach in Section 3.1. The result is Nimble-HDFS, a version of HDFS that detects rollbacks.

To measure this overhead, we provision two Azure F64s v2 machines, one to run the namenode and the other the datanode of HDFS or Nimble-HDFS. We then run Hadoop’s NNThroughputBenchmark [9], which is a standard benchmark that measures the performance of HDFS operations such as `create`, `mkdir`, etc. We configure Nimble-HDFS to append an entry to Nimble every 100 operations. At the peak throughput, the window of vulnerability is tens of ms.

Figure 6 depicts our results. For some operations, Nimble-HDFS has no overhead over the baseline, particularly those that do not append entries to Nimble (deviations are basically experimental noise). For others, Nimble-HDFS introduces up to a 2 or 3× overhead over the baseline, depending on the backing store. This cost comes from computing digests, sending them over HTTP to Nimble’s endpoint, and flushing operations to disk before moving on.

At first glance, these added costs might appear problematic.

But the reality is that the overhead of Nimble-HDFS is minimal for real applications. To demonstrate this, we run Intel’s HiBench Suite [2], which consists of big data applications that run on top of MapReduce. We configure MapReduce to use either standard HDFS or Nimble-HDFS. The results are in Figure 7. As we can see, there is essentially no difference in the job completion time for most of these applications when using Nimble; the exception is the extended DFSIO benchmark which is I/O heavy and is meant to measure the performance of the underlying HDFS instance.

## 8 Related work

This section discusses works that directly relate to Nimble; while there are many other works on building untrusted storage systems [14, 16, 24, 33, 34, 36], our focus here is on projects that guarantee linearizability.

**Rollback protection.** Many TEEs (e.g., Intel SGX) support *sealing*. Sealing enables applications running inside TEEs to encrypt and sign their state with secret keys known only to the TEE, prior to storing in untrusted disk. Sealing alone does not provide rollback protection, but one can additionally use monotonic counters supported by TEEs. There are several drawbacks to this combination. First, operations on counters are slow (e.g., increment latencies are 80–250ms) and wear out in a few days [12, 35], though recent systems like SPEICHER [12] partially address this issue. Second, monotonic counters are not as secure as expected (e.g., removing the BIOS battery or reinstalling TEE software often resets these counters). Finally, monotonic counters are specific to a given machine so a crashed application cannot be launched on a different machine—which is unacceptable in cloud settings.

Memoir [40] provides rollback protection by maintaining a history of application requests in an append-only hash chain (which itself is in an untrusted storage) and tracking tail of the chain in a trusted non-volatile memory supported by a TPM. If an application restarts, it uses state in the trusted non-volatile memory and the hash chain to reconstruct its state. Ariadne [45] similarly uses a TPM’s non-volatile memory but with a different abstraction (counter instead of hash chain). The challenge with these approaches in cloud settings is that, if the TPM or its machine fails, the system becomes unavailable. Nimble solves this challenge by developing a fault-tolerant version of Memoir that stores the state in several TEEs’ volatile memory and supports reconfiguration.

ROTE [35], Narrator [39], and TEEMS [22] are similar to Nimble in that they propose a solution to help confidential applications in TEEs detect rollbacks. The main difference with Nimble is that these works lack a reconfiguration protocol, so there is no obvious way to add or remove replicas.

CCF [41] provides rollback-resistance and supports reconfiguration but it is significantly more complex than Nimble and has a very large TCB since it is designed to run and validate smart contracts and other blockchain constructs.

Kaptchuk et al. [29] formalizes the interactions of a TEE with an append-only ledger as a way to provide rollback protection. A key distinction with Nimble is that their work assumes the existence of the ledger, whereas Nimble focuses on building the ledger itself.

Wang et al. [49] study pitfalls with running a crash fault-tolerant replication protocol inside TEEs to achieve a Byzantine fault-tolerance. In particular, they describe concrete attacks including rollback attacks on state kept by individual nodes on their local disks. For rollback attacks, they propose a solution based on ROTE [35] that inherits its drawbacks.

**Replicated systems with a small TCB.** A2M [18] and Trinc [32] propose trusted primitives for nodes in a distributed system to prevent malicious nodes from equivocating (i.e., sending conflicting messages to different nodes). Unfortunately, these trusted primitives do not aim to provide fault-tolerance on their own. A straightforward use of a replication protocol to add fault-tolerance (including reconfigurations) results in a large TCB, analogous to CCF's.

A recent line of work focuses on using minimal trusted primitives to improve various aspects of replication protocols. Yandamuri et al. [52] use a Trinc-type minimal trusted hardware in communication-efficient Byzantine fault-tolerant protocols [10, 53] to preserve communication efficiency while achieving improved fault thresholds. Similarly, Damysus [21] separates safety and liveness concerns in HotStuff [53] and describes minimal trusted components that improve fault thresholds. Hybster [13] and FlexiTrust [26] observe that Trinc-type trusted hardware forces sequential invocations of consensus instances, so they introduce variants that support parallel instances and achieve better performance. Unfortunately, these works do not yet support reconfiguration.

## 9 Discussion

### 9.1 Disaster recovery

Recall that Nimble runs a set of endorsers inside TEEs and receipts consist of signatures from a quorum of endorsers. This raises a question: what happens if Nimble loses a majority of endorsers? If the endorsers are alive but disconnected (e.g., network partition), then Nimble will experience unavailability until a quorum is accessible again. If the endorsers actually crashed and their volatile state is gone, then we refer to this scenario as a *total disaster*. This could happen for a number of reasons. Perhaps the service provider experiences a massive attack or a natural disaster takes down multiple datacenters.

The good news is that total disasters do not affect safety properties like freshness. By design and implementation, endorsers cannot be restarted. If Nimble loses a majority of its endorsers, then there is no longer a quorum of endorsers that can sign responses that a client will accept. The bad news is that this leads Nimble to lose liveness.

There are some ways to reduce the chance of total disasters. The most important one is with a reconfiguration protocol

so that failures do not pile up and cause the system to lose a quorum of endorsers. This is why we developed one for Nimble. Second, deploy endorsers in different fault domains (cloud providers already do this for their replicated systems).

Even with such measures, total disasters could still occur. Unfortunately, there is no “playbook” for how to proceed. An option is for customers to periodically snapshot the tails of their ledgers and store them in some location they trust. After a total disaster, the customer can ask the service provider if they have a snapshot that is more recent than the one they have (the customer can check that it includes more updates than their own and in fact the snapshot is legitimate by verifying receipts). Then, customers can explicitly ask the service to create a new instance of Nimble that starts with that agreed-upon snapshot. Of course, if the snapshot is stale then the system will not reflect the most recent operations (i.e., the responses will not be fresh), but observe that a provider cannot do this unilaterally: the customer must explicitly ask for it. If a customer does not want to maintain snapshots, then an option is to accept a snapshot provided by the provider (the customer can still verify that some prior endorsers signed those tails). This might be acceptable in extreme situations such as when the total disaster was due to a public natural disaster that took down datacenters where endorsers were deployed.

### 9.2 TCB changes

Our description has so far assumed that endorsers' trusted code does *not* change (i.e., when verifying receipts  $R_{exist}$  and  $R_{next}$ , an endorser checks that its own measurement matches the measurements of an existing quorum of endorsers and those of a new quorum of endorsers). But what if that trusted code needs to be updated? For example, if there was an update to a library or the attestation verification procedure changed.

To address this, we sketch a solution, which omits the aforementioned check requiring measurements to match; instead customers have to do certain checks. Specifically, the service provider persists  $R_{exist}$  and  $R_{next}$  whenever a reconfiguration occurs, along with a copy of the code running in an endorser (and other configuration information to reproduce binaries loaded inside TEEs). The provider then uses this information to prove to customers that all configuration changes (including code changes in the TCB) were legitimate. Customers must audit code changes and verify attestation reports, and decide whether to accept the latest set of endorsers.

Note that the above proposal crucially assumes that whenever the provider reconfigures from an existing set of endorsers  $\mathcal{E}$  to a new set of endorsers  $\mathcal{N}$  with a *new* trusted code, a quorum of endorsers in  $\mathcal{E}$  was not exploited by an adversary *before* the reconfiguration. This is because after a quorum of endorsers in  $\mathcal{E}$  finalize their state (which is necessary for reconfiguration), they erase their signing keys (Footnote 2). However, there is no known way to prove that the trusted code was updated before it was exploited by an adversary.

## Acknowledgments

We thank Leslie Lamport, Melissa Chase, the OSDI reviewers, and our shepherd, Brad Karp, for their thorough comments and helpful conversations. We thank Jonathan Lee and Jay Lorch for helpful discussions when the project began, and Amaury Chamayou and Cédric Fournet for helping us better understand CCF. ## Abstract

The infinite capacity of cloud computing is an illusion: in reality, cloud providers cannot always have enough capacity of the right type, in the right place, at the right time to meet all demand. Consequently, cloud providers need to implement admission-control policies to ensure accepted capacity requests experience high availability. However, admission control in the public cloud is hard due to dynamic changes in both supply and demand: hardware might become unavailable, and actual VM consumption could vary for a variety of reasons including tenant scale-outs and fulfillment of VM *reservations* made by customers ahead of time. In this paper, we design and implement *Kerveros*, a flexible admission-control system that has three desired properties: i) high computational scalability to handle a large inventory, ii) accurate capacity provisioning for high VM availability, and iii) good packing efficiency to optimize resource usage. To achieve this, *Kerveros* uses novel bookkeeping techniques to quickly estimate the capacity available for incoming VM requests. Our system has been deployed in Microsoft Azure. Results from both simulations and production confirm that *Kerveros* achieves more than four nines of availability while sustaining request processing latencies of a few milliseconds.

## 1 Introduction

Cloud capacity appears to be limitless. However, in reality, cloud providers need to deal with the limitations of datacenters with a finite number of machines while respecting contractual service-level agreements (SLAs) that provide availability guarantees to customer VMs. These SLAs might be severely compromised if the provider runs out of resources. Additionally, users expect predictability: not being able to launch new VMs when required can critically impact a customer’s business [31]. An admission-control system is thus necessary to ensure cloud providers do not *overcommit* resources, provide seamless elasticity, and are robust to capacity loss due to failures. This paper describes the design and implementation of *Kerveros*: a scalable and efficient

admission-control system for Microsoft Azure.

Admission control in the cloud is hard because it needs to account for a variety of fluctuations in both supply and demand across a large number of workload and machine types. On the supply side, datacenter machines and racks regularly fail at scale and maintenance tasks like software updates may also require rebooting machines. The cloud provider needs to maintain high availability amidst both deterministic and stochastic events by keeping enough resources free to provide seamless failover if necessary. On the demand side, to facilitate predictability, cloud providers have recently introduced the notion of “reserved resources” (or capacity *reservations*) [4, 6, 7, 20, 35] to guarantee the availability of capacity in the future. With such reservations, customers pay to have the provider set aside resources that can be claimed later. Accordingly, admission-control systems need to accommodate both on-demand VM requests and reservations.

The goal of our cloud admission-control system is to ensure that it simultaneously achieves *high computational scalability* and *a low rate of SLA violations* while avoiding inefficient capacity usage (which can lead to negative margins). One possible approach to accomplish this is to re-use existing VM allocators [21, 43] to directly allocate space for reservations, maintenance, and potential tenant growth (scale-outs). However, such a “placeholder” approach is slow and inherently inflexible, since the capacity allocated to such placeholders cannot be immediately used for other incoming VM requests that can pack well in the reserved space.

Instead, our solution is based on an approximate *buffer* approach that avoids early binding of placeholders. At a high level, we maintain buffers of resources for handling failures, maintenance, growth, reservations, etc., and track the total number of remaining resources after accounting for currently running VMs *and* buffers. Implementing this idea involves several algorithmic challenges, such as reasoning about the capacity required by VMs with multi-dimensional resource demands (e.g., CPU, memory, disk), quantifying the impact of buffers on a large variety of possible VM requests (e.g., Azure has more than 1000 VM types; see Figure 3 for details),

Figure 1: Consider an empty cluster of two machines with capacity 100 units each. Suppose one reservation with total size of 120 has already been accepted. We consider two cases: (i) the reservation consists of two VMs of size 60; (ii) the reservation consists of six VMs of size 20. A new single VM request of size 50 enters the system. Note that by solely taking the available capacity units into account (i.e.,  $200 - 120 = 80 \geq 50$ ), the system would accept the new request in both cases. However, when accounting for packing considerations, the request should be accepted only in case (ii). Further, if the underlying allocation algorithm was designed to load balance the VMs corresponding to a reservation, then the request should be rejected in both cases.

simultaneously accounting for buffers defined at different levels of the datacenter hierarchy (e.g., cluster vs. zone), and mimicking how the allocator would place VMs belonging to admitted reservations. Indeed, simple back-of-the-envelope buffer calculations might result in two undesired scenarios: (i) rejecting a request that can actually fit in the cloud, or worse, (ii) accepting a request at the cost of compromising reservation and availability guarantees; Figure 1 illustrates this scenario.

To address these challenges, we introduce a novel admission control mechanism which relies on *Allocable VM (AV)* counts, a bookkeeping technique for quickly determining the capacity available for an incoming VM request or reservation. The AV count, defined per VM type, quantifies the number of VMs that can fit in the inventory at a given time, and reduces the multi-dimensional problem into a formulation with a single dimension (the AV count). *Kerveros* exposes AV counts to the allocator, which can then accept or reject incoming VM or reservation requests based on a simple comparison (i.e., is the requested capacity less than the current AV count?). Importantly, this allows the allocator to respond to requests with high throughput and low latency, a critical requirement for extreme-scale VM allocation platforms [21, 43].

To enable these highly efficient capacity checks, we design the Conversion Ratio Algorithm (CRA), which allows *Kerveros* to quickly translate all buffer sizes to a common unit: the AV count of the incoming request’s VM type. We supplement CRA with a data-driven Linear Adjustment Algorithm (LAA), which periodically emulates the allocator to reduce potential biases of CRA. We implement these algorithms in Azure’s resource-allocation platform, while selectively reusing and enhancing existing allocator infrastructure (e.g., data stores, request handling agents, etc.). We further accelerate the algorithm with a caching layer that allows for incremental AV count updates.

Our results from both simulation and production measurements demonstrate that *Kerveros* sustains at least four nines of availability without any significant degradation

in request-processing throughput. Our admission-control strategy estimates the available capacity with less than 1% error at the 95th percentile. Importantly, this level of accuracy enables Azure to avoid capacity wastage, leading to high return on investment (ROI). We emphasize that for today’s global-scale cloud providers, even a 1% improvement in such a capacity-efficiency metric can be worth 100s of millions of dollars in saved hardware expenditure, translating to sizable impact on the cloud provider’s bottom-line margin.

To the best of our knowledge, this paper is the first to describe the design, implementation and evaluation of an admission-control system deployed in a large public cloud. Prior research on datacenter resource management (e.g., Protean [21] and Borg [43, 45]) focuses mostly on on-demand VM placement. The closest work available is Meta’s RAS system [34], which partitions resources at the granularity of machines to different sub-organizations and periodically re-assigns machines across partitions by solving a mixed integer linear program. While this approach can suit a first-party workload with a modest number of partitions, it is less efficient for dynamic public-cloud workloads (§5).

In summary, our main contributions are:

- The design of scalable and efficient admission-control algorithms for a large and heterogeneous public cloud inventory (§3).
- A robust system design that separates the admission-control logic from the components that enforce it, allowing for latencies of a few milliseconds for admission and placement decisions (§4). Our system has been successfully deployed in Microsoft Azure.
- Our extensive evaluation using measurements from both simulations and production demonstrate that our design achieves scalable and accurate admission control (§5).
- Supplementary to this paper, we release a new trace that can be used by the research community to design and test different packing and admission-control algorithms: <https://github.com/Azure/AzurePublicDataset>.

Figure 2: Cloud topology. A zone contains one or more datacenters that house a heterogeneous mix of clusters. Each cluster is comprised of homogeneous machines organized in racks. Racks provide isolation for fault tolerance.

## 2 Background and Motivation

Microsoft Azure is a large public geo-distributed cloud provider with a massive global footprint. Resources in Azure are organized into regions, each of which consists of one or more availability zones (Figure 2). Every zone contains one or more datacenters. Each datacenter is further divided into clusters and racks. Each cluster has a homogeneous set of machines (or servers); however, a zone can have a heterogeneous mix of clusters. As Figure 3 shows, zones can have tens of different hardware types. A zone can have hundreds of thousands of machines, while a cluster is much smaller (at most a few thousand machines).

Each zone has its own allocation service (or simply, *allocator*) that assigns VMs to physical machines. The assignment (or placement) considers a set of hard and soft constraints, which are evaluated sequentially for each VM. Examples of hard constraints include not violating the physical capacity of a machine and not running a VM type on hardware that does not support it. An example of a soft constraint is to prefer an already-occupied machine to increase packing efficiency [21].

In this section, we discuss the general resource management problem in Azure by focusing first on challenges arising from both dynamic and diverse demand patterns (§2.1), as well as fluctuations in the available compute supply (§2.2). These challenges, coupled with the fact that demand might exceed supply, motivate the need for a robust admission-control system; we outline its requirements in §2.3.

### 2.1 Demand Versatility

Azure has multiple different offerings for compute, which each impose specific requirements on the underlying allocation system.

**VM requests.** Azure has multiple hardware generations in its datacenter and offers over a thousand VM types. The majority of VM types are supported on most hardware generations, but some types require specialized hardware (e.g., GPUs for ML). We note that other major cloud providers like AWS and GCP also offer a large number of VM types [5, 19].

Figure 3: Histograms for number of different hardware types (left) and supported VM types (right) across Azure zones.

New VM types are regularly introduced as new hardware types and scenarios are onboarded to the cloud.

On-demand *VM requests* are the most common capacity consumption mode. A VM request specifies the type of the VM (which in turn determines the number of CPU cores, memory, disk, network requirements for the VM, and optional accelerators) and the VM’s priority. Multiple VM requests may be grouped into a *tenant request*. A tenant request is accompanied by a tenant service model, where additional constraints can be imposed on the collection of VM requests (e.g., fault-domain requirements).

By default, VMs are spread across an entire zone. However, a tenant may request all its VMs be co-located within specific inventory boundaries such as a cluster or datacenter. A tenant using legacy Azure services can also be pinned to a single cluster; this means that such a tenant cannot create new VMs outside its cluster.

A tenant request succeeds only if all its associated VM requests are successfully allocated. There is no explicit SLA on allocation time, but it is desirable to keep these times as low as possible to ensure a fast and reliable deployment experience. The volume of VM requests is large: a zone can handle more than two million requests in a day. The demand pattern can be quite bursty: Figure 4 shows that a zone can easily receive a few thousand requests per minute. Hence, low latency and high throughput are critical requirements for the VM allocation service (see §2.3).

Higher-order consumption modes, such as Function-as-a-Service (FaaS or serverless computation [39]) are internally provisioned through VMs.

**Customer scale-outs.** Customers may decide to increase the number of VMs in their tenants; these are termed *tenant scale-outs*. Any allocation request, including a scale-out request, must be handled within milliseconds; the system can either accept or reject the scale-out request based on available capacity. Though there is no external acceptance SLA for scale-outs, Azure internally tracks the acceptance rate of these requests and attempts to sustain very high acceptance rates (at least 4 nines). Towards this end, the admission-control logic must explicitly reserve capacity within individual clusters for scale-out of pinned tenants (see §3.1). We note that

Figure 4: Number of high-priority allocations per minute for a zone over a day, aggregated over a 2-week period. Demand in the tail is bursty with large spikes.

Figure 5: Tenant size versus allocator's acceptance rate. Data is obtained from one zone during a busy month. Tenant requests above 300 VMs are currently offered only internally.

Azure does not distinguish between scale-outs and new tenant requests for tenants that can span across an entire zone.

**Reservations.** Consider a scenario where a user wishes to terminate their VMs for the day, but expects to re-instantiate the VMs the following morning. Doing so through a regular on-demand tenant request might result in delays if capacity is not immediately available in the morning. As Figure 5 shows, this issue is exacerbated for large tenant requests. To address such scenarios, Azure offers the *reservation* option. A reservation request includes the VM type and the quantity. A reservation need not result in *actual* allocation of VMs; instead, it serves as a commitment from Azure to provide the desired number of VMs in the future, whenever the customer decides to materialize the reservation.

Reservations are active as soon as the request is accepted (i.e., we do not support reservation requests with future start dates). The user can terminate a reservation at any time. To support economy of scale, VMs that are created against a reservation cannot be pinned to a single cluster. This basic reservation model is offered by large public clouds as an *On-Demand Capacity Reservation* [4, 7]. We briefly discuss direct extensions of this basic reservation model, such as reservations with a future start date, in §6. Other reservation models are surveyed in §7.

## 2.2 Supply Fluctuations

Supply in Azure can change dynamically. In this subsection, we outline the situations that can trigger these changes.

Figure 6: Network and machine failures across 30 days. The average network failure is around 0.01%, but each network failure can affect several machines. Outside of network failures, ~3.5% of machines are in a failed state every day.

**Machine and other hardware failures.** Figure 6 shows the failure frequencies for machines and network hardware over a period of 30 days. As the figure demonstrates, a network failure is much less probable. However, network failures impact more machines (e.g., a top-of-rack switch can affect around 50 machines). The cloud provider has to account for such failures and set aside capacity to migrate the VMs in affected machines to respect availability SLAs. It is thus crucial to both predict and have readily available mitigation for such failures.

**Additional events affecting supply.** Azure, like any other large cloud supplier, experiences other events that affect the available supply. One can roughly classify these events based on their predictability. *Deterministic* events include planned maintenance of machines (e.g., software updates) and decommissioning of hardware. *Stochastic* events include urgent security updates to patch a zero-day vulnerability, hotfixes to handle software bugs, and malicious attacks that overload the system.

## 2.3 Admission Control

We now describe the problem of admission control, and highlight requirements and design challenges for *Kerveros*. Admission control can be defined as the set of decisions that determine the acceptance of any form of resource request (new tenant, scale-out, reservation). Admission-control decisions need to take into account not only the present state of the zone, but also potential realizations of future state. Future state is influenced by a variety of factors including reservations that have been admitted but not yet materialized, potential hardware failures, tenant scale-outs, etc.

**Challenges.** As mentioned earlier, admission control in the cloud presents several challenges:

1. **Multiple elements affecting demand and supply.** *Kerveros* has to consider multiple elements with different characteristics: on the demand side, one has to consider

different modes of consumption (e.g., tenant vs. reservation requests) as well as potential tenant growth. On the supply side, we have different types of events (e.g., machine failures, rack maintenance) that affect inventory availability.

2. **Zone heterogeneity.** Beyond the inherent stochasticity in demand and supply, it is hard to determine how much capacity to set aside since not all machines can serve all VM types. For example, a new VM series might be served only on new hardware generations.
3. **Numerous VM sizes and fragmentation.** Unlike traditional resource allocation problems, which are often “single dimensional”, admission control for the cloud needs to make decisions for VMs that request different types of resources (e.g., CPU, memory, disk). These multiple dimensions can cause fragmentation.
4. **Accounting for unclaimed capacity.** Reservations and other types of capacity protection impose an additional challenge since we would ideally like to “late bind” resources to such requests. This makes machine utilization an imperfect metric to determine if enough capacity is available for a new request.

**Requirements.** An admission-control system also has to meet several requirements to operate effectively within the context of a large cloud provider:

1. **Scalability.** Even for very large zone inventories, the decision of whether to accept or reject a tenant or reservation request has to be made within milliseconds.
2. **Respect admitted reservations.** All VMs that are requested against a previously accepted reservation should be fulfilled (i.e., assigned to machines) whenever the user opts to materialize the reservation.
3. **Availability.** The cloud provider must ensure high availability to customers. Accordingly, capacity must be set aside to facilitate the migration of VMs to other machines in case of machine failures or other events affecting supply.
4. **Elasticity.** An admission-control system should reserve capacity to allow tenants pinned to clusters to scale out.
5. **Accuracy.** The system should not reject requests when capacity is in fact available.
6. **Efficiency.** The system should set aside as little capacity as possible while satisfying the above properties (i.e., increase the return on investment).

**Time scale of decision making.** We observe that the above challenges and requirements necessitate that decisions be made at different time scales. For example, estimating how much capacity to set aside for failures or growth requires comprehensive data analysis that is inherently time consuming. On the other hand, the VM allocation service itself has to remain highly performant and process requests at low latency. Consequently, a natural design choice is to decouple the overall admission-control responsibility between fast- and slow-twitch systems. Accordingly, the allocator only executes

low-overhead capacity limit checks to determine whether to accept or reject a resource request (i.e., admission control *enforcer*)<sup>1</sup>. The entire logic for estimating the available capacity is performed by *Kerveros*, the focus of this paper, and is performed off the critical path.

### 3 Design of *Kerveros*

The high-level goal of *Kerveros* is to answer the following question: *How much capacity is available for an incoming tenant or reservation request?* As described earlier, this information is used by the allocator to accept / reject requests.

To address the complexities of demand and supply fluctuations (§2), our approach relies on two main concepts: (i) *buffers*, to specify a need for capacity; and (ii) *allocable VM count*, an auxiliary bookkeeping technique to quickly determine the available capacity for an incoming tenant or reservation request.

#### 3.1 Buffers

A buffer is an accounting of capacity that must be protected for a specific purpose. The allocator treats this capacity as unavailable when admitting tenant or reservation requests. *Kerveros* supports three buffer types: (i) *Reservation buffers* to accommodate already admitted reservations; (ii) *Growth buffers* to accommodate existing tenant growth; (iii) *Healing buffers* to accommodate currently-running VMs that might need to be migrated in case of hardware failures.

As we detail below, we use appropriate counts of VM types to quantify the size of each buffer. Formally, a buffer is defined as a tuple  $(t, x)$ , where  $t$  is the VM type and  $x$  is the number of VMs of that type that ought to be protected. The size of each buffer may change over time. For instance, a reservation buffer can become smaller as the customer gradually starts using VMs corresponding to that reservation. On the other hand, a healing buffer may become larger over time, e.g., as hardware ages and failures become more likely.

We make an important design choice for buffers: although capacity is protected, it is *not* mapped to specific physical machines. Buffers are defined at higher levels of the cloud hierarchy (e.g., cluster or zone) to reflect the amount of capacity that must be protected in aggregate at that level. The physical allocation occurs only when the protected capacity is needed to fulfill its purpose. For example, after hardware failures, healing buffer capacity can be used for migrating VMs from the affected machines. To ensure maximum utilization of resources, we use unclaimed protected capacity to offer spot VMs [2,3], which can be immediately preempted to free up capacity whenever buffer capacity is claimed.

---

<sup>1</sup>For a tenant request, the capacity limit check is immediately followed by an actual allocation of the VMs to physical machines. For reservation requests, the allocator performs only the limit check since placement is late-bound for reservations in our design.

We next provide more details on how *Kerveros* sets sizes of buffers of different types.

**Reservation buffers.** Setting reservation buffers is straightforward: the buffer size is set exactly according to the user-provided reservation requirement. That is, suppose reservation  $k$  requires  $x$  VMs of type  $t$  within a certain zone; *Kerveros* sets the respective zone-level buffer as  $R_k = (t, x)$ . When the user claims  $u$  VMs of that reservation, the buffer is updated to  $R_k = (t, x - u)$ .

**Growth buffers.** Growth buffers are used at a cluster level to account for the expansion of existing tenants pinned to each cluster. *Kerveros* defines a single growth buffer for each VM type. Intuitively, the buffer size should be proportional to the current consumption of that VM type. More specifically, for a given cluster  $c$  and VM type  $t$ , let  $x_{tc}$  be the current number of active VMs belonging to tenants pinned to cluster  $c$ . Then we set the corresponding growth buffer to  $G_{tc} = (t, \alpha_{tc} x_{tc})$ , where  $\alpha_{tc} > 1$  is the effective growth rate. We use a ML model to set this parameter. In a nutshell, we consider a small set of possible effective growth rates (e.g., five values in the range between 1.03 and 1.1). The input features to the ML model consist of tenants' information (e.g., account IDs, VM lifetimes), hardware details (e.g., generation, SKU), and cluster-specific fragmentation details (intuitively, a cluster that is "badly" packed would induce higher effective growth rates); the statistics on fragmentation are obtained from the allocator. The ML model (implemented using XGBoost) is trained daily using historical growth data.

**Healing buffers.** *Kerveros* uses healing buffers to account for hardware failures and other events affecting supply (§2). For example, the protected capacity may be used to migrate VMs away from non-functional hardware. Since tenants can be constrained to specific clusters, healing buffers are maintained at the cluster level. Since full-machine VMs are the hardest to allocate (as they require a completely empty machine), the healing buffer is defined in units of full-machine VMs; formally, the buffer is of the form  $H_c = (L, x_c)$ , where  $L$  denotes the full-machine VM type, and  $x_c$  is the quantity.

We calculate  $x_c$  using a data-driven approach. The high-level idea is to set  $x_c$  in proportion to the hardware failure probability (i.e., the buffers should be larger if the failure probability is higher). More specifically, we would like to ensure that the total number of non-functional machines does not exceed the buffer size  $x_c$  with high probability; let  $p_c$  denote that probability (e.g.,  $p_c = 99.9\%$ ). Towards this end, we extract from historical failure data the empirical distribution of the total number of non-functional machines over a given period of time (e.g., a day). The total number accounts for a variety of events including machine and network failures as well as maintenance events. Then,  $x_c$  is simply derived as the  $p_c$ -percentile value of this distribution. *Kerveros* may add some slack to the obtained value (e.g., 10%) for clusters that are highly fragmented (as perceived

by the allocator). The choice of  $p_c$  is specific to the cluster, and depends on various factors. For example, *Kerveros* uses higher  $p_c$  values for clusters that have a high ratio of tenants pinned to that cluster, since such tenants have fewer fallback options in case of failures.

In rare cases, the healing buffer capacity is increased to allow completion of urgent software updates.

## 3.2 Allocable VMs

*Kerveros* uses the notion of allocable VM counts (AV counts) to reason about available capacity. Specifically, the AV count,  $\mathbb{A}[t]$ , gives the number of additional VMs of type  $t$  that can currently fit in the zone. For an incoming VM request of type  $t$  and demand  $x$ , *Kerveros* first calculates<sup>2</sup>  $\mathbb{A}[t]$ , and then the allocator rejects the request if  $\mathbb{A}[t] < x$ .

In this section, we describe how *Kerveros* calculates the AV counts across entire clusters and zones. The calculations are non-trivial because they require a *conversion* mechanism that accounts for buffers of different VM types  $t$  defined at different hierarchies of the datacenter (cluster versus zone). We note that other approaches that do not explicitly account for multiple resource dimensions might result in either under- or over-estimating the available capacity.

### 3.2.1 Overview

The high-level pseudocode of our AV count calculation is provided in Algorithm 1. Informally, the algorithm implements the following calculation:

$$\mathbb{A}[t] = \left[ \begin{array}{c} \text{available capacity for} \\ \text{type } t \text{ across clusters} \end{array} \right] - \left[ \begin{array}{c} \text{buffers converted from} \\ \text{type } t' \text{ to type } t \end{array} \right].$$

The algorithm starts by initializing the AV counts, excluding buffers, and accounting only for the active VMs in the system (Step 1). Since certain buffers are defined only at a zone level, the algorithm then proceeds to transform them to cluster-level buffers (Step 2), so that all buffers can be analyzed at the same level of the cloud hierarchy. The remaining calculations are done at a cluster level, except a final aggregation step. The heart of the algorithm is converting buffers of other VM types into buffers of type  $t$  (Step 7) and then deducting them from the current AV count (Step 8). This conversion step is the subtle part of the algorithm. We term the full algorithm the *Conversion Ratio Algorithm (CRA)*.

### 3.2.2 CRA Algorithmic Details

We next describe each of these steps in detail.

**AV count initialization (Step 1).** The initialization step calculates  $\mathbb{A}[t, c]$ : the number of VMs of type  $t$  that can fit in cluster  $c$ , excluding buffers. Each VM type requires different quantities of the various compute resources (e.g., CPU, memory) available in a machine; thus these non-buffered AV counts are obtained by calculating the maximum

<sup>2</sup>In practice, we update the AV counts only periodically (every minute), and use caching to track the updated AV counts. See §4 for details.

---

**Algorithm 1** CRA: Calculating AV Counts for a VM type  $t$ .

- 1: Calculate the AV counts excluding buffers:  $A[t', c]$  for all  $t'$ .
  - 2: Distribute zone-level buffers to clusters.
  - 3: **for** each cluster  $c$  **do** ▷ Calculate per-cluster counts.
  - 4:      $a_c = A[t, c]$
  - 5:     Aggregate buffers per VM type.
  - 6:     **for** each aggregate buffer  $(t', x)$  **do**
  - 7:         Convert buffer from  $t'$  into type  $t$ :  $\mathbb{C}(t' \rightarrow t, x, c)$ .
  - 8:          $a_c -= \mathbb{C}(t' \rightarrow t, x, c)$  ▷ Deduct from current total.
  - 9:     Aggregate cluster counts for zone:  $\mathbb{A}[t] = \sum_c a_c$ .
- 

number of VMs that can fit in each machine (considering all resource dimensions) and taking the sum over all machines in the cluster:

$$A[t, c] = \sum_{\substack{\text{machine in} \\ \text{cluster } c}} \min_d \left\lfloor \frac{\text{Available resource } d \text{ on machine}}{\text{Required resource } d \text{ for type } t \text{ on machine}} \right\rfloor.$$

**Going from zone- to cluster-level (Step 2).** *Kerveros* temporarily breaks down the zone-level reservation buffers into cluster-level buffers, so that all buffers can be analyzed at the cluster level. The apportioning to cluster-level buffers is done by mimicking how the allocator would spread the VMs across multiple clusters when reservations are materialized. Considerations that are taken into account include load balancing, prioritizing newer-generation hardware for new VM types, and more. We omit details for brevity.

**Aggregating cluster buffers per VM type (Step 5).** Each cluster may have multiple buffers of the same VM type. We aggregate all buffers of the same type into a single buffer by summing their sizes. Intuitively, having a single buffer makes the conversion across types (discussed next) less lossy and more efficient.

**Converting buffers into other VM types (Step 7).** We convert a buffer from one type ( $t'$ ) to another ( $t$ ) to estimate the impact that the original buffer has on allocations of type  $t$ .

One way to accomplish this is by using conversion ratios that encode the relative sizes of VM types  $t$  and  $t'$ . However, naïve conversion ratios have issues, since VMs have multi-dimensional sizes. To illustrate this, consider a simplified example with the following assumptions:

- Two requested resource types: CPUs and memory.
- Two VM types: large (2 CPUs, 4 GB) and small (1 CPU, 1 GB).
- Two machine sizes:  $M_1$  (25 CPUs, 40 GB) and  $M_2$  (25 CPUs, 25 GB).

Table 1 shows the counts of each VM type that can fit in one empty  $M_1$  and  $M_2$  machine, and also the counts after adding 10 and 20 small VMs using various counting methods. Simple conversion ratios based on resource ratios in isolation (CPU and RAM in Table 1) can lead to sub-optimal (yellow bars) or incorrect outcomes (red bars). This has repercussions on packing efficiency and SLA adherence: underestimates can

| Machine State | Method | AV Counts      |                |                        |    |
|---------------|--------|----------------|----------------|------------------------|----|
|               |        | Large on $M_1$ | Large on $M_2$ | Small on $M_1$ & $M_2$ |    |
| Empty         | Actual |                |                |                        |    |
| 10 small      | Actual |                |                |                        | 15 |
|               | CPU    |                |                |                        | 15 |
|               | RAM    |                |                |                        | 15 |
|               | CRA    |                |                |                        | 15 |
| 20 small      | Actual |                |                |                        | 5  |
|               | CPU    |                |                |                        | 5  |
|               | RAM    |                |                |                        | 5  |
|               | CRA    |                |                |                        | 5  |

Table 1: Counts of large and small VMs that can fit in two machines  $M_1$  and  $M_2$  using various other conversion-ratio-based methods compared to the true count (Actual). CPU treats 1 small VM as 1/2 a large VM, and RAM treats 1 small VM as 1/4 a large VM.

strand resources (leading to fragmentation and worse packing efficiency) and overestimates can violate hardware constraints (leading to SLA violations). The optimal conversion ratio depends both on the machine size and the VMs already allocated (i.e., resources *remaining* on the machine).

We use the ratio of AV counts as a low-dimensional approximation instead. Formally, a buffer of type  $t'$  with size  $x$  is converted to a buffer of type  $t$  with size:

$$\mathbb{C}(t' \rightarrow t, x, c) = \left\lfloor \frac{A[t, c]}{A[t', c]} \cdot x \right\rfloor.$$

This works well in practice (empirical results in §5).

**Example.** To illustrate CRA, we return to the example in Figure 1. As a quick recap, we consider a single cluster with two empty machines, each with size of 100 units (for simplicity, we assume only a single resource dimension). The three VM types small ( $S$ ), medium ( $M$ ), and large ( $L$ ) have sizes 20, 50, and 60 units respectively. A single medium-sized VM is requested – this request is rejected if  $\mathbb{A}[M] < 1$ . We first initialize the counts for our VM types ( $S$ ,  $M$  and  $L$ ):

$$A[S, c] = 2 \cdot \left\lfloor \frac{100}{20} \right\rfloor = 10, \quad A[M, c] = 2 \cdot \left\lfloor \frac{100}{50} \right\rfloor = 4, \\ A[L, c] = 2 \cdot \left\lfloor \frac{100}{60} \right\rfloor = 2.$$

In both scenarios in Figure 1, there is a single incoming request of size 50 and buffers of 120 units total that need to be taken into account; the only difference between the scenarios is the VM type of these buffers:

- *Large buffers.* Assume that we have two large buffers. We convert these buffers to type medium, which yields  $\mathbb{C}(L \rightarrow M, 2, c) = 4$  medium VMs. This results in  $\mathbb{A}[M] = 0 < 1$ , so we reject the request.

$$\mathbb{A}[M] = A[M, c] - \mathbb{C}(L \rightarrow M, 2, c) \\ = A[M, c] - \left\lfloor \frac{A[M, c]}{A[L, c]} \cdot 2 \right\rfloor = 4 - \left\lfloor \frac{4}{2} \cdot 2 \right\rfloor = 0.$$

Figure 7: CRA versus emulation for two VM types, where the AV count is expressed as a percentage of the total capacity. Simulated results from a single trace.

- *Small buffers.* Assume that we have six small buffers. We convert these buffers to type medium, which yields  $\mathbb{C}(S \rightarrow M, 6, c) = 3$  medium VMs. This results in  $\mathbb{A}[M] = 1 \not\leq 1$ , so we accept the request.

$$\begin{aligned} \mathbb{A}[M] &= \mathbb{A}[M, c] - \mathbb{C}(S \rightarrow M, 6, c) \\ &= \mathbb{A}[M, c] - \left[ \frac{\mathbb{A}[M, c]}{\mathbb{A}[S, c]} \cdot 6 \right] = 4 - \left[ \frac{4}{10} \cdot 6 \right] = 1. \end{aligned}$$

In Appendix A, we provide a theoretical analysis of CRA under simplified assumptions; specifically, we prove that the conversion results in a bounded waste of resources.

### 3.2.3 Linear Adjustment Algorithm (LAA)

The Conversion Ratio Algorithm offers an efficient and scalable approach for obtaining the AV counts. Nevertheless, the output of this algorithm might sometimes be fairly inaccurate. The main reasons for inaccuracy are potential fragmentation issues while dealing with conversion between multi-dimensional VM types and not explicitly modeling how the VMs would be placed using the allocator (e.g., erroneously assuming the rightmost outcome in Figure 1 and rejecting the new request).

The above limitations can be mitigated if *Kerveros* could emulate the placing of the different buffers and filling up of the inventory by allocating VMs using the allocator. This is the main idea behind the *Linear Adjustment Algorithm (LAA)*. Since such emulation is compute-intensive and time-consuming, we run it periodically (every 30 minutes) and in isolation, i.e., without interfering with the handling of customer requests (more details in §4.1.2). We then use the emulation result to calibrate CRA’s output.

To see how the emulation output should be accounted for, we compare its output to CRA’s output. Figure 7 shows a time series of emulation and CRA’s output for two different VM types. We observe that the gap between the two methods is steady at times, but is spiky at other times. The LAA should account for both these phenomena.

Formally, for any VM type  $t$ , let  $\mathbb{A}'[t]$  and  $\mathbb{E}'[t]$  be the AV counts obtained by CRA and the allocator emulation at the time when the emulation was run last, respectively. We then

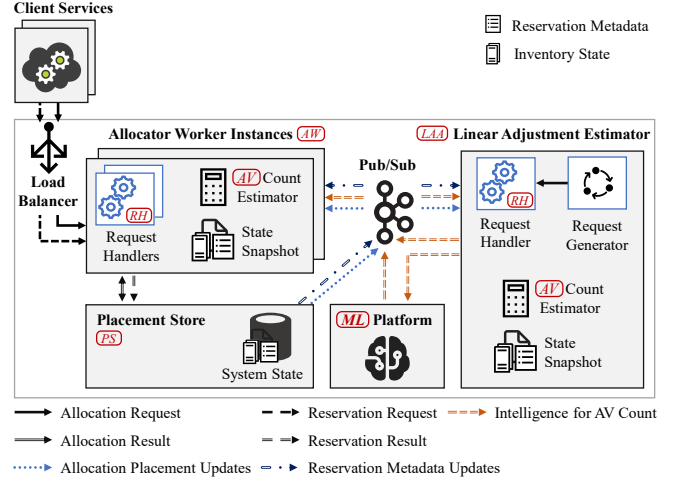

Figure 8: *Kerveros* system architecture.

adjust the current VM count estimate  $\mathbb{A}[t]$  (result of CRA) to obtain a new estimate:

$$\mathbb{A}_{\text{adjusted}}[t] := \beta_1' \cdot \mathbb{A}[t] + \beta_2' \cdot \mathbb{A}'[t] + \beta_3' \cdot \mathbb{E}'[t] + \beta_4', \quad (1)$$

where the coefficients  $\beta_i'$  are learnt using standard linear regression, with the emulation outputs serving as ground truth for training.  $\beta_2'$  and  $\beta_3'$  incorporate information on the gap between ground-truth and CRA in the previous time step, and  $\beta_4'$  models the constant gap between the two methods. In §5, we show that LAA substantially decreases AV count error, while maintaining scalability.

## 4 System Implementation

In this section, we first describe *Kerveros*’s various microservices that allow it to respond to allocation and reservation requests in an availability zone and enforce its admission-control logic in an efficient and scalable manner (§4.1). We then discuss tradeoffs that arise from various design decisions made in our implementation (§4.2).

### 4.1 Architecture

*Kerveros*’s microservices work in concert to handle allocation and reservation requests, estimate AV counts, execute emulation runs for AV count adjustment, persist state when allocations and reservations are accepted by the system, and train ML models as required (Figure 8). The microservices primarily use a distributed publish-subscribe (pub-sub) platform [42] to transfer state among themselves.

#### 4.1.1 Allocation Worker Instances

Multiple *stateless* allocation worker instances (AW) are used to handle both reservation and tenant allocation requests. An allocation worker instance is a process typically running on a dedicated machine. Each instance has two types of agents:

request-handling (RH) agents to serve requests, and an AV count estimation agent to periodically compute the number of allocable VMs. The number of worker instances and RH agents deployed in a zone is configured based on the request demand in the zone and size of the allocation inventory.

**Request handlers (RH).** A RH handles both reservation and tenant requests.

*Reservation requests.* For a reservation request, the RH performs a zonal admission-control check. The zonal check evaluates whether there is enough capacity in the zone by comparing the number of requested VMs with the zonal AV count. All buffer types (reservation, healing, and growth) are considered for this check. On success, the reservation metadata is persisted to the placement store (see below).

*Tenant requests.* For new tenant requests, the same zonal admission-control check is executed. The agent then proceeds to filter and sort the inventory machines for each requested VM, following a series of hard and soft constraints respectively, to assign a specific machine for each VM. One of the filtering steps involves performing cluster-scope admission-control checks to ensure clusters have sufficient capacity for the requested VMs.

The buffers used in the admission-control steps are adjusted based on the nature of the request and scope of the check. For example, at cluster scope, only healing and growth buffers are considered for new tenants when computing AV counts. Similarly, only healing buffers are considered for tenant growth requests. As another example, all admission-control checks are skipped for reservation-backed VM requests (i.e., requests for VMs against an already-accepted reservation) and healing requests, since these requests have already been accepted (either as part of the reservation or as part of the original VM / tenant request before hardware failure).

On success, the “VM → machine” mapping is persisted in the placement store.

**AV count estimator (AV).** The AV count estimator executes both CRA (§3.2.2) and the linear adjustments (§3.2.3). To avoid adding latency to the RH response time, the estimator is implemented as a separate agent off the critical path of the RH. It runs in a tight loop (every minute), and updates the RHs with new AV counts through in-memory state transfer.

To obtain the AV counts, the estimator requires information about machine occupancy and health, reservation metadata, adjustment coefficients, and reservation-VM maps for VMs allocated against reservations. Each estimator learns about this information through the pub-sub platform. This information is organized through multiple pub-sub topics. Given the distributed nature of the platform, each estimator works with a somewhat stale view of the inventory and reservations (we discuss the impacts of this in §4.2).

#### 4.1.2 LAA Instance

The LAA instance performs periodic emulation to obtain more accurate AV counts (§3.2.3). To do so, it listens to the same pub-sub topics as the worker instance, but does not handle customer requests and does not persist any results to the placement store. It starts each emulation run from a snapshot of the entire inventory (with buffer information). It then creates allocation requests corresponding to the buffers and allocates them using the snapshot of the inventory state. These results are stored as local in-memory modifications on the initial inventory snapshot. Once the buffers are allocated, the LAA instance computes more accurate AV counts for each VM type from the remaining available capacity by repeatedly allocating (till failure) and deallocating VMs for each type. We note that these operations do not interfere with the critical path of real request handling or admission-control enforcement. Finally, the LAA instance sends relevant estimation data to the ML platform, which runs the linear regression required to tune the  $\beta_i$  parameters in Equation 1; the training is performed at a coarser time granularity (every day, using a week’s worth of emulations results).

#### 4.1.3 Offline ML Platform

The offline ML platform (ML) performs relevant ML training tasks; its output is consumed by the AV count estimators. In addition to updating the LAA coefficients, the platform provides the predictions required for buffer management (e.g., determining the effective growth rate for a cluster).

#### 4.1.4 Placement Store

A *stateful* microservice, called the placement store (PS), persists the results of the computations performed by the RH agents in the worker instances.

Correctness of the VM→machine assignment is critical since incorrect assignments can lead to VM start failures and violation of explicit guarantees provided to customers. Hence, the PS validates each VM→machine assignment to check for conflicting assignments made by other concurrent RH agents, and returns a retry if validation is not successful. This ensures that the RH’s stale view of the inventory does not lead to correctness issues. PS uses fine-grained machine-level locking to allow results from multiple machines to be checked and persisted concurrently.

On the other hand, validating admission-control checks at a zonal level with concurrent allocation workers would require the PS to take a global lock on the entire inventory. This would severely compromise scalability. Hence, the PS does not perform any *global* capacity checks, which means that buffer enforcement is not guaranteed to be correct for every request. We note however that temporary reductions in buffer capacity are rarely seen in practice and are more acceptable (see discussion below).

## 4.2 Practical Considerations

We now briefly discuss the implications of some of these design decisions.

**Dependence on underlying allocator.** While we build and design *Kerveros* within the context of Azure, we note that other major public clouds face similar challenges (e.g., a multitude of VM types and consumption modes, hardware failures, efficiency requirements). Moreover, *Kerveros*'s algorithms are agnostic to the details of the underlying allocator (e.g., exact hard and soft constraints enforced).

**Caching.** As described in §3.2, AV counts are computed for every machine separately and then aggregated to derive the allocable VMs that can fit in the cluster. Instead of computing AVs for every machine from scratch, the AV counts are maintained in an in-memory cache per machine and per cluster. This cache is initialized when the AV count estimator starts, and then is updated incrementally only for the machines that are modified because of changes in machine occupancy or health. Caching the AV counts in this manner massively reduces the computation overhead because the number of machines altered between consecutive AV count updates is orders of magnitude smaller than the total number of machines in the inventory. The periodic nature of AV count computation (as opposed to calculating AV counts for every request) might lead to using protected capacity.

**Optimistic concurrency.** As noted earlier, *Kerveros* uses optimistic concurrency control for better scalability, which allows allocation worker instances to see stale versions of state in the system. This is a limitation, since it allows the possibility of accepting multiple requests eating into the "same" protected capacity. This can occur, for example, when multiple worker instances accept requests or reservations simultaneously while not being aware of each other.

Due to dynamic churn (in particular VM shutdowns) in the workload (Figure 9), usages of protected capacity are temporary and rarely result in SLA violations. Running out of capacity due to stale AV counts or optimistic concurrency is rare, but if it happens, we have multiple knobs for mitigation, such as temporarily eating into healing buffers, evicting internal non-critical workloads, restricting the creation of new VMs, and migrating VMs to reduce fragmentation.

## 5 Evaluation

In this section, we seek to answer the following questions:

- Does *Kerveros* perform better than relevant baselines on the following dimensions: packing efficiency, SLA violations, and runtime?
- How well do *Kerveros*'s various optimizations work to count AVs accurately (e.g., LAA)?
- How does *Kerveros* trade off accuracy vs. compute effort?

Figure 9: *Churn* for high-priority workloads in a single zone. Average is computed over 5-minute intervals, and computed over a 2-week period. Workload is weighted by the size of VM requested and normalized by the total volume of the zone. That is, roughly an average of 0.3% of total workload arrives and exits the zone every 5 minutes.

## 5.1 Experimental Setup

In this section, we outline the metrics of comparison, the baselines, as well as details on how we run experiments in production and simulation.

**Metrics.** We use the following metrics to measure *Kerveros*'s effectiveness:

- **Packing efficiency.** This metric estimates the capacity wasted by resource fragmentation due to inefficient packing. To measure packing efficiency, we temporarily fill the system with full-node VM requests, and set packing efficiency to be the final system load (including unused buffers) as a percentage of total cores (proxy). We choose full-node VM requests since they are generally the hardest to place.
- **Scalability.** The runtime (latency) of *Kerveros*'s AV count estimator.
- **SLA violations.** The proportion of requests where SLAs (machine failures, growth, reservation) are violated.
- **AV error.** The deviation in AV counts between offline emulation (which serves as an oracle) and other approaches. We use this metric to study the effectiveness of *Kerveros*'s approximate AV counting approaches.

**Baselines.** We compare *Kerveros* against the following:

- **Offline emulation (Oracle).** In the event of a tenant or reservation request, the allocator first makes temporary allocations for all unused buffers in the system. The allocator then checks the feasibility of accepting the current request; if there are not enough resources to satisfy the request, it is rejected. All temporary allocations for unused buffers are then discarded. This is slow but gives an accurate AV count, which can then be used as ground truth to estimate the AV error described above.
- **Placeholder (PH).** All buffers are allocated and assigned to physical machines at the time of request (or update). For example, an accepted reservation is allocated all of its required resources at admission time.

Figure 10: Comparison of packing efficiency across various baselines against the inventory partitioning algorithm (PT). The results are computed over a single trace. As can be seen, PT does not work well with our workloads.

Figure 11: Packing efficiency vs. unused buffer size. We show the median and 25/75<sup>th</sup> percentiles, aggregated over all traces.

- **Inventory partitioning (PT).** Each buffer is allocated its own set of dedicated machines, enough to satisfy demand. The partitioning approach is similar to the method used by RAS [34], where *machines* are dynamically partitioned as new reservations arrive.

**Production.** Azure collects telemetry on different aspects of VM resource management in an internal data analytics platform. We use this data to measure healing and growth failures as well as latencies (§5.2). All production metrics are gathered for a period of one month in 2022.

**Simulator.** Production data is not sufficient to provide a full evaluation of *Kerveros*. In particular, comparison against other approaches requires a simulator since the baselines we consider are not deployed in our production setting.

To this end, we use our event-driven simulator to test various aspects of the entire admission control system (including both the allocator and *Kerveros*). Due to the allocator’s relative complexity, the simulator includes only a lightweight version, which supports the key constraints of the allocator logic. The simulator handles both tenant and reservation events (arrival, departure, and updates). Despite supporting a subset of the allocator’s logic, the simulator provides an excellent approximation of the system in production and is able to scale adequately to large inventories. We have extended the simulator to support the above baselines.

Figure 12: Latency (25/50/75<sup>th</sup> percentiles) versus inventory size, extracted from Azure over a month. Randomly-sampled allocation times are included for further context. End-to-end allocation latency is more significantly affected by inventory size compared to the AV count computations.

**Simulation traces.** We run simulation experiments on twenty traces that include both tenant and reservation requests. The traces use historical production data for tenant requests. Reservations, on the other hand, are a relatively new offering without significant traffic yet. Consequently, we synthetically add reservations to augment the historical data. The reservation characteristics, such as VM type and size, are extrapolated from real reservations.

## 5.2 End-to-End Experiments

Our goal here is to show that *Kerveros*’s CRA and LAA approaches outperform other baselines along three axes: packing efficiency, scalability, and SLA adherence.

### 5.2.1 Packing Efficiency

Figure 10 shows a timeline view of packing efficiency for one of the traces. The partitioning (PT) approach of splitting by machine is inefficient for our workloads: PT might work well in other limited settings (e.g., small number of total tenants). However, our general setting includes a large number of requests which require many fractions of machines. We therefore exclude PT from the rest of the analysis.

We now further explore the remaining baselines and aggregate results over all traces. Figure 11 illustrates how unused buffer sizes influence packing efficiency. As the unused buffer size increases, CRA suffers from accumulated rounding errors, and the PH algorithm can lock into sub-optimal packing decisions, resulting in inferior packing efficiency. LAA can compensate for rounding errors, and sustains high packing efficiency even with large unused buffers.

### 5.2.2 Scalability

Figure 12 shows the latency of the AV count computation for various inventory sizes. For reference, we also show the allocator’s latency for a single VM. We observe that *Kerveros*’s approximate AV counting algorithm scales well with inventory size, taking less than ten milliseconds even for inventories of over a hundred thousand machines. Approximate AV counting is cheap because the underlying computation is proportional to the number of VM types; in

Figure 13: Cumulative density function (CDF) of AV error from LAA. SLA violations can occur when the AV error is positive (i.e., the algorithm overestimates AV counts, or asserts that there is more available capacity than reality).

Figure 15: Illustration of healing buffer size, where  $x_c = \lceil 13.4 \rceil = 14$  machine-equivalent buffers are prepared to satisfy the desired 99.99% SLA.

(a) Healing.

(b) Growth.

Figure 14: The impact on availability due to healing and growth failures. Note that these values are not weighted by time, but represent a normalized count of all failures within each day. The actual loss of availability to each customer is less than what is indicated above. This historical data is aggregated over the entire cloud for a month in 2022.

contrast, the allocator runtime depends on the inventory size (since the allocator has to choose the most suitable machine for allocation). Overall, the results indicate that *Kerveros*'s AV-based approach is not the computational bottleneck.

### 5.2.3 SLA Violations

We also want to verify that *Kerveros*'s approach results in a low number of SLA violations. We verify this in both production and simulation.

**Reservation.** Figure 13 shows the cumulative density function (CDF) of AV errors obtained from simulation. When the AV error is positive, *Kerveros* overestimates the available capacity. This behavior might lead to reservation SLA violations in some extreme cases (for example, if all users' reservations, healing buffers, and growth buffers are claimed almost simultaneously). As the LAA curve shows, *Kerveros* reserves sufficient capacity to cover all promised resources around 86% of the time; *Kerveros* requires less than 1% additional capacity to satisfy requests about 99.7% of the time. With typical workload churn, we expect to obtain this additional capacity promptly.

**Healing.** Figure 14a shows production data over a month for instantaneous SLA violations due to healing failures.

Figure 16: Tradeoff between healing buffer size and healing success rate.

We observe that *Kerveros* is able to sustain four nines of availability through the entire month by appropriately sizing healing buffers.

As Figure 15 shows, we calculate the healing buffer size based on a data-driven method (see §3.1). To better understand the tradeoff between packing efficiency and SLA adherence quantitatively for healing, we show how the healing buffer size influences the healing success rate based on data over a month in 2022, as shown in Figure 16. The  $x$ -axis shows the ratio of the buffer size compared to the size used in production, where 100% healing buffer size corresponds to the current production's decisions. When the ratio is zero, *Kerveros* does not reserve any healing buffers, but can still heal VMs affected by hardware failures if enough resources are coincidentally available in the cluster.

**Growth.** Figure 14b shows production data on instantaneous growth failures for the same month. We observe that growth is supported more than 99.9% of the time.

## 5.3 Deep Dive on AV Counting Algorithms

We now further evaluate the various components used to calculate AV counts.

**Improvements from linear adjustment.** Figure 17 shows the AV error of CRA (top) and LAA (bottom) versus the size of unused buffers. The estimation error with CRA increases with the unused buffer size, as fragmentation is amplified. LAA is more robust by fixing biases periodically (§3.2.3).

Figure 17: AV errors when calculating AV counts for two VM types (small and large) versus unused buffer size. The top graph, with average and 25/75<sup>th</sup> percentiles for CRA, shows CRA performing increasingly worse as unused buffer grows. LAA with an adjustment frequency of 30 minutes obtains small error even as the unused buffer percentage becomes large. We show 95<sup>th</sup> percentiles for LAA for emphasis.

Figure 18: AV errors versus adjustment frequency in LAA. As we increase the frequency of adjustment, error is reduced at the expense of additional computation. In the  $x$ -axis, ‘m’ stands for minute, ‘h’ for hour, and ‘d’ for day.

**Adjustment frequency.** Figure 18 shows how the AV error changes with the frequency of LAA emulation. The figure shows that emulating every few minutes does not drastically reduce AV error. Consequently, we choose an emulation frequency of 30 minutes. Interestingly, we find that even with just one adjustment a day, the LAA algorithm still performs better than the basic CRA approach.

## 6 Discussion

We briefly discuss additional considerations relevant to *Kerveros*.

**The public cloud eco-system.** Modern public clouds have a large number of components that interact with each other, making multi-faceted decisions related to economically incentivizing usage, managing quota, provisioning capacity, etc. For example, special permissions or quotas are needed for very large customer demands; similarly, discounts are often offered to incentivize prominent customers. Such decisions are made on a slower time scale, often involving humans in

the loop, and influence the inputs to *Kerveros*.

**Constraints beyond capacity checks.** The decision of admitting a tenant request is complex, and involves a variety of constraints beyond capacity checks (e.g., fault domains, locality). However, when *Kerveros* reserves buffers (healing, growth, reservations), it can afford to take a simplified view, relying on the economy of scale (large inventory, workload churn) and mitigation actions as a last resort. Accordingly, the basic CRA algorithm does not account for the entire set of constraints. Nonetheless, CRA is supplemented by LAA. LAA in turn strongly relies on emulating the allocator’s logic, which does account for multiple preferences and constraints and uses realistic tenant requests against unused reservations. We note that the actual tenant requests against reservations can only specify a limited set of constraints by design (e.g., limit the maximum number of fault domains). The net effect is that *Kerveros* has proven to be reliable in production, despite the simplifying assumptions.

**Priorities.** While some business priorities are enforced at higher layers, allocation requests to *Kerveros* can have different priorities based on preemption level: higher-priority requests can preempt lower-priority ones to grab capacity [21, 45]. However, all buffers (reservation, growth, healing) are maintained only for the highest (non-preemptible) priority. Regardless of their priority, *Kerveros* handles all tenant and reservation requests on a first-come-first-serve basis.

**Predictive modeling.** Having a large percentage of unused buffers impacts resource efficiency; running preemptible workloads (e.g., spot VMs) on unused buffers is a partial mitigation. Currently, we avoid setting aside capacity in anticipation for future new customers. Incorporating ML models into *Kerveros* to predict resource usage and utilize the unused capacity even more aggressively is an interesting future direction.

**Comparison to early binding.** As an alternative to *Kerveros*’s late-binding approach, an early-binding or placeholder approach that exploits the existing allocation system to allocate buffers when needed (e.g., when a reservation request is accepted, or when a machine failure occurs) may seem like a more natural solution. Our evaluation of *Kerveros* against the baseline placeholder solution (PH) in §5 showed that this strategy suffers from worse packing efficiency. In addition, it introduces other various complications:

- Early binding requires lock-in of VM configuration parameters (e.g., VM type) when not necessary yet, reducing flexibility on the clients’ side.
- Buffers like the healing buffer need to have their sizes updated regularly, which is more inefficient with the early-binding approach.
- Early binding makes it harder to support over-subscription using spot VMs or harvest VMs.

- Early binding might require complex migration logic to move “placeholder” VMs between machines to pack VMs efficiently on the available physical machines.
- The early-binding approach incurs an additional caching cost, even if live migrations are free, i.e., the corresponding caches that reference the source and destination machines for each placeholder migration need to be invalidated.

**Reservations with future start dates.** *Kerveros* only supports reservations starting immediately. To guarantee reservations starting at future time  $t$ , we either need accurate estimates of the capacity at  $t$  (high risk), or we can reserve capacity now and hold it until  $t$  (high cost). Both approaches have significant issues that become worse as  $t$  is pushed out further into the future; these issues are also exacerbated by larger reservations (both in terms of the number and size of the reservation). It might be possible to estimate future capacity using a probability distribution, but we expect the accuracy to be poor without a reservation end time. Alternatively, rather than requesting a specific start and end time for a reservation, a user could specify a reservation with a *demand profile* that indicates the desired usage and expected growth over time.

## 7 Related Work

*Kerveros* builds on a rich line of previous work on admission control and reservations in the cloud.

**Admission control.** Admission control is a broad topic that has been studied in a variety of contexts such as cloud systems [9, 16, 26, 27, 29, 43, 45, 51, 52, 55], computer networks [8, 11, 18, 28, 30, 36, 44, 46, 47, 53], cellular networks [37, 50], mobile edge computing [1, 23, 24], real-time database systems [12, 22, 32, 38, 48], distributed systems [13–15, 41, 49, 54], and caching systems [10, 33, 40], among others. Each domain provides unique challenges and requirements that advocate for custom solutions to be developed. This work focuses on datacenter-scale VM admission control with support for VM reservations. To the best of our knowledge, there is no published work in this space that explicitly covers availability, scalability, and efficiency considerations. The bulk of the related papers in this space is centered more around VM allocation and placement, and admission control is addressed only at a high level. Similarly, reservations are a relatively new offering and are not directly addressed. For example, Protean [21] describes Microsoft’s rule-based zonal allocator, while focusing on systems enhancements to reduce latencies. However, Protean does not address either the problems of admission control or support for reservations. Google’s Borg [43, 45] scheduler introduces efficient packing and machine-sharing techniques to achieve high resource utilization, but admission control is only briefly described in terms of a quota system, and managing the fragmentation and quota allocation of the admission control is outside the scope of the paper. In terms of reservations, Borg uses the concept

of Borg Allocs, which are akin to the placeholder approach that we compare against.

**Reserving cloud resources.** The (VM) reservations we consider in this paper are a relatively new consumption mode that has been introduced to provide predictability to customers. Note that this mode is different from reserved instances (RIs) [6, 7, 17, 20, 35], under which customers make a 1-3 year *commitment* in return for a significant discount over on-demand offerings. For reservations in datacenters, we are only aware of Meta’s RAS [34] system, which manages user reservations at the granularity of a server. RAS works by partitioning machines and dynamically migrating machines between partitions, guided by a mixed-integer linear program. While the partitioning approach works well for Meta’s internal services, it is not well-suited for our public cloud setting (§5).

Resource reservations have also been proposed for internal big data analytics systems (e.g., [16, 25]). However, the provider there has more information about the jobs (e.g., job duration and deadline) and can better create an explicit resource allocation plan over time.

## 8 Conclusion

This paper describes the design, implementation, and evaluation of *Kerveros*, an admission-control system deployed in a large public cloud. Our design accurately retains capacity for hardware failures, tenant scale-out, and reservations while being computationally scalable to large inventories and peak loads. *Kerveros* can be extended to support additional scenarios such as improving margin efficiency through reservation overbooking and supporting enhanced reservation semantics (e.g., reservations with a start date).

# Appendix

## A Theoretical Guarantees

In this section, we show that the conversion ratio approach does not lead to an excessive wastage of resources.

**Notation.** We start by defining some useful notation.

- Let  $y_m^t$  denote the type- $t$  VMs that can fit in a machine  $m$ , ignoring buffers.
- Let  $x_c^t$  denote the number of VMs of type  $t$  required for buffers in cluster  $c$ , and let  $x_c^{t' \rightarrow t} = \mathbb{C}(t' \rightarrow t, x_c^t, c)$  be the converted number of VMs from type  $t'$  to type  $t$ .
- We define  $C_{t' \rightarrow t} = \frac{A[t, c]}{A[t', c]}$ , which allows us to write the conversion ratio from type  $t'$  to type  $t$  as

$$x_c^{t' \rightarrow t} = \mathbb{C}(t' \rightarrow t, x_c^t, c) = \lceil C_{t' \rightarrow t} \cdot x_c^t \rceil.$$

**Setting.** Our analysis focuses on the following setting:

- We assume that one of the resources (e.g., CPU) is the main bottleneck in a cluster; let  $q_t$  denote the amount of that resource that VM type  $t$  requires.
- When  $C_{t' \rightarrow t} < 1$  (i.e., we are converting from “smaller” to “larger” VMs), we omit the ceiling function from the converted AV count calculation. Instead,  $x_c^{t' \rightarrow t} = C_{t' \rightarrow t} \cdot x_c^t$ .
- Let  $M_c^{t, t'}$  denote the set of machines in cluster  $c$  that can currently fit both VM types  $t'$  and  $t$ . The conversion ratio from  $t'$  to  $t$  is then calculated using only the machines in  $M_c^{t, t'}$ . Specifically, we let  $A[t, c] = \sum_{m \in M_c^{t, t'}} y_m^t$  and  $A[t', c] = \sum_{m \in M_c^{t, t'}} y_m^{t'}$  for calculating  $C_{t' \rightarrow t}$ .

**Results.** To quantify the waste in resources, we compare the total capacity of the VMs that are being converted with the total capacity of the AV counts that are deducted by this conversion. In particular, let  $U_{original} = \sum_{t'} x_c^{t'} \cdot q_{t'}$  denote the total capacity of the VM types before conversion (i.e., “real” capacity of buffers), and  $U_{converted} = q_t \cdot \sum_{t'} x_c^{t' \rightarrow t}$  denote the converted capacity of these VMs.

**Theorem 1** *The conversion guarantees at least  $\frac{1}{4}$ -utilization of the converted AV counts’ capacity; explicitly:  $U_{original} \geq \frac{1}{4} \cdot U_{converted}$ .*

To prove Theorem 1, we will need the following auxiliary lemma that relates the conversion ratio with the sizes of the VM types.

**Lemma 1** *Under the above assumptions,  $C_{t' \rightarrow t} \leq 2 \cdot \frac{q_{t'}}{q_t}$ .*

**Proof of Lemma 1.** Consider a machine  $m$  that can currently fit at least one VM of type  $t$  or one VM of type  $t'$ . Let  $Q_m$  denote the available capacity of the bottleneck resource (e.g., CPU) of machine  $m$ . By definition,  $y_m^t = \lfloor \frac{Q_m}{q_t} \rfloor$  and  $y_m^{t'} = \lfloor \frac{Q_m}{q_{t'}} \rfloor$ . Then, the following are true:

$$q_t \cdot y_m^t \leq Q_m \quad \text{and} \quad q_{t'} \cdot (y_m^{t'} + 1) > Q_m.$$

Combining the above two inequalities, we obtain:

$$q_t \cdot y_m^t < q_{t'} \cdot (y_m^{t'} + 1) \Rightarrow \frac{y_m^t}{y_m^{t'}} < \frac{q_{t'}}{q_t} + \frac{q_{t'}}{q_t \cdot y_m^{t'}} \leq 2 \cdot \frac{q_{t'}}{q_t}$$

where the last inequality follows from the fact  $y_m^{t'} \geq 1$ .

Since this is true for all machines  $m$  that fit both VM types, we obtain:

$$A[t, c] = \sum_{m \in M_c^{t, t'}} y_m^t \leq 2 \cdot \frac{q_{t'}}{q_t} \sum_{m \in M_c^{t, t'}} y_m^{t'} = 2 \cdot \frac{q_{t'}}{q_t} \cdot A[t', c].$$

We can then easily see that:

$$C_{t' \rightarrow t} = \frac{A[t, c]}{A[t', c]} \leq 2 \cdot \frac{q_{t'}}{q_t}.$$

**Proof of Theorem 1.** We need to consider two cases.

- **Case 1:**  $C_{t' \rightarrow t} < 1$ . In this case, we obtain the following:

$$x_c^{t' \rightarrow t} = C_{t' \rightarrow t} \cdot x_c^t \leq 2 \cdot \frac{q_{t'}}{q_t} \cdot x_c^t.$$

We then get for the original and converted capacity of VM type  $t'$ :

$$q_{t'} \cdot x_c^{t'} \geq \frac{1}{2} \cdot q_t \cdot x_c^{t' \rightarrow t}.$$

- **Case 2:**  $C_{t' \rightarrow t} \geq 1$ . Similarly, in this case:

$$\begin{aligned} x_c^{t' \rightarrow t} &= \lceil C_{t' \rightarrow t} \cdot x_c^t \rceil \leq C_{t' \rightarrow t} \cdot x_c^t + 1 \leq C_{t' \rightarrow t} \cdot (x_c^t + 1) \\ &\leq 2 \cdot C_{t' \rightarrow t} \cdot x_c^t \leq 4 \cdot \frac{q_{t'}}{q_t} \cdot x_c^t. \end{aligned}$$

In the above, the second inequality follows from  $C_{t' \rightarrow t} \geq 1$ . The third inequality is due to  $x_c^t \geq 1$  (otherwise, no buffer of type  $t'$  would exist, clearly leading to zero waste in the conversion by default). Finally, the last inequality uses Lemma 1. As a result,

$$q_{t'} \cdot x_c^{t'} \geq \frac{1}{4} \cdot q_t \cdot x_c^{t' \rightarrow t}.$$

Putting both cases together, we can see that for all converted VM types  $t'$ , we have:

$$q_{t'} \cdot x_c^{t'} \geq \frac{1}{4} \cdot q_t \cdot x_c^{t' \rightarrow t}.$$

Summing over all such VM types:

$$\sum_{t'} q_{t'} \cdot x_c^{t'} \geq \frac{1}{4} \cdot \sum_{t'} q_t \cdot x_c^{t' \rightarrow t} \Rightarrow U_{original} \geq \frac{1}{4} \cdot U_{converted}.$$

which concludes the proof of Theorem 1.

# Security and Performance in the Delegated User-level Virtualization

## Abstract

Today’s mainstream virtualization systems are plagued by severe security threats due to the large attack surface exposed by in-kernel hypervisor components such as KVM. To address this issue, this paper proposes a novel design called delegated virtualization, which decouples the commodity hypervisor into two planes: the *hypervisor plane* for hypervisor control (which is typically small and has fixed logic) and the *VM plane* for handling virtual machine (VM) requests and exceptions at runtime. As our investigation reveals that all known hypervisor vulnerabilities that threaten the host kernel lie in the VM plane, delegated virtualization completely offloads the in-kernel VM plane to a user-space hypervisor called DuVisor that directly interacts with its VM without exiting to the host kernel, based on a small hardware extension (481 lines of Chisel). We have implemented the hardware extension on an open-source RISC-V CPU on FireSim and built a Rust-based DuVisor atop it. The evaluation results demonstrate that DuVisor significantly reduces the attack surface with negligible performance overhead (< 5%). DuVisor’s source code is publicly available at <https://github.com/IPADS-DuVisor>.

## 1 Introduction

The technique of system virtualization, also known as virtualization, is essential for efficiently running concurrent virtual machines (VMs). Since its conception, virtualization has undergone three rough stages of evolution, gradually moving hypervisor functions outside of kernel mode. In the first stage (Figure 1-a), all hypervisor functions were implemented in kernel mode to multiplex scarce resources of large mainframe machines, such as the IBM VM/370 [44, 48, 54, 83]. In the second stage (Figure 1-b), mainstream hypervisors began to offload hypervisor functions to user mode, which issued system calls to take advantage of a host operating system (OS) [42, 43] or a management VM [40]. However, some functions still remained in kernel mode, such as instruction

emulation and memory virtualization. The third stage (Figure 1-c) began with the release of hardware extensions (e.g., Intel VMX [19] and AMD SVM [2]), which further reduced the kernel involvement in virtualization by shifting some virtualization functions to hardware.

Nowadays, third-stage hypervisors that are based on hardware extensions typically utilize a split model consisting of two cooperative components: a kernel-mode module and a user-mode helper. For instance, the most popular Linux/KVM-based virtualization system<sup>1</sup> includes a global KVM kernel module [49, 61] and a per-VM user-mode helper, such as QEMU [26]. The KVM module interacts with hardware extensions and the host kernel, while the user-mode helper is responsible for VM management and I/O virtualization.

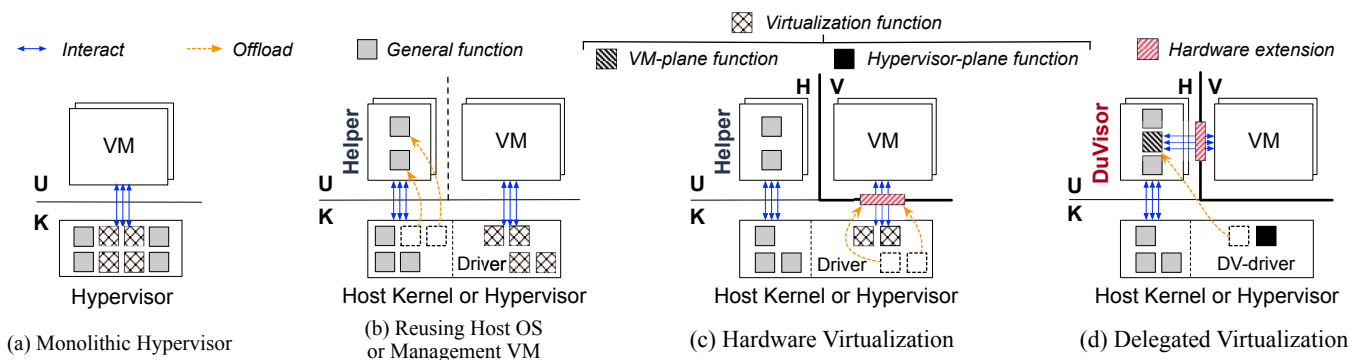

Unfortunately, vulnerabilities in the kernel-mode component of virtualization systems are discovered from time to time, making them a major threat to host security. For example, there have been more than a hundred CVEs reported in KVM during the course of its evolution [22]. These vulnerabilities can be exploited by a malicious VM to compromise the KVM component that interacts with the VM directly. The majority of these CVEs can be utilized to launch denial of service (DoS) attacks, causing host crashes and undermining the reliability of the host kernel as well as all co-located VMs [10, 16]. Even more concerning, once the KVM kernel module is hacked, the attacker may gain control of the entire system and carry out more severe attacks [3, 13]. In contrast, a compromised QEMU has a considerably smaller impact, usually limited to the current user-mode process and not affecting the host kernel or other VMs, thanks to the isolation between applications and kernel [24, 37].

The key idea of this paper is to **move all hypervisor components that directly interact with VMs at runtime to user space**, with the aim of minimizing the impact of any security bugs and reliability issues found in the user-mode hypervisor. However, there are three significant challenges

\* Co-first authors.

<sup>1</sup>Xen [40] and VMware products [36, 88] also exhibit a similar architecture.

**Figure 1: The architectural evolution of mainstream hypervisors (a → b → c) that gradually demote hypervisor functionalities out of kernel mode and the delegated virtualization proposed by this paper (d).** *U* and *K* represent user mode and kernel mode; *H* and *V* are hypervisor mode and virtualization mode introduced by hardware virtualization. The *Virtualization functions* includes ① *VM-plane functions* serving VMs directly at runtime, and ② *hypervisor-plane functions* performing resource control and error handling for the VM plane. The *General functions* comprises other VM-required functions such as virtualizing I/O devices. (a) Stage-1: The monolithic hypervisor puts all functions in kernel mode; (b) Stage-2: Offloading some functions to a user-mode helper process (e.g., I/O backend drivers), which can reuse host OS or management VM that manage hardware resources; (c) Stage-3: Offloading some virtualization functions into hardware (e.g., shadow paging → nested paging); (d) We propose the DuVisor approach that delegates all VM-plane functions (e.g., VM exit handling) to user space and minimizes direct interactions between the host kernel and VMs at runtime.

that make the design more complex than it initially appears: 1) *Privilege Restriction*: modern hardware virtualization extensions are only configurable in kernel mode, such as setting a VM’s stage-2 page table. This necessitates the presence of a hypervisor component in the host kernel to use these extensions. 2) *Security Risk*: simply moving all the management of VMs’ hardware resources to user mode violates the least privilege principle and enlarges the attack surface. For instance, if QEMU is allowed to modify a VM’s stage-2 page table, it can then access any physical memory pages, posing a significant security risk. 3) *Performance Overhead*: most VM exits are now forwarded by the kernel to the user-mode functions to handle. Then, the control flow must return to the kernel again to resume VMs’ execution, resulting in excessive runtime ring crossings and unacceptable performance costs [56, 91].

We identify that the tight coupling between hardware virtualization extensions and kernel mode is the root cause of the challenges mentioned above. Fortunately, we observe that recent hardware advancements have made it possible to expose many hardware resources that were previously only accessible by the kernel to user mode. One prominent example is that Intel has released user-level interrupts, which allow a user-level process to handle physical interrupts [20]. Another example is physical memory checking, such as RISC-V Physical Memory Protection (PMP) [32, 63], which limits the physical memory range a program can access. With these recent hardware trends, we believe it is time to retrofit existing hardware virtualization extensions and expose virtualization interfaces to user mode securely and efficiently, addressing the challenges mentioned above.

This paper proposes a hypervisor design principle of **decoupling the VM plane from the hypervisor plane**. The *VM plane* frequently interacts with VMs at runtime by han-

dling their VM exits, and enables various virtual resources through instruction emulation, nested paging, device virtualization, etc. In contrast, the *hypervisor plane* serves the VM plane with physical resource control (e.g., invoking kernel interfaces to manage resources) and fatal error handling. Following this principle, we propose a delegated virtualization architecture, which eliminates the notion that the kernel mode should provide VM abstractions. Instead, delegated virtualization offloads the VM plane that interacts directly with VMs into per-VM hypervisors running in user mode, called *DuVisor*<sup>2</sup>, while only leaving a tiny *DV-driver* in kernel mode responsible for the hypervisor plane.

As shown in Figure 1-d, we introduce a novel hardware extension called *Delegated Virtualization Extension (DV-Ext)* by slightly extending the existing hardware virtualization mechanism to securely expose hardware virtualization interfaces to user mode. Based on DV-Ext, all VM-plane functions in the existing hypervisor are offloaded to the user-mode *DuVisor* process. Specifically, *DuVisor* can directly utilize DV-Ext’s registers and instructions to serve runtime VM exits without trapping into the host kernel. On the other hand, the tiny *DV-driver* remaining in the kernel only wakes up occasionally to allocate physical resources or handle fatal errors for *DuVisor* processes.

*DuVisor* efficiently provides different virtualization functions in user mode with strong security guarantees. For CPU virtualization (§5.1), the *DuVisor* process creates a dedicated thread (*vthread*) for each virtual CPU (vCPU), and the *vthread* utilizes DV-Ext to handle this vCPU’s VM exits in user mode. For memory virtualization (§5.2), *DuVisor* configures a stage-2 page table for its VM and processes stage-2 page faults in user mode with a pre-allocated range of phys-

<sup>2</sup>Short for Delegated user-level HyperVisor

ical memory. The range used by a DuVisor and its VM is restricted by the DV-driver and DV-Ext via hardware physical memory checking. For I/O virtualization (§5.3), paravirtualized (PV) backend drivers in DuVisor directly communicate with their frontends in VMs. DuVisor further uses user-level posted interrupt to completely bypass the host kernel when sending notifications to its VM.

We have implemented DV-Ext based on a RISC-V Rocket CPU using FPGA. DV-Ext can be easily implemented by reusing existing hardware features, including hypervisor extension (H-Ext [28]) and user-level interrupts extension (N-Ext [33]). It only adds 481 lines of Chisel code. Based on DV-Ext, we use Rust to build DuVisor, and the code size is about 7K LoC. We also extend the Linux kernel v5.10.26 with a tiny DV-driver to cooperate with DuVisor by adding 337 LoC. Through software-hardware co-design, the kernel attack surface exposed to guest VMs is minimized, and any vulnerabilities that threaten existing hypervisors are now confined in the DuVisor process. Performance evaluation on cycle-accurate FireSim [59] shows that DuVisor incurs only negligible performance overhead for architectural operations and real-world applications.

In summary, the contributions of the paper are:

- We propose a delegated virtualization architecture that offloads the entire VM plane to the user-level DuVisor and leaves only a tiny DV-driver in the host kernel, minimizing the attack surface exposed to guest VMs and protecting the entire system from being impacted by the security and reliability issues in traditional hypervisors.
- We design a lightweight hardware DV-Ext that enables DuVisor to serve VM entirely in user mode.
- We implement the hardware extension on RISC-V with minimal modification and build a Rust-based DuVisor prototype.
- We evaluate the performance of DuVisor on AWS F1 FPGAs using cycle-accurate FireSim with a suite of real-world applications.

## 2 Background and Motivation

### 2.1 Hardware-assisted Virtualization

Mainstream hardware virtualization extensions [2, 4, 19, 28] offer comparable functionalities. We use RISC-V’s H-Ext as an exemplar due to its open-sourced implementations. As illustrated in Figure 1-c, H-Ext introduces two distinct modes, namely H mode and V mode, which are orthogonal to the existing privilege levels (U and K for user and kernel, respectively<sup>3</sup>). H mode is exclusively reserved for the hypervisor, while VMs operate in V mode. Only the hypervisor kernel mode (HK mode) is authorized to employ the virtualization interface for initiating, configuring, and resuming a VM, receiving traps from a VM to the hypervisor (also

<sup>3</sup>Although RISC-V kernel mode is referred to as “supervisor” (S) mode, we shall use the term kernel mode in this paper.

**Table 1: CVE analyses of KVM [22] and Xen [38].** *Host* stands for the vulnerabilities that could lead to an attack on the host kernel, including *PE* (privilege escalation), *DoS* (denial of service), and *DL* (data leakage). *Other* refers to CVEs that only attack guest VMs or cannot be exploited. *LoC* shows the code size in LoCs of each hypervisor. *Time Scale* indicates the year strides for each of the two hypervisor CVE analyses.

| Name | Total | Host |    |     | Other | LoC  | Time Scale |
|------|-------|------|----|-----|-------|------|------------|
|      |       | PE   | DL | DoS |       |      |            |
| KVM  | 111   | 21   | 7  | 52  | 31    | 142K | 2008-2022  |
| Xen  | 370   | 101  | 19 | 179 | 71    | 345K | 2007-2022  |

known as VM exits), injecting virtual interrupts into a VM, and installing a stage-2 page table (S2PT). To control VMs, the helper process in hypervisor user mode (HU mode) must issue system calls to invoke functions provided by the kernel driver (e.g., KVM) in HK mode.

In this paper, we define the VM plane as all VM-serving functions that handle VM exits and virtualize resources at runtime, while referring to the hypervisor plane as the set of all hypervisor-serving functions that initialize the VM plane, manage physical resources, and handle emergency events. The VM plane in existing hypervisors spans the HK mode (e.g., CPU and memory virtualization) and the HU mode (e.g., device virtualization), whereas the hypervisor plane is located solely in the HK mode. Whenever a VM exit occurs, the hardware first switches the CPU control flow to the in-kernel VM plane. Most VM exits can be handled directly in the HK mode without switching to the user-mode helper. For instance, in the case of a stage-2 page fault (#S2PF), the hypervisor plane obtains a physical page, and the in-kernel VM plane inserts a new address mapping to the VM’s stage-2 page table before resuming the VM directly. However, other VM exits, such as some Memory-Mapped I/O (MMIO) trapings, cannot be entirely resolved by the in-kernel VM plane and must be forwarded to the user-level helper for emulation.

### 2.2 Vulnerabilities of Hypervisors

In contrast to the user-mode helper, which features a clear isolation boundary with the kernel, vulnerabilities arising from the in-kernel components of hypervisors pose significantly more severe threats to the host kernel. This is due to the fact that these components possess the highest level of privilege and interact directly and most frequently with VMs during runtime, thereby exposing a greater number of attack surfaces to VMs. The in-kernel components of hypervisors have accumulated a considerable number of publicly revealed vulnerabilities, underscoring their weak security and fault isolation. While there are also many vulnerabilities in the non-hypervisor components of the host kernel, this paper primarily focuses on hypervisor vulnerabilities, with non-hypervisor vulnerabilities being discussed in §7 and §9. Table 1 presents the statistics of disclosed vulnerabilities in KVM [22] and Xen [38], highlighting three key characteris-

**Table 2: CVE classification based on subsystems of KVM.** The data excludes 31 CVEs in the *Other* column of Table 1 that do not harm the host kernel. *Original* represents the original number of host-attacking CVEs in the KVM. *After Offload* means the number of host-attacking CVEs that remain in HK mode after offloading most components to HU mode by existing works [87, 91].

|                  | Subsystem                 | Number of CVEs |               |
|------------------|---------------------------|----------------|---------------|
|                  |                           | Original       | After Offload |
| VM Plane         | Memory Virtualization     | 10             | 2             |
|                  | Interrupt Virtualization  | 18             | 18            |
|                  | ISA Emulation             | 19             | 10            |
|                  | Para-Virtualization       | 4              | 0             |
|                  | VM Exit Handling          | 17             | 17            |
|                  | Device Virtualization     | 12             | 0             |
| Hypervisor Plane | Hypervisor Initialization | 0              | -             |
|                  | Resource Control          | 0              | -             |
|                  | Emergency Handling        | 0              | -             |

tics of the vulnerabilities in the in-kernel components.

- **Large Vulnerability Quantity.** There are 111 and 370 disclosed CVEs in KVM and Xen, respectively. 72.07% and 80.81% of them cause kernel-level exploits, including information leakage, host DoS [10, 16, 84], and privilege escalation of a guest VM [3, 12, 13, 27, 82, 86].
- **Severe Security Threats.** Due to the high privilege of in-kernel components, their vulnerabilities can easily crash the entire system, disrupting the execution of other co-located VMs. As shown in Table 1, 65.77% and 75.68% of CVEs (i.e., PE and DoS) in KVM and Xen, respectively, can be exploited to launch DoS attacks via vulnerabilities such as NULL pointer dereferences [17] or out-of-bounds reads/writes [15]. Even worse, carefully crafted exploits may enable attackers to escalate a VM’s privilege and compromise the entire system, including all other VMs.
- **Low Exploit Costs.** CVE exploits can be researched and crafted at relatively low costs by well-financed experts who are motivated by the significant profit potential of successful attacks. For instance, it took just two months for a Google expert to develop an exploit that enabled VM escape via a vulnerability in KVM code [3].

### 2.3 Limitations of Deprivileged Execution

A long line of work has attempted to deprivilege the in-kernel functionalities of hypervisors to mitigate the threats of vulnerabilities in existing hypervisors [46, 80, 87, 91]. For example, NOVA [87] builds a microhypervisor based on the microkernel architecture. DeHype [91] endeavors to demote most parts of KVM into user mode while leaving a HypLet in kernel mode because the sensitive hardware virtualization instructions can only be executed in this mode. However, such deprivileged execution methods have two limitations:

**Non-eliminable In-kernel Vulnerabilities.** We investigated the 80 host-attacking CVEs of KVM from Table 1 and identified the subsystems in which they are present. As

**Table 3: Breakdown of the latency of handling an MMIO read in QEMU/KVM on ARM, RISC-V and x86-64.** *Kernel* represents the cycles spent on the in-kernel transfer operations. *User* stands for the cycles consumed by the I/O emulation and VM entry/exit.

| Platform | Kernel | User  | Total |
|----------|--------|-------|-------|
| ARM      | 4,323  | 1,596 | 5,919 |
| RISC-V   | 3,135  | 4,067 | 7,202 |
| x86-64   | 2,415  | 1,704 | 4,119 |

shown in the *Original* column of Table 2, these CVEs are distributed throughout all VM-plane subsystems, whereas none of them exist in the hypervisor plane. We further examined whether these CVEs could be addressed by prior works [87, 91] that attempted to offload as many VM-plane components as possible to user space. The CVE number that remains in the host kernel after offloading is displayed in the right-most column of Table 2. Unfortunately, the majority (58.75%) of CVEs cannot be eliminated because the VM-plane subsystems in which they reside must operate in the HK mode due to hardware privilege restrictions. For example, the interrupt virtualization subsystem accesses privileged registers, so it must remain in the HK mode. Similarly, some memory virtualization functions, particularly those configuring sensitive stage-2 page tables for VMs, must also remain in the HK mode. As a result, the in-kernel VM plane poses entrenched security and reliability risks to the host kernel.

**Redundant and Costly Mode Switching.** Because the hypervisor must use the kernel component to drive the hardware virtualization extension, moving most of the kernel component to user space will result in more frequent and expensive interactions between the VM and the user-level hypervisor due to the kernel’s involvement, leading to higher performance overhead. To understand the cost associated with kernel involvement, we break down the handling procedure of an MMIO read operation in QEMU/KVM to illustrate the VM-VMM communication cost and find that 73.04%, 43.53%, and 58.63% of CPU cycles are consumed by in-kernel transfer operations on ARM, RISC-V, and x86-64, respectively (Table 3). As a result, minimizing the host kernel part by delegating more kernel functions to user space [87, 91] will lead to significant performance overhead due to the expensive VM-VMM communication costs on each VM exit handling.

## 3 System Design Overview

In this paper, we introduce **delegated virtualization** to safeguard the overall security and reliability of virtualization systems by preventing compromised hypervisor components from directly breaching the host kernel. To circumvent the privilege restrictions of existing hardware virtualization, delegated virtualization simply exposes the existing virtualization interfaces to user mode without requiring intrusive hardware modifications. We explicitly decouple the VM plane from the hypervisor plane and offload all VM-plane func-

**Figure 2: The architecture overview of DuVisor.** *DV-Ext* is Delegated Virtualization Extension.

tions to the user-mode DuVisor. A tiny DV-driver in the host kernel serves as the hypervisor plane, which is removed from all runtime interactions (VM plane) between DuVisor and its VM.

The design of delegated virtualization offers two significant advantages. First, it minimizes the attack surface of the host kernel’s hypervisor components accessible to VMs and confines hypervisor vulnerabilities to user space, largely improving security and fault isolation between the VMs and the host kernel. Furthermore, the security and reliability benefits are obtained without any performance penalty due to the direct runtime interactions between a guest and its hypervisor.

The architecture of delegated virtualization, as depicted in Figure 2, comprises three primary components: the Delegated Virtualization Extension (DV-Ext), per-VM DuVisor hypervisor processes, and a global DV-driver in the kernel.

The Delegated Virtualization Extension (DV-Ext) must be installed on the hardware (§4). It empowers the host kernel to determine whether or not to delegate hardware virtualization functions to HU mode. If the delegated mode is enabled, the hardware virtualization interface can be accessed by unprivileged software without trapping into the host kernel. If it is not enabled, DV-Ext functions similarly to traditional hardware virtualization for compatibility.

An HU-mode DuVisor process leverages the hardware interface exposed by DV-Ext to control an unmodified VM (§5). To support the normal execution of a VM, DuVisor dynamically virtualizes physical resources to handle runtime VM exits. In this paper, this workflow is defined as the VM plane and is handled by the DuVisor process in HU mode. Moreover, to support memory virtualization in HU mode, the DuVisor process builds a stage-2 page table for its VM. If stage-2 page faults occur due to missing or illegal page mappings, DuVisor dynamically adds or updates mapping entries in the stage-2 page table. Like conventional hypervisors, DuVisor spawns distinct user-level threads for each vCPU, referred to as *vthreads*. It also supports PV I/O devices and virtual interrupts (including timers) for this VM. DuVisor can depend not only on the host kernel to manage external de-

**Table 4: The registers and instructions added (or modified) by DV-Ext.** The lowercase and uppercase names stand for registers and instructions. The registers starting with “hu” are accessible in HU mode while those starting with “h” can only be accessed in HK mode. The two instructions can be invoked in HU mode.

| Type         | Mode    | Name                                    | Description                             |
|--------------|---------|-----------------------------------------|-----------------------------------------|
| Registers    | HU      | hu_er                                   | VM exit reason                          |
|              |         | hu_einfo                                | Additional information about a VM exit  |
|              |         | hu_vpc                                  | IP address of a faulted vCPU            |
|              |         | hu_ehb                                  | Base address of the VM exit handler     |
|              |         | hu_vcpuid                               | The vCPU ID running on a physical core  |
|              | hu_vitr | Virtual interrupt number to be inserted |                                         |
| Instructions | HU      | HURET                                   | Resume the vCPU execution               |
|              |         | HUFLUSHGPA                              | Flush TLB entries associated with a GPA |
|              |         | h_enable                                | Turn on DV-Ext                          |
| HK           | HK      | h_deleg                                 | Delegate VM exits to HU mode            |
|              |         | h_vmids                                 | The VM ID running on a physical core    |

vices like storage media and network cards but also control devices in HU mode by DPDK [18] to boost I/O virtualization.

A tiny DV-driver is inserted into the host kernel (§6) as the hypervisor plane, which occasionally participates in the management of physical resources for each DuVisor without interfering with runtime VM exits processing. Specifically, the DV-driver uses DV-Ext to enable/disable delegated mode and allocates resources (such as physical memory) for DuVisor processes. To mitigate security risks, it also restricts DuVisor’s physical memory view and handles emergencies, such as exceptions triggered by illegal physical memory accesses by untrusted VMs. DuVisor still relies on the host kernel to schedule all its threads and VMs.

**Assumptions and Threat Model.** We assume that the hardware (including DV-Ext) is correctly implemented and trusted. The goal of DuVisor is to defend the host kernel against malicious VMs, so that the host kernel and the DV-driver are trusted as well. However, in a multi-tenant cloud environment, a guest VM controlled by a hostile tenant may exploit vulnerabilities in DuVisor to compromise the hypervisor. Therefore, the user-level DuVisor process is considered untrusted by the host kernel. Side-channel attacks [73, 74] and corresponding defense methods [37, 45, 76] are orthogonal to the design of DuVisor and are not considered in this paper.

## 4 Delegated Virtualization Extension

In this section, we describe the design of DV-Ext, which lifts the restriction that hardware virtualization extensions are inaccessible to user mode. DV-Ext provides hardware interfaces to user-level DuVisor for obtaining VM information and controlling VM behaviors. These hardware interfaces can take different forms on varied hardware architectures. This section elaborates on register-based hardware interfaces as an example to present a detailed design of DV-Ext, which is suitable for the RISC-V and ARM architectures mentioned earlier. Additionally, we discuss the design of hardware interfaces based on memory and specialized instructions in §9 to

demonstrate DV-Ext’s universality. Table 4 shows the registers and instructions of DV-Ext.

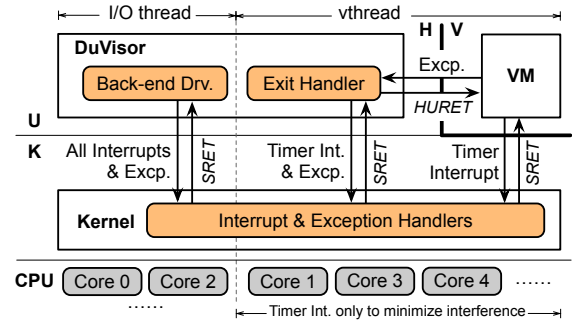

**HU-mode Registers and Instructions.** We observe that certain privileged registers are only configured during hypervisor initialization and are rarely accessed at runtime. Therefore, these registers can be considered hypervisor-plane registers and are not exposed to HU mode. The remaining registers, however, are frequently used during VM runtime and are defined as VM-plane registers. Accordingly, DV-Ext allows HU mode to access these registers without restriction.

VM-plane registers, as shown in Table 4, are denoted by names beginning with “*hu*”. They are accessible in HU mode when HK mode activates DV-Ext by setting up the *h\_enable* register. The VM-plane registers are classified into two categories. The first category records VM information for VM exits, such as *hu\_er* and *hu\_einfo*, which the hypervisor reads for handling VM exits. The second category controls the runtime behaviors of the hypervisor or VMs. For example, a hypervisor can configure *hu\_vitr* to inject a virtual interrupt to a vCPU.

**Delegatable VM Exits.** DV-Ext provides delegatable VM exits (DVE), which enables a VM to immediately trap to its DuVisor process in HU mode. The kernel mode can configure DVEs by modifying the *h\_deleg* register, whose individual bits regulate the delegation of specific types of VM exits. For instance, the DV-driver in HK mode can delegate stage-2 page faults and sensitive instruction faults such as WFI (i.e., wait-for-interrupt instruction for entering low-power standby CPU state, similar to HLT on x86) to HU mode by setting the corresponding bits in *h\_deleg*. When a DVE occurs, the hardware searches for a hypervisor handler using the address specified in *hu\_ehb*. DV-Ext additionally provides the *HURET* instruction for HU mode to resume VM execution after handling a DVE, and the entry point of the VM is stored in the *hu\_vpc* register.

**HU-mode Memory Virtualization.** Since the register storing the base address of a stage-2 page table is rarely modified after a VM is booted, DV-Ext does not expose it to HU mode. However, in HU mode, the user-level hypervisor can still freely update stage-2 translation by exposing the in-memory stage-2 page table to HU mode. Therefore, the page table format is consistent with the original stage-2 page table used in HK mode. As HU mode needs to flush TLB entries after updating stage-2 translation, DV-Ext exposes a TLB maintenance instruction to HU mode as the *HUFLUSHGPA* instruction, which can flush TLB entries associated with a specific GPA and VMID.

**Exitless Interrupt Virtualization.** Posted interrupt allows the hypervisor to deliver virtual interrupts to a running vCPU without VM exit. DV-Ext enables user-level posted interrupt that DuVisor can directly utilize for injecting virtual external interrupts in HU mode. DuVisor should specify the receiving vCPU’s VCPUID and the interrupt vector in *hu\_vitr*. Similarly, DV-Ext supports V-mode posted interrupt that a

**Figure 3: Exception and physical interrupt handling when running a DuVisor VM.** I/O threads and vthreads can be dynamically scheduled on different CPU cores. To minimize the involvement of the host kernel as well as the interference of physical interrupts, the DV-driver can configure those cores that run vthreads (e.g., core 1/3/4) to trigger solely timer interrupts. For other physical interrupts such as external interrupts generated by I/O devices, it is natural to route them to cores that run I/O threads of the backend drivers (e.g., core 0/2).

vCPU can issue a virtual inter-processor interrupt (IPI) without VM exit by configuring *hu\_vitr*. To prevent misdelivery, the hardware checks the VMID in *h\_vmids* and the VCPUID information pre-configured by the DV-driver before triggering a virtual interrupt. An illegal operand triggers a fault into HK mode to wake up the DV-driver. DV-Ext also adds virtual timer interrupts that can be triggered without VM exit.

## 5 DuVisor Design

### 5.1 Handling VM Exits

VM exits are caused by either exceptions or physical interrupts. In existing virtualization systems, all VM exits are trapped to the in-kernel hypervisor component for handling, but this is not the case in DuVisor. In contrast, all exceptions that result in VM exits are sent to the user-level DuVisor, while physical interrupts continue to be trapped and handled by the host kernel. It is inappropriate to direct physical interrupts to HU mode (DuVisor) due to their vital importance to the host kernel for tasks such as scheduling and device management, as HU mode is not trusted.

Figure 3 illustrates how exceptions and physical interrupts are handled when running a DuVisor VM. During the preparation of the VM execution environment, I/O threads of the backend driver and vthreads are scheduled to different CPU cores. After preparation, vthreads in DuVisor execute an *HURET* instruction to enter V mode and start running guest code until a VM exit occurs. For VM exits caused by synchronous exceptions, the CPU control flow directly traps from the VM to DuVisor’s VM exit handler. The handler then determines the exception type by accessing corresponding HU mode registers provided by DV-Ext. After handling the VM exit, the vthread resumes the VM by executing *HURET* again.

On the other hand, VM exits caused by physical interrupts

are directed to the interrupt handler in HK mode. To ensure that the register states of DuVisor VMs are not corrupted due to scheduling, the DV-driver saves all DV-Ext-related registers before handling the physical interrupt and restores them before directly returning to V mode with an *SRET* instruction. Due to the small number of DV-Ext-related registers, the performance impact from this additional save/restore logic is minimal (§8.4).

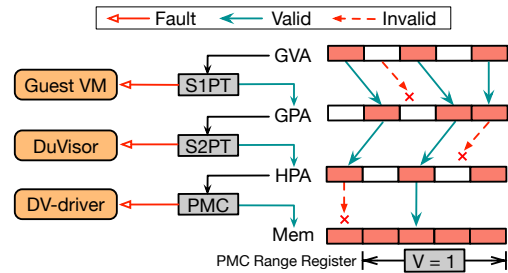

To minimize interference, we configure the DV-driver so that only physical timer interrupts periodically occur on cores where vthreads are running. For physical external interrupts generated by physical devices, a PV I/O device in DuVisor relies on the in-kernel device driver to handle them. Hence, it is natural to direct these external interrupts to the same cores as the I/O threads of the backend driver. Moreover, if IOMMU [29] is available, a physical device can be passthrough into the VM for better performance, which sends posted interrupts that directly inject physical external interrupts to the VM without VM exit. Additionally, there are few physical IPIs between vthreads and I/O threads, thanks to the exitless interrupt virtualization (§5.3). Therefore, only physical timer interrupts may periodically trigger on cores running vthreads and bring the running VM into HK mode.

## 5.2 Restricted Memory Virtualization

In contrast to traditional hypervisors' in-kernel stage-2 page table management, a DuVisor process handles stage-2 page faults and provides memory virtualization in HU mode without involving the kernel. To establish mappings of guest physical addresses (GPAs) for the VM, DuVisor populates stage-2 page table entries with host physical addresses (HPAs) in HU mode. Therefore, it requests the DV-driver to allocate contiguous memory regions with HPA information. Each stage-2 page fault traps to DuVisor, which then adds a free physical page from the pre-allocated memory region into the VM's GPA space by updating its stage-2 page table.

One natural challenge is how to prevent the untrusted DuVisor from maliciously configuring the stage-2 page table to access arbitrary HPA. A malicious DuVisor, for instance, may allow its VM to access (or alter) sensitive data in another VM's memory by directly mapping the attacker VM's GPA to the victim's HPA. Worse, the rogue VM can use this method to read and modify the host kernel memory. This issue can be addressed with a straightforward technique that requires DuVisor to manage a fake stage-2 page table instead of the real one. DuVisor only manages the fake stage-2 page table and must invoke system calls to ask the DV-driver to check this table and synchronize it to the real one. Although this method sounds reasonable, it frequently involves the kernel at runtime, leading to significant costs for memory-intensive workloads. Moreover, it complicates the memory management of the DV-driver.

We adopt an alternative approach, allowing DuVisor to manage the real stage-2 page table freely in HU mode

**Figure 4: The translation and checking procedure of a memory access request issued from the V mode.**

without entering kernel mode. Emerging hardware mechanisms, such as Intel TDX's Physical Address Metadata Table (PAMT) [47], AMD SEV-SNP's Reverse Mapping Table (RMP) [1], and ARM CCA's Granule Protection Table (GPT) [5], can dynamically restrict access to physical memory. Take RISC-V Physical Memory Protection (PMP) for example, it checks every memory access against up to 64 PMP entries configured on each core. Inspired by this, we propose to utilize such physical memory checking (PMC) mechanisms to limit the physical memory range that VMs can access.

With PMC, we can allow DuVisor to configure its stage-2 page table optimistically. The MMU automatically checks whether the target HPAs of the VM's memory accesses exceed the range limit of the pre-allocated physical memory regions. If so, the MMU triggers a fault to wake up the DV-driver. This design eliminates the stage-2 memory management module in the DV-driver. Furthermore, the overhead of dynamic checking is negligible since it is achieved by merely comparing offsets.

However, the current PMC technique is not specifically designed to restrict VM memory accesses. It examines every HPA access issued from the current physical core, which also restricts the host kernel and DuVisor from using physical addresses out of the configured entries. This is a significant constraint because the host OS can map the virtual addresses of the kernel and DuVisor to arbitrary physical memory addresses, which may exceed the ranges specified by the limited number of PMC regions. To overcome this constraint, DV-Ext extends the existing PMC mechanism slightly to make it work only for HPAs targeted by the V-mode memory accesses. DV-Ext adds a "Virtualization" (V) bit to each of the current PMC range registers. If the bit is set, the PMC only verifies the V-mode memory accesses according to the range registers.

Figure 4 illustrates how a guest virtual address (GVA) is translated into an HPA and finally reaches physical memory. The GVA is first translated into a GPA via MMU hardware according to the stage-1 page table (S1PT) built by the guest VM. Similarly, the GPA is translated into an HPA referring to the stage-2 page table controlled by DuVisor. A translation failure in the stage-2 page table triggers a stage-2 page fault into DuVisor for handling. Eventually, the PMC pre-

configured by the DV-driver checks the output HPA before accessing physical memory.

The DV-driver is responsible for allocating multiple physical memory regions for each VM, with each region being protected by a single PMP region. If the HPA exceeds the memory range specified by all PMP regions, the PMC will generate an exception and awaken the DV-driver to handle the situation. For example, the DV-driver may terminate the VM that triggered the exception and proceed to run other VMs. As the per-core PMP configurations are tied to a specific VM, the host kernel must save the PMP register values of the previous VM and install those of the next VM when switching between them.

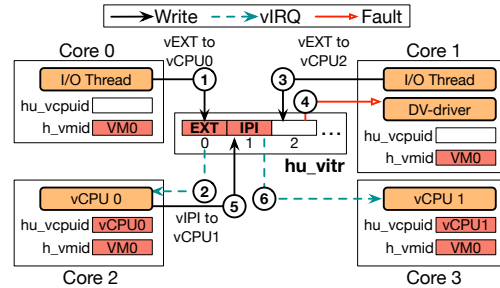

### 5.3 I/O and Interrupt Virtualization

I/O virtualization in DuVisor works similarly to existing approaches. It supports PV (e.g., virtio) and emulated (e.g., tty) I/O devices for its VM. Although DuVisor is compatible with passthrough devices, its current implementation does not support them due to the lack of IOMMU on the RISC-V platform. However, we can easily support them when IOMMU becomes available (§ 9).

For each PV and emulated device, DuVisor spawns dedicated I/O thread(s) during VM initialization. These threads are responsible for responding to VM I/O requests and interacting with host I/O devices. For instance, a TX thread is launched for a virtio network device’s TX queue to handle network packets from the guest VM. To reduce the kernel attack surface, DuVisor can be combined with kernel-bypass virtio backends such as vhost-user. In particular, the RX thread keeps polling the NIC in HU mode to receive incoming network packets and notifies the guest VM through virtual external interrupts (vEXTs).

To enable efficient PV I/O notifications, DV-Ext supports directly injecting vEXTs into a running VM through user-level posted interrupt. Posted interrupt is the most efficient mechanism for interrupt virtualization, which allows a virtual interrupt to be injected into a running VM without triggering VM exits. However, on existing hardware, a hypervisor must enter kernel mode to send a posted interrupt, which means that communications between vCPUs and between the HU-mode helper and its VM must go through the host kernel, contrary to the design principle of DuVisor. By contrast, the user-level posted interrupt in DV-Ext does not require kernel participation. Specifically, the I/O thread injects vEXTs by writing the interrupt vector to the posted interrupt register in HU mode. If the target vCPU is running on a core, DV-Ext immediately triggers the vEXT on that core. Otherwise, DV-Ext records the vEXT information and does not deliver it until the target vCPU resumes execution.

The DV-driver assigns a unique VMID to each DuVisor during initialization and writes this VMID to the per-core *h\_vmid* register every time a DuVisor is scheduled on a physical core. The VMID ensures that DuVisor’s I/O threads can

**Figure 5: Exitless interrupt virtualization with user-level posted interrupt and V-mode posted interrupt.** *vEXT* represents virtual external interrupt and *vIPI* represents virtual IPI.

only send posted interrupts to vCPUs with the same VMID as theirs. Since *h\_vmid* is only accessible in HK mode, the DuVisor process and the guest VM cannot modify its value. Each vCPU has its VCPUID, which the guest kernel writes to *hu\_vcpuid* during the boot process of each corresponding vCPU. The VCPUID is used by DV-Ext to identify the core on which the target vCPU is executing before delivering an interrupt.

Figure 5 depicts how a vEXT is delivered using user-level posted interrupts. For example, the I/O thread on core 0 attempts to insert a vEXT to vCPU 0 by writing the target vCPU’s associated location in *hu\_vitr* ①. DV-Ext then finds that vCPU 0 is executing on core 2 and generates a vEXT on core 2 ②. If the sending thread attempts to send a wrong VCPUID or has a different VMID from the receiver, writing to *hu\_vitr* will trigger a fault and wake up the DV-driver to handle this issue. For instance, the I/O thread on core 1 attempts to deliver a vEXT to a nonexistent vCPU 2 ③, and DV-Ext identifies this as an invalid operation and informs the DV-driver to handle the fault ④.

In addition to vEXTs, a multi-vCPU VM also requires efficient virtual IPIs (vIPIs) for inter-vCPU communications. To this end, DV-Ext supports V-mode posted interrupts that allow both sender and receiver vCPUs to incur no VM exit for a vIPI. Figure 5 also shows how a vIPI is generated using V-mode posted interrupts. The VMID and the VCPUID have the same effect as they do in user-level posted interrupt cases. Specifically, the vIPI issued from vCPU 0 on core 2 to vCPU 1 via writing *hu\_vitr* ⑤ is triggered by DV-Ext on core 3, where vCPU 1 is running ⑥.

Furthermore, virtual timer interrupts (vTimers) are necessary for each DuVisor VM. DV-Ext supports directly firing an expired vTimer inside the VM. Currently, a DuVisor VM can receive vTimers without VM exits, but it must trap to the DuVisor to set up timer events. Although the hardware can further remove the VM exits of setting timer events, we do not consider it necessary because the infrequent vTimers have little impact on VM performance.

## 6 Implementation

### 6.1 DV-Ext Implementation

We chose the RISC-V platform to implement DV-Ext because it has rich open-sourced implementations of system-on-chip (SoC). We used a 5-stage in-order scalar processor, specifically the RISC-V Rocket Core [34], with a configuration of 16KB L1 ICache, 16KB L1 DCache, 512KB shared L2 cache, and 16GB DRAM.

DV-Ext does not require intrusive modifications to the CPU hardware to implement these VM-plane registers and instructions. Specifically, *hu\_er*, *hu\_einfo*, *hu\_vpc*, and *hu\_ehb* are aliases of *ucause*, *utval*, *uepc*, and *utvec* from RISC-V N-Ext (i.e., the user-level interrupts extension), and *HURET* is implemented based on N-Ext’s *URET*. The *HU-FLUSHGPA* instruction is implemented by exposing H-Ext’s *HFENCE.GVMA* to the HU mode. Similarly, *h\_enable* and *h\_deleg* are implemented by extending H-Ext’s *hstatus*, *hideleg*, and *hedeleg*. Therefore, most architectural implementations for these registers and instructions can be reused. Only *hu\_vcpuid*, *hu\_vitr*, and *h\_vmid* are newly added registers for exitless interrupt virtualization.

Our DV-Ext implementation added 481 lines of Chisel to extend the existing H-Ext implementation [35] and support DVE. Additionally, we added 14 lines of Chisel to extend RISC-V PMP for VM memory restriction.

### 6.2 Software Implementation

Our prototype system of DuVisor consists of 7,128 LoC (5,052 lines of Rust, 166 lines of assembly, and 1,910 lines of C). The code of libraries we use is not included in the implementation effort. To implement the virtualization of CPU, memory and interrupt, 4,984 lines of Rust and 166 lines of assembly were written, in which the assembly is used to access architecture-dependent registers. For the virtualization of I/O devices, we ported the I/O backend of virtio block and virtio network devices from the *kvmtool* to DuVisor to reduce coding effort, accounting for 1,287 lines of C. We applied our design (e.g., the user-level posted interrupts) to these virtual devices as well as made some optimizations. Since there is no available DPDK support for RISC-V platforms currently, We also extended the virtio network backend with a user-space NIC driver using 623 lines of C to achieve a relatively fair performance comparison with KVM’s mature *vhost-net* backend. These I/O backend implementations comprise 1,910 lines of C in total.

We wrote a tiny Linux kernel module to work as the DV-driver and it has 337 LoC. DV-driver provides an *ioctl* system call for DuVisor to request several services. First, the DV-driver detects whether the hardware supports DV-Ext and enables it when a user process requests it. Second, it sets up the *h\_deleg* register to configure DVEs. Third, the DV-driver allocates contiguous physical memory regions for DuVisor from Linux’s contiguous memory allocator (CMA) and pins

**Table 5: CVEs in different KVM subsystems that can be successfully exploited in NOVA/DeHype and DuVisor’s architecture.** We omit 31 CVEs that cannot attack the host kernel.

| Subsystem                | KVM |           |    | NOVA/DeHype |           |    | DuVisor |          |    |

| Para-Virtualization      | 0   | 4         | 0  | 0           | 0         | 0  | 0       | 0        | 0  |
| VM Exit Handling         | 6   | 11        | 0  | 6           | 11        | 0  | 0       | 0        | 0  |
| Device Virtualization    | 5   | 4         | 3  | 0           | 0         | 0  | 0       | 0        | 0  |
| <b>Sum</b>               |     | <b>80</b> |    |             | <b>47</b> |    |         | <b>0</b> |    |

the physical memory regions to ensure their availability at runtime. Before returning to HU mode, the DV-driver also dives into the M-mode OpenSBI and configures the PMP entries to restrict the VM’s physical memory access range. Each PMP entry is set up with a *pmpcfg* register specifying the V bit and memory accessibility as well as a *pmpaddr* register recording the physical address and length. The host kernel should also have a PMP fault handler that terminates the fault process gracefully. Currently, our prototype does not implement such a fault handler for simplicity, but it is not hard to extend the existing exception handler to implement one. Lastly, the DV-driver initializes a VMID for each DuVisor process that will be used by interrupt virtualization.

Based on the Linux kernel which already switches the general purpose registers and V-mode CSRs, we further modified the context switch logic (74 LoC) to save and restore the DV-Ext registers if the process has enabled DV-Ext. If the next scheduled thread is not a vthread from the same VM, the PMP registers are also switched.

## 7 Security Analysis and Evaluation

In this section, we analyze the overall system security of DuVisor from the perspective of an attacker.

**Attack from Guest to Host Kernel.** A hostile VM can exploit vulnerabilities to compromise the hypervisor. If these vulnerabilities are exploited in kernel mode, the attacker can achieve VM escape, steal sensitive kernel data, and even crash the entire kernel. Table 5 shows such CVEs in different KVM subsystems and how many of them can be successfully exploited in NOVA [87]/DeHype [91] and DuVisor’s architecture. NOVA and DeHype, limited by hardware, cannot fully move these subsystems to user mode, thus still leaving 58.75% of the vulnerabilities undefended. In contrast, DuVisor has deprivileged all of these subsystems in HU mode, reducing the host kernel’s attack surface and preventing any of these CVEs from directly jeopardizing it.

Table 6 lists typical vulnerabilities that we evaluated on DuVisor. Their security and reliability threats are confined within the DuVisor processes. Therefore, they cannot harm the host kernel directly.

**Attack from Guest to DuVisor.** In theory, a malicious guest can exploit vulnerabilities to attack the user-level DuVisor. To enhance security, DuVisor is developed in Rust, a

**Table 6: Case studies of KVM CVEs.** This table lists 6 representative KVM CVEs that have the potential to disrupt the normal execution of the host kernel, resulting in DoS or even more severe attacks. To evaluate the impact of these CVEs on a system running DuVisor, we emulated the vulnerabilities in the corresponding subsystems of DuVisor. The results show that these CVEs only cause DuVisor itself to crash, while the host kernel can continue to execute other programs (including DuVisor VMs) correctly.

| CVE-*      | Attack Effect                                                                                                                                                                      |
|------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 2017-12188 | <b>Memory Virtualization:</b> KVM’s misconfiguration of the stage-2 page table allows the guest to access host memory, which can cause the host OS to crash or even be controlled. |
| 2018-16882 | <b>Interrupt Virtualization:</b> A use-after-free issue in the posted interrupt handling may allow hostile VMs to execute arbitrary code in HK mode.                               |
| 2016-8630  | <b>ISA Emulation:</b> Improper implementation for instruction decoding of KVM may cause host kernel crashes and jeopardize the availability of the host OS.                        |
| 2020-8834  | <b>VM Exit Handling:</b> KVM’s imperfect isolation of the guest states allows malicious VMs to corrupt the stack and destroy the availability of the entire system.                |
| 2016-5412  | <b>Para-Virtualization:</b> The incorrect implementation of a hypercall in KVM could lead to an infinite loop that crashes the host kernel.                                        |
| 2019-6974  | <b>Device Virtualization:</b> A use-after-free vulnerability in device virtualization may lead to VM escape in the kernel.                                                         |

high-performance language that guarantees memory safety and thread safety. This greatly reduces the security risks associated with memory vulnerabilities [6, 7, 9, 12, 14] and threading vulnerabilities [8, 11, 14], such as the use-after-free bugs [9, 12] in traditional hypervisors written in C/C++. In addition, a vulnerable DuVisor can be promptly patched in user space without rebooting the host OS.

**Attack from DuVisor to Host Kernel.** Although the DuVisor design prevents a malicious VM from directly compromising the host kernel through the in-kernel hypervisor component, the VM may still attempt to attack the host kernel after controlling the DuVisor. Various existing techniques can be leveraged to defend against such user-level attacks, which are orthogonal to the DuVisor design. The static resource allocation and vhost-user devices in DuVisor significantly reduce the system calls. For example, DuVisor only requires 17 system calls to serve a Linux VM at runtime. Therefore, the kernel can use seccomp [24] to effectively restrict the system calls and their parameters that a DuVisor can invoke at runtime. The host kernel can also be reconstructed as a microkernel to improve its isolation, although this is beyond the scope of this paper.

Furthermore, neither the DV-driver nor the DV-Ext interface gives DuVisor additional capabilities to compromise the host kernel. First, the DV-driver has a small enough code base that it could be formally verified. Second, although the DV-driver allows user-level processes to request physical memory, it can still effectively isolate them with the help of the dynamic PMC mechanism. Third, the registers and instructions introduced by DV-Ext cannot be exploited by user-level code to attack the kernel. The *hu\_er* and *hu\_einfo* registers provide information related to DVE and do not leak any data from the host kernel. The *hu\_vitr*, *hu\_vcpuid*, *hu\_vpc*, and *hu\_ehb* reg-

isters, as well as *HUFLUSHGPA*, only control VM behaviors and have no effect on the host kernel. The *HURET* instruction and DVE implement mode switches between the HU mode and a VM, but cannot directly enter the HK mode.

## 8 Performance Evaluation

We answer the following four questions in this section:

**Q1:** How does the DuVisor compare to the KVM/QEMU in terms of hypervisor primitive cost? (§8.2)

**Q2:** How does the performance of applications running on DuVisor compare to that of KVM/QEMU? (§8.3)

**Q3:** What is the performance impact of DV-Ext on the co-located KVM/QEMU that does not use this extension? (§8.4)

**Q4:** How much performance impact does the extended PMP mechanism have on DuVisor’s performance? (§8.5)

### 8.1 Experimental Setup

We ran experiments on the cycle-accurate FireSim platform [59], which consists of two FPGA boards. Each FPGA board has eight RISC-V processors (3.2GHz, rv64imafdch), 16GB RAM, and 115GB storage. We created a local area network (LAN) between the two boards using 1Gbps IceNICs for network-related benchmarks. Both FPGA boards were controlled by an EC2 instance running CentOS 7.6.1810 on a 16-core Intel E5-2686 v4 CPU (2.3 GHz) and 240 GB RAM. We used OpenSBI v0.8 [31] as the firmware for RISC-V, and used Linux kernel 5.10.26 as the host kernel, which was equipped with the DV-driver. The baseline is KVM [23] (with H-Ext [35] support) and *QEMU* v7.0.0-rc0 running on Linux 5.16.

For **Q1** and **Q2**, posted interrupts can greatly improve the performance in interrupt-intensive scenarios, but the current open-sourced RISC-V hardware does not support this feature. To make a fair performance comparison, we extended DV-Ext’s interrupt virtualization support to the kernel level and implemented an optimized KVM/QEMU (“**KVM-OPT**”) that enables kernel-level posted interrupts. To answer **Q3**, we compared KVM with a slightly modified KVM (“**KVM-DVext**”) that was patched with context save/restore code related to DV-Ext and virtualization registers. For **Q4**, we compared DuVisor with a PMP-less version (“**DuVisor-noPMP**”) that removes PMP checking from the hardware.

### 8.2 Microbenchmarks

In this section, we quantify the performance of five frequently used hypervisor primitives. We leveraged the *cycle* CSR to measure CPU cycles. Figure 6 shows the average cost of the five operations in KVM and DuVisor. We calculated the average cycle count after recording the total time spent performing each operation 10,000 times. For three synchronous exceptions, we only compared DuVisor with KVM because there is no difference between KVM and KVM-OPT when interrupt virtualization is not involved. For the other two asynchronous exceptions, results of KVM, KVM-OPT

**Figure 6: Breakdown of different hypervisor primitives (Unit: cycles).** (a) shows a *null* hypercall. *Exit*: from invoking a hypercall in the guest VM to arriving at the hypercall handler in the hypervisor. *Entry*: the reverse procedure of *Exit*. *Handling*: processing in the hypercall handler. (b) shows a stage-2 page fault handling. *Entry/Exit*: from triggering a stage-2 page fault in the VM to arriving at the #S2PF handler, and the reverse procedure. *GetPage*: getting the available physical page for the fault GPA. *Mapping*: the PTE update in the stage-2 page table. *Metadata*: maintaining the metadata of the physical page to be mapped. *Other*: other logic such as lock protections and fault GPA checking. (c) shows an MMIO emulation. *Entry/Exit*: from invoking an MMIO operation in the VM to arriving at the user-space MMIO handler, and the reverse procedure. *Transfer*: transfers between the kernel in HK mode and the user-space VMM in HU mode, which DuVisor gets rid of. *Decode*: decoding the corresponding virtual MMIO device according to the fault address. *Other*: other logic, such as checking if the fault address belongs to the MMIO address range. (d) shows a virtual IPI sending. *vIPI Insert*: For KVM, from the hypervisor inserting the virtual IPI and kicking the receiver vCPU to the receiver vCPU's arriving at the IPI handler. For KVM-OPT and DuVisor, from the sender vCPU's writing *hu\_vitr* register to the receiver vCPU's arriving at the IPI handler. *Exit*: Only for KVM, from the sender vCPU's invoking *SEND\_IPI* hypercall to the hypervisor's insertion, and from the receiver vCPU's being kicked to it being inserted with the pending virtual IPI. (e) shows an I/O notification sending. *vEXT Insert*: For KVM-OPT and DuVisor, from the I/O thread's writing *hu\_vitr* register to the vCPU thread's arriving at the IRQ handler. For KVM, from the I/O thread invoking the *SET\_INTERRUPT* interface to the receiver vCPU's arriving at the IPI handler.

and DuVisor are shown.

In the hypercall microbenchmark, both KVM and DuVisor ran a guest VM with a single vCPU pinned to a pCPU. The guest VM invoked a *null* hypercall, which trapped to the hypercall handler and then returned immediately without doing any functional operations. The number of cycles between the start of the hypercall and its return position was counted. As shown in Figure 6-a, DuVisor consumes 65.37% (404 cycles) less time during the hypercall procedure than KVM. This is because DuVisor in the user space does not need to perform operations that are only necessary in the kernel (e.g., enabling and disabling preemption and interrupts).

For stage-2 page fault handling, each hypervisor ran a guest VM with a single vCPU pinned to a pCPU. The guest VM read one byte from a page unmapped in the stage-2 page table, triggering a stage-2 page fault exception trapped to the hypervisor. The hypervisor allocated memory and established a valid mapping in the stage-2 page table before resuming the vCPU execution. We collected cycles before and after the guest VM read. As shown in Figure 6-b, DuVisor spends about 89.06% (5,650 cycles) less time compared with KVM. The main reason for the decreased cycles is that the KVM implementation is generic but more complex, whereas DuVisor can choose a dedicated but more concise implementation. According to our breakdown of the stage-2 page fault handling in KVM, most of the time is spent on getting the available physical page for the guest fault address, accounting for about 59.52% (3,776 cycles) of the total time as the *GetPage* part shows. Similarly, the *Other* and *Metadata* parts in KVM account for 23.31% (1,479 cycles) of the whole process, consisting of many generic Linux kernel logic, such as finding *virtual memory area (VMA)*, taking locks of *mmap* and maintaining metadata in Linux page structures. In com-

parison, DuVisor only spends 26 cycles in the *GetPage* part and 324 cycles in the *Other* and *Metadata* part.

For MMIO emulation, a single-vCPU guest VM pinned to a pCPU performed a load operation from an MMIO address of a virtual console device, which trapped to the user-level hypervisor and immediately returns. We counted the elapsed cycles of the MMIO read operation. The result shows that DuVisor takes 89.62% (4,264 cycles) less time than KVM primarily due to the shorter path of MMIO handling as shown in Figure 6-c. Traditional hypervisors such as KVM offload most MMIO emulations to user mode for security and reliability, which leads to a longer path than DuVisor. The breakdown shows that 65.89% (3,135 cycles) of the time during the MMIO emulation in KVM is spent on multiple world switches: VM(V)  $\leftrightarrow$  KVM(HK)  $\leftrightarrow$  QEMU(HU).

For vIPIs, both KVM and DuVisor ran a dual-vCPU guest VM and pin two vCPUs to separate cores. The sender vCPU sent an IPI and waited for the ACK from the receiver vCPU by polling on the shared memory, while the receiver vCPU wrote to the shared memory as soon as entering the IPI handler to inform the sender. We calculated the cycles on the sender vCPU from sending IPI to getting ACK from the shared memory. Figure 6-d shows the results. Since both KVM-OPT and DuVisor leverage hardware posted interrupt support, their virtual IPI processes are done without hypervisor involvement and thus equally cost 147 cycles. In contrast, the KVM spends 4,692 cycles on sending a vIPI. To send an IPI, the sender vCPU has to invoke a hypercall and trap to the KVM (*Exit* part), which occupies 11.83% of the total cost. While the rest 88.17% is cost by the cumbersome *vIPI Insert* part, in which the hypervisor sends the vIPI request, kicks the receiver vCPU, and inserts the vIPI before resuming the receiver vCPU.

For virtual external interrupts, a single-vCPU guest VM pinned to a pCPU spun and waited for external interrupts. We calculated the average consumed cycles from the hypervisor inserting a virtual external interrupt to the vCPU acknowledging the inserted interrupt in the interrupt handler. Using the same hardware posted interrupt support, both KVM-OPT and DuVisor averagely spend 184 cycles. While KVM needs 4,084 cycles in total due to the long emulation processes, such as kicking the vCPU.

### 8.3 Application Benchmarks

**Table 7: Descriptions of application benchmarks.**

| Name      | Description                                                                                                                                                                                                             |
|-----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Netperf   | Netserver v2.6.0 on the local server (guest VM) and Netperf v2.6.0 on the remote client (native) to test the TCP stream throughput for 5 seconds.                                                                       |
| iperf3    | iperf v3.9 on both the local server (guest VM) and the remote client (native) to test the TCP throughput for 10 seconds.                                                                                                |
| Memcached | Memcached v1.6.10 running the memtier benchmark 1.3.0 on the remote client to test transactions per second. The thread number is set to the same as the number of server vCPUs. Each round of the test lasts 5 seconds. |
| Hackbench | Hackbench using Unix domain sockets and default 10 process groups running in 100 loops, measuring the time cost.                                                                                                        |
| CPUPrime  | CPU test in sysbench v0.4.12 that calculates prime numbers up to the max prime 10000. The thread number is set to the same as the number of server CPUs.                                                                |

In this section, we evaluated the performance of five application benchmarks described in Table 7, compared KVM-OPT and DuVisor’s results with native, and analyzed the reasons for the performance differences. We ran the benchmark in three VMs with 1, 2 and 4 vCPUs, respectively. Every VM was equipped with 512MB memory, a virtio-based network device, and a virtio-based block device. In each case, we assigned the same number of CPUs and memory size to native as to VMs via *maxcpus* and *mem* using the kernel command line. To demonstrate the best performance of the in-kernel KVM, we used vhost-net as the network backend of the KVM-OPT VMs. For DuVisor VMs, we implemented a lightweight user-space network backend driver by porting *ixy* [51], a 1,000-LoC user-space ixgbe driver, to FireSim’s IceNet. Each vCPU and I/O thread of a guest VM was pinned to a separate physical CPU to avoid instability caused by the host kernel scheduler. All applications were evaluated after warmup to eliminate stage-2 page faults during benchmarks.

As shown in Figure 7-a and Figure 7-b, both KVM-OPT and DuVisor make full use of the NIC’s bandwidth with different vCPU numbers and have no significant overhead compared to native. Because KVM-OPT and DuVisor used different network backends, their performance when running network-intensive applications can vary due to backend implementations. Nevertheless, what we intend to demonstrate is that DuVisor can attain comparable performance to KVM-OPT’s mature vhost-net with a simply-implemented user-space network backend. For the network-intensive memcached application shown in Figure 7-c, DuVisor has a similar performance to KVM-OPT. However, they introduce up to 35% virtualization overhead when compared with the native. According to our analysis, the reasons for the perfor-

mance degradation mainly consist of the longer network data transfer path and the sub-optimal frontend/backend notifications. Massive small memcached requests travel longer than native before reaching the memcached in VMs due to the I/O virtualization. Besides, guest VMs’ interrupt frequency during the benchmark is much higher than that of the native due to the frequent notifications from the backend drivers, making memcached threads in VMs have less CPU time to process requests. We also compared QEMU/KVM with native on Intel and ARM platforms with similar configurations and find that they also introduce 15% to 40% overhead.

As shown in Figure 7-d, DuVisor is also comparable to KVM-OPT and native for hackbench. It is worth noting that KVM, which did not use the hardware interrupt virtualization, will incur about 12% more overhead in this experiment. The reason is that many IPIs are generated under this test, and the virtual IPI operation can be effectively accelerated by the posted interrupt, as shown in Figure 6-d. This also explains why DuVisor’s better microbenchmark performance results in no better application performance than KVM-OPT. Infrequent VM exits in DuVisor and KVM-OPT result in very low costs for hypervisor primitives (<5% CPU cycles), which are hardly observable in application benchmarks. Figure 7-e indicates that KVM-OPT and DuVisor attain the same performance as native execution in the CPUPrime benchmark.

As a result, the design of DuVisor does not introduce performance overhead compared with KVM-OPT, while achieving better host kernel security and reliability.

### 8.4 Impact on Co-located KVM VMs

When co-locating a traditional in-kernel hypervisor together with a user-level hypervisor, both hypervisors can independently configure registers related to virtualization, which can lead to VM state conflicts if not handled properly. Therefore, the host kernel needs to save and restore virtualization-related registers during context switches between them, introducing additional switching latency. To clarify how much impact such delay has on KVM, we evaluated and compared the application performance of KVM and KVM-DVext (with necessary context save/restore code). Figure 8 shows that there is no discernible performance difference between KVM and KVM-DVext, indicating that such additional switching latency due to DuVisor’s co-location has little impact on traditional VMs.

### 8.5 Memory Virtualization Overhead

**Scaling Memory:** To show DuVisor’s memory scalability compared with KVM-OPT, we ran memcached in a 4-vCPU guest VM with 512MB, 1024MB, 1536MB and 2048MB memory. As shown in Figure 9-a, DuVisor achieves almost the same performance as KVM-OPT in all cases. Compared with KVM-OPT, the memory virtualization of DuVisor differs only in that it places the stage-2 page table configuration in the user space and extends PMP for security checks. There-

**Figure 7: Normalized VM performance of real-world applications running in KVM-OPT and DuVisor.** The Y-axis is the normalized overhead compared with the corresponding native environment. Error bars are added due to the performance fluctuation.

**Figure 8: Normalized performance overhead of real-world applications of KVM-DVext compared with KVM.**

fore, there is little impact on the memory access latency and thus scales well as the memory size grows.

**Impact of PMP:** DuVisor slightly extends the PMP hardware with a V bit to verify the validity of memory accesses from guest VMs. To evaluate whether this memory protection mechanism degrades the memory performance of the VM, we compared the memory test results of *lmbench* between DuVisor and DuVisor-noPMP in a dual-vCPU VM with 512MB memory. As shown in Figure 9-b, the memory bandwidth of the VM is almost the same with and without PMP checking. The result shows that the design of PMC does not introduce significant overhead to VMs.

**Figure 9: Performance of DuVisor's memory virtualization.** (a) DuVisor's normalized overhead of different sizes of memory compared with KVM-OPT using memcached. (b) DuVisor's memory performance w/ and w/o PMC using *bw\_mem* of *lmbench*.

## 9 Discussion and Limitations

**Nested Virtualization.** In traditional nested virtualization [41, 71, 77, 92], VM exits are intercepted by the L0 hypervisor (bare-metal one) before being handled by the L1 hypervisor (nested one), incurring tremendous runtime overhead. Prior work [72] optimizes nested VM exits via paravirtualization and passthrough. In the future, we plan to extend the idea of DVE to optimize nested virtualization by directly trapping VM exits to the L1 hypervisor.

**Memory Utilization.** DuVisor's PMP-based memory virtualization may lead to low memory utilization. To cover all VM memory with a limited number of PMP regions, we use the coarse-grained physical memory protection that can result in memory fragmentation and scalability issues. Addi-

tionally, it is difficult to support memory multiplexing (e.g., deduplication and overcommitment) among VMs based on PMP. Fortunately, such limitations can be mitigated by memory migration software mechanisms [65]. They can also be resolved through scalable fine-grained memory protection hardware mechanisms. For example, the RISC-V PMP table [25] has been proposed recently, which extends PMP to support physical memory restriction in page granularity.

**IOMMU Support.** Although IOMMU [29] is not yet supported on currently available RISC-V hardware, DuVisor is theoretically able to support it. Specifically, the stage-2 page table of IOMMU can be directly controlled by DuVisor, as the DV-driver can restrict access from guest devices by the IOPMP mechanism [30] with the V bit introduced by DV-Ext. The passthrough of the guest devices and the management of IOMMU's stage-1 page table within VMs is no different from traditional virtualization.

**DV-Ext Universality.** While the current prototype is implemented on RISC-V platforms, applying DV-Ext to other architectures would also be feasible, as they all share the same high-level virtualization functions. Consider Intel VMX hardware virtualization as an example.

*CPU virtualization:* Intel VMX directs all VM exits to the host kernel mode, and guest states in the in-memory VMCS can only be obtained and configured with the kernel-only VMREAD and VMWRITE instructions. To apply DV-Ext, Intel can just take VM exits and expose such VMX instructions to the DuVisor in the host user mode, while preventing access to host states (e.g., host CR3) in the VMCS.

*Memory virtualization:* The stage-2 page tables can be managed by the user-mode DuVisor without hardware modifications. However, PMP-like primitives are also necessary to enforce security. Fortunately, such hardware has emerged with confidential VM extensions [1, 21, 64, 69]. To apply DV-Ext, Intel can extend existing TDX's Physical Address Metadata Table (PAMT) [47] to provide fine-grained physical memory protection for DuVisor.

*Interrupt virtualization:* Intel can expose VMCS fields related to virtual interrupts to the DuVisor to deliver virtual interrupts. Specifically, virtual interrupts can be issued in user space by writing the VMCS with the user-mode VMX instructions mentioned above.

**Host Kernel Vulnerability.** Although DuVisor minimizes the attack surfaces of in-kernel hypervisors that are exposed to VMs, it does not completely exclude the host kernel from the VMs' runtime. Resource management (e.g., schedul-

ing and physical interrupt handling) involves non-hypervisor components in the host kernel, which may still contain many vulnerabilities, especially in mainstream monolithic kernels. Consequently, DuVisor is still vulnerable to the vulnerabilities of non-hypervisor components. Reconstructing it as microkernels may mitigate the problem, however, there are tradeoffs among compatibility, performance, and security.

## 10 Related Work

**Moving Kernel Functions to Userspace.** Deprivileging kernel features to userspace is a classic approach to enhance security, ease development, and improve performance. Microkernel is one typical design [52,62,70,78], where system services such as file systems and drivers run in user mode. For monolithic kernels, similar methods also exist, which implement the file systems [50,79], scheduler [57], network service [75] and sandbox [53] in user space. In terms of hypervisor functions, research focuses on reducing the hypervisor TCB by moving some of its functions to userspace, as demonstrated by designs such as DeHype [91] and NOVA [87]. Unlike DuVisor, they still require an in-kernel trusted module to perform VM-plane functions via hardware virtualization interfaces. DuVisor is the first system that entirely moves runtime VM-plane functions to user space, benefiting virtualization architectures on both monolithic kernels [40,61] and microkernels [55].

**Securing VMs.** Apart from the above solutions, many other studies have investigated how to achieve better isolation for VMs atop unreliable hypervisors. Numerous efforts have focused on reducing the hypervisor TCB [66,81,85,92]. CloudVisor [92] leverages nested virtualization to deprivilege the Xen [40] hypervisor. HypSec [66] separates a tiny CoreVisor as TCB from the KVM hypervisor. Other approaches have worked on hardening the hypervisor TCB, such as SeKVM [67,68], which use formal verification to ensure security guarantees of hypervisors. Unlike DuVisor, these solutions still rely on in-kernel hardware virtualization interfaces and incur modest performance overhead compared to unmodified traditional hypervisors.

Some solutions improve hypervisor reliability by providing per-VM hypervisor instances that are isolated from each other. Nexen [84] deconstructs the hypervisor into per-VM non-privileged service slices. HyperLock [90] decomposes the hypervisor into isolated shadow copies for each VM. In contrast to DuVisor, they still rely on traditional hardware virtualization interfaces and suffer from performance penalties of software isolation mechanisms. Others propose hardware extensions to remove the vulnerable hypervisor from the TCB [39,58,60,66,89]. NoHype [60] eliminates the hypervisor and its attack surfaces by static partitioning physical resources with hardware modifications. Nonetheless, it disallows resource oversubscription and is thus impractical for deployment in production scenarios.

Industrial confidential virtual machine (CVM) solutions,

such as AMD SEV-SNP [1] and ARM CCA [5,69], leverage specialized hardware security extensions to protect the data of VMs against a malicious hypervisor, which cannot access or taint the memory and registers of VMs. Both CVMs and DuVisor are vulnerable to non-hypervisor DoS attacks because they both rely on the host kernel. However, unlike CVMs, DuVisor can avoid DoS attacks due to in-kernel hypervisor vulnerabilities by deprivileging all VM-plane functions to user space to minimize the host kernel's runtime attack surfaces exposed to VMs. On the other hand, CVMs require guest OS device driver modifications, while DuVisor supports unmodified VMs.

CVM and DuVisor are orthogonal techniques that can be combined for greater benefits. The design of DuVisor can be applied to defend against DoS attacks due to in-kernel hypervisor vulnerabilities for CVMs, which we plan to explore as future work. Existing CVMs are controlled by the in-kernel hypervisor through secure firmware interfaces (e.g., ARM CCA's RMM and TF-A, Intel TDX module) that can only be invoked in the host kernel. DuVisor can be used alongside CVMs by exposing these interfaces to user space, thereby eliminating shared in-kernel hypervisor vulnerabilities.

## 11 Conclusion

We introduce the first delegated virtualization architecture that delegates all VM-plane virtualization functions to user space without trapping into the host kernel, minimizing attack surfaces exposed to VMs by in-kernel hypervisor components. To enable delegated virtualization, we present DV-Ext and DuVisor. DV-Ext is a hardware virtualization extension that securely exposes hardware virtualization interfaces to user space. DuVisor is a user-level hypervisor design that directly serves VM-hypervisor interactions in user space. We also present security techniques to prevent malicious use of DV-Ext. We have implemented a prototype for DV-Ext and DuVisor on the RISC-V platform. The security and performance evaluation results demonstrate that DuVisor protects the host kernel from hypervisor vulnerabilities without compromising performance compared to Linux KVM, establishing a new direction for secure virtualization research and development.

## 12 Acknowledgments

We express our sincere gratitude to our shepherd Jason Nieh for providing us with valuable suggestions that significantly helped in improving our paper. We thank the anonymous OSDI reviewers for their insightful suggestions. We are grateful to Yubin Xia and Rong Chen for their thorough and constructive comments that greatly improved this paper. We also thank Chenhui Ji and Yifan Tan for their contributions to the artifact evaluation. This work was supported in part by the National Natural Science Foundation of China (No. 62002218, 61925206, 62132014).

## A Artifact Appendix

### Abstract

The artifact evaluation of DuVisor contains two parts: the security evaluation and the performance evaluation. For security evaluation, we evaluate representative CVEs in the DuVisor on the QEMU-emulated RISC-V platform. For performance evaluation, we measure the performance of various microbenchmarks and application benchmarks on native, DuVisor, vanilla KVM and optimized KVM using the cycle-accurate FireSim platform.

### Scope

**Security Evaluation:** DuVisor is able to prevent host kernel from crashing even if the user-level VM-plane is attacked. As mentioned in the Table 6 of our paper, this artifact emulates 6 representative KVM CVEs and evaluates their impact on the system. The results can show that these CVEs could crash DuVisor itself, but the host kernel can continue to execute other programs (including DuVisor VMs) normally.

**Performance Evaluation:** DuVisor achieves higher security while also maintains comparable performance to the optimized KVM (i.e., KVM-OPT in our paper). As shown in Figure 7-10 of our paper, this artifact compares various benchmarks between DuVisor and KVM, and also evaluates the impact of DV-Ext hardware extension KVM.

The results can show that DuVisor performs good and DV-Ext has little impact on existing KVM.

## Contents

- **Run-time environment:** FireSim cycle-accurate FPGA platform based on AWS EC2 instances (two C5 and one F1)
- **Hardware:** QEMU (security AE) and RocketChip (performance AE)
- **Software:** OpenSBI, Linux, QEMU, DuVisor, related benchmarks
- **Metrics:** Benchmark results, usually latency and throughput
- **Estimated time:** about 20 hours with pre-built software images

- **Available on GitHub:** <https://github.com/IPADS-DuVisor/ae-guide/tree/main/>

## Hosting

The artifacts are available on the GitHub, please refer to the main branch of this guide: <https://github.com/IPADS-DuVisor/ae-guide/tree/main/>

## Requirements

Because the FireSim platform relies on special AWS FPGA (F1) instances, requiring multiple machines and complicated environment configurations. Besides, a newer version of FireSim platform may not be compatible with an older one. To simplify the AE procedure, we provided pre-configured AWS instances for reviewers.

# Core slicing: closing the gap between leaky confidential VMs and bare-metal cloud

## Abstract

Virtual machines are the basis of resource isolation in today’s public clouds, yet the security risks of entrusting that isolation to a cloud provider’s hypervisor are substantial. Such concerns have motivated hardware extensions for “confidential VMs” that seek to remove the hypervisor from the trusted computing base by adding a highly-privileged firmware layer that checks hypervisor actions, and supports memory encryption and remote attestation. However, the hypervisor retains control of resource management and observes associated guest actions including nested page table faults and CPU scheduling, and thus confidential VMs remain vulnerable to an ever-changing variety of hypervisor-level side channel attacks. Bare-metal cloud servers avoid such leaks, but remain a niche due to the high cost of dedicated hardware.

We observe that typical cloud VMs run with a static allocation of memory and discrete cores, and increasingly rely on I/O offload, thus negating the apparent need for a hypervisor and the fragile hypervisor/guest isolation boundary. Our design, *core slicing*, enables multiple untrusted guest OSes to run on shared bare-metal hardware. To ensure isolation without the complexity of virtualization, we propose simple hardware extensions that restrict guests to a static *slice* of a machine’s cores, memory and virtual I/O devices, and delegate resource allocation to a dedicated management slice. We demonstrate practicality and evaluate performance with prototypes for RISC-V and x86.

## 1 Introduction

We are in the early stages of a new generation of trusted execution environment (TEE). Motivated by cloud workloads, their main new feature is the ability to run “*confidential VMs*” inside the TEE [13, 17, 53]. Driven by the demand for secure cloud computing in which the user need not trust the cloud

provider [78], these TEEs are expected to see much wider adoption than their predecessors [50]. Although confidential VMs offer enhanced functionality, their security model and architecture are largely identical to earlier TEEs such as SGX. The user shares one or more processor cores with a powerful adversary who controls hardware resources. Processor extensions provide the TEE with private memory and a trusted “context switch” to prevent the administrator-adversary from directly breaking the confidentiality and integrity of the TEE.

However, the past decade has produced a broad and rapidly growing spectrum of attacks on this model [22, 25, 41, 44, 62, 65, 67, 68, 72, 82, 90, 98, 104, 110, 112–116], including the complete breakdown of SGX security on several occasions [112, 114, 115]. Most of these can be described as side-channel attacks. As §2.3 will describe, they take advantage of the fact that attacker and victim run on the same core and share a multitude of sometimes obscure microarchitectural components. The same risks [39, 44, 67, 68] exist in confidential VMs. Although today’s confidential VM architectures remove privileges from the host hypervisor (e.g., the ability to read plaintext guest memory), it retains a large degree of control over guest execution, such as the ability to arbitrarily interrupt guests, leading inexorably to side-channel attacks.

It is this paper’s thesis – backed by evidence from recent work on computer architecture [31, 96, 97] and security [60] – that these failures of TEE hardware are not isolated events of the past. More than a decade of microarchitectural optimizations have taken processor complexity to a level where it is practically impossible to reason about isolation boundaries within a core [60, 96]. This problem is not only the likely ultimate root cause of the known attacks, but it is also bound to result in periodic breakdowns of TEE security for the foreseeable future. Indeed, Intel takes the position that side channels “can’t be eliminated” [48, 51, 56] but that it will provide mitigations as new vulnerabilities are found. While similar to the current approach to software vulnerabilities, this expects the users of confidential cloud computing (e.g., financial institutions and governments) to tolerate data leaks whenever a new side channel is discovered.

<sup>†</sup>Yizhou Shan is now at Huawei Cloud.

<sup>‡</sup>Xinyang Ge is now at Databricks.

<sup>§</sup>Andrew Baumann is now at Google.

In this paper, we present a much more robust TEE architecture, *core slicing*, that is realistic for infrastructure-as-a-service (IaaS) workloads. Rather than making confidential guests share cores with an adversarial hypervisor, we give the guest exclusive access to its own CPU cores. This moves the isolation boundary to the much more defensible and robust one between processor cores. We show that this boundary can be enforced with simple (and thus less fragile) hardware.

We observe that, although cloud guests may benefit from a VM-level execution abstraction, cloud providers do not exploit the full complexity enabled by hypervisor-based virtual machines for IaaS workloads. For example, although hypervisors support time-slicing VMs on shared cores, VMs offered by major public cloud providers including Amazon [11] and Azure [81] are sized at core granularity and scheduled on distinct physical cores [7, 76, 77]. Likewise, the memory allocated to guest VMs is static; techniques such as memory ballooning [118] or transparent page sharing [118, 124] are avoided. Cloud providers are also moving to reduce the overhead of I/O virtualization by offloading I/O processing to dedicated hardware [5, 8, 36]. To ensure that resources sold match those available, cloud providers limit oversubscription to only their own (first-party) VMs [28] or disable it entirely [7]. Overall, although today's cloud runs virtual machines, leading public cloud providers do so using an effectively static allocation of cores and memory. The hypervisor is relied upon for isolation, but it does so merely by partitioning platform resources.

By giving the guest exclusive access to CPU cores, core slicing eliminates the potential for the entire class of side channels where the attacker shares per-core microarchitectural resources with its victim. Moreover, we enforce this isolation boundary with a new hardware mechanism that is self-contained and simple enough to permit reasoning about confidentiality and integrity. Fully isolated guest OSes (or, potentially, guest hypervisors) run in their own *slice* of a machine. Each slice consists of a dedicated, static allocation of cores, memory, and directly-assigned I/O devices (e.g., the virtual functions of network and storage controllers); hardware ensures that the cores of a slice are sequestered such that they have no access to memory or I/O devices outside the slice, nor can they interrupt cores of other slices. Because *only* a single guest runs code on any given core, a huge class of microarchitectural side-channel leaks are out of scope, and continued innovation in complex microarchitectural performance optimizations is unhindered, since those cannot impact the TEE isolation boundary. While core slicing eliminates intra-core leakage, it does not prevent *cross-core* side channels such as CrossTalk [91] which will have to be addressed by other means. Nevertheless, we believe that obviating intra-core channels removes by far the largest and most serious part of today's side channel problem in terms of the number and seriousness of known attacks, granularity of sharing, and number of shared components.

Resource allocations are determined by a *slice manager* that runs on a dedicated core (ideally, a separate low-power processor), and is responsible for starting and stopping slices, but is otherwise untrusted by the guest. Guest kernels (or guest hypervisors) are enlightened if necessary to run within a slice, ensuring that they attempt only access to those named resources available to them. For example, a guest cannot assume that physical memory starts at address 0, nor that processors have contiguous IDs; in practice, modern kernels including Linux make no such assumptions, and it suffices to pass boot-time information on the accessible resources.

In the following §2, we elaborate on the security risks of confidential VMs, and explore the way VMs are deployed in the cloud today. Like Keller et al. [58] over 10 years ago, we find that hypervisors add significant needless complexity to the cloud's trusted computing base. However, their system No-Hype [107] did not protect VMs from the (fully trusted) cloud provider and relied on virtualization hardware to enforce isolation. The numerous attacks demonstrated since [31, 62, 97] showed that the security provided by this hardware is fragile [62, 96]. By contrast, core slicing maintains a strict separation between core processor logic that is performance-critical and thus complex, and the hardware that enforces isolation, which is not performance critical and simple. It also permits guests to run their own bare-metal hypervisors.

To grant guests bare-metal access to cores in a shared machine while still securely isolating them from one another raises a key design challenge: *without a more privileged software layer on the core, what can enforce isolation?* The key insight behind our design is that simple hardware techniques used to enable trusted execution features such as secure boot and remote attestation for an entire system [127] can be adapted and applied at the granularity of individual cores to help resolve this dilemma. Specifically, §3 contributes *lockable filter registers* and a *core-local secure reset* mechanism, and describes how they can be used to enable core slicing.

To test the practicality of our design, we build two prototypes. The first (§4) leverages RISC-V physical-memory protection (PMP) registers [93, §3.6] to run multiple isolated Linux slices. The other x86-based prototype (§5) lacks security but enables an evaluation (§6) showing that core slicing offers bare-metal performance without VM overheads, with a substantially smaller TCB, while closing side channels based on caches, page faults [128], and other intra-CPU resources. We also analyze traces from a public cloud to find that we can allocate physically-contiguous slice memory, and confirm that our extensions add minimal hardware cost to an existing design. Finally, §7 outlines a path to applying our design to more mainstream architectures, §8 covers related work, and §9 concludes.

## 2 Background and motivation

### 2.1 Hardware-accelerated virtualization

Since VMware first demonstrated the value of virtual machines on commodity platforms [23], hardware vendors have added features to progressively reduce the overhead of virtualization. Although first-generation VM hardware suffered poor performance [1], the gap closed to the point where today's cloud platforms rely fully on hardware support for CPU virtualization, with features such as nested paging and virtual APICs ensuring that many guest VMs now run with low (<5%) CPU overhead compared to bare-metal execution [2]. Unfortunately, this is not true of all VMs; a recent study by Teabe et al. [108] found that up to 30% of CPU time was consumed by virtualization overheads on memory-intensive workloads, even when using nested address translation with huge pages. Other studies reported similar or worse address translation overheads (even with huge pages) [3, 37, 88].

Besides CPU features, modern hardware also supports efficient virtualization of I/O, through advanced IOMMUs [12, 49] and single-root I/O virtualization (SR-IOV) devices [32, 63]. These enable low-overhead virtual I/O by permitting a single physical I/O adapter (such as a network interface or storage controller) to export multiple virtual PCI functions. These are configured by a hypervisor and assigned to guest VMs by installing appropriate IOMMU translations and interrupt mappings. A guest OS thus interacts directly with the device, without the software overhead of traditional I/O virtualization [117]. The hypervisor's role is reduced to configuring the virtual devices and mapping them to the guests, a slower (control path) operation generally performed at startup.

### 2.2 Confidential VMs

Notwithstanding attempts to reduce the size or attack surface of cloud hypervisors [27, 66, 105, 107, 121, 125], the cloud's trusted computing base is controlled by cloud providers and opaque to its users. Threats such as supply-chain attacks [85] and rogue employees (e.g., cloud administrators and developers) have alternatives to traditional cloud architecture [55, 106, 126]: new architecture extensions such as AMD SEV-SNP [13, 78], Intel TDX [53] and Arm Realms [17] seek to remove the hypervisor entirely from the guest's TCB by extending the approach of earlier user-level TEEs such as Intel SGX [50]. In these designs, guest memory and register context are encrypted by hardware, and resource management actions of the hypervisor, such as mapping of memory to the guest, are checked for consistency with the expected VM state. This prevents, for example, a compromised hypervisor from interfering with a guest's memory layout. Finally, like other trusted computing technologies, these designs include a hardware root of trust with support for remote attestation of the guest VMs, enabling a cloud user to verify that their VM has

been correctly launched before trusting it with any secrets.

While the various architectures share many similarities, they differ in the trusted components that check hypervisor operations and enable remote attestation. In AMD's design, these are delegated to firmware on a separate platform security processor, whereas in the Intel and Arm designs these are performed by trusted and attested software running on the CPU itself. Regardless of where it runs, the relevant firmware/software must be trusted by both host and guest, and although it is simpler than a full hypervisor, that is hardly a guarantee of correctness. Notably, AMD's firmware (the only one of the three to have reached production) has already suffered serious vulnerabilities [13, 14, 24, 26].

### 2.3 Side channels in processor-based TEEs

Because confidential VMs inherit from SGX the key design feature of a privileged attacker who controls resources and shares processor time with the TEE, we expect them to remain vulnerable to many forms of side-channel attacks similar to those that devastated SGX [112, 114, 115].

Several attacks have demonstrated that the processor's address translation mechanism can be used to extract information such as cryptographic keys, text documents or JPEG images from SGX enclaves [101, 111, 128]. In these attacks, the adversary manipulates or simply monitors page tables to observe addresses accessed by the victim. While these attacks were demonstrated for SGX, it is clear that they carry over to TEEs like AMD SEV where the attacker controls nested page tables and handles nested page faults.

Other transmission channels include processor caches [22, 41, 82], branch prediction hardware [65] and interrupt latency [90, 113]. Some of these attacks generalize not only beyond SGX but also beyond TEEs. These channels also form the basis for tools that allow the adversary to single-step instruction-by-instruction through the enclave code [110] and to replay TEE instructions arbitrarily many times without having to rerun the TEE code [104]. Both techniques generalize beyond SGX, as they only require the adversary to control address translation and interrupts, respectively.

Speculative execution attacks have been used to leak information across all x86 isolation boundaries, including virtual machines and SGX [25, 62, 72, 98, 112, 114–116]. For example, Foreshadow [112] results in the disclosure of the entire enclave memory and the processor's SGX attestation key. To mitigate such attacks, confidential VMs rely on the same basic approach as SGX: microarchitectural tweaks and microcode patches to the "context switch" path between TEE and host code. More recent research demonstrates that side channels remain a problem on AMD SEV, including SQUIP attacks [39] via scheduler queues within the *same CPU core*; CipherLeaks [68] via *online encrypted memory analysis*; and attacks via *hypervisor-observable nested page faults* [44, 67]. By contrast, core slicing avoids the shared core resources,

the online memory access from other security domains (i.e., slices), and the hypervisor.

## 2.4 VMs as used in public clouds

We next look at how VMs are deployed in clouds today, focusing on infrastructure-as-a-service platforms, which offer VMs backed by guaranteed resources (CPUs, memory, and in some cases accelerators and I/O bandwidth). We consider Amazon EC2 and Microsoft Azure, as they collectively represent 60% of the worldwide IaaS market [38]. We do not consider non-IaaS workloads such as serverless or micro instances for which core slicing may be a poor fit.

**VMs are allocated at core granularity.** Despite offering a plethora of different VM sizes [11], all current-generation VMs in Amazon EC2 occupy at least an entire core (i.e., two vCPUs on platforms that support hyperthreading), and Amazon states explicitly that host cores are “pinned” to specific guest vCPUs and are not shared across guests [7]. Microsoft Azure also offers a wide range of VM configurations [81]. Like Amazon, Azure does not oversubscribe customer vCPUs: Cortez et al. [28] note explicitly that their system will “only oversubscribe servers running first-party workloads.”

For both providers, *burstable VMs* [10, 80, 119] represent the main special case as far as CPU allocation is concerned. These VM types are optimized for workloads that are mostly idle, with only occasional bursts of CPU activity. Like all cloud VMs, they have a fixed number of vCPUs, but consume on average only a fraction of their vCPU allocation in physical CPU runtime. Thus, of all the VM types offered across EC2 and Azure, burstable VMs are the only type that fundamentally requires the use of a hypervisor to perform time-slicing, in order to account for the VM’s actual CPU utilization, and (presumably) to benefit from sharing CPUs across burstable VMs. All other VMs have a guaranteed allocation of physical CPUs, and for these the cloud provider derives no obvious benefit from hypervisor time-slicing.

**Virtual I/O is becoming fully offloaded.** Cloud vendors have deployed dedicated hardware “cards” that replace software I/O virtualization stacks, exposing virtual devices to guests directly via SR-IOV. For example, Amazon Nitro [5, 7] and Azure AccelNet [36] enable low-overhead networking. EC2 also supports direct access to NVMe storage [8], and Azure supports SR-IOV for InfiniBand and GPUs [57]. It thus seems reasonable to assume that, in the near future, the only I/O devices that are still emulated by host software will be those that are not performance sensitive, such as the virtual serial port or console device used for debugging.

**Advanced VM features are not needed.** Cloud providers rely on VMs to isolate tenants, but make little to no use of

the advanced features enabled by full virtualization. Some features are incompatible with the IaaS model of dedicated resources. For example, a customer paying for a VM with 16 GiB of RAM has no incentive to enable memory ballooning [118] and return unused memory to the hypervisor. Other features, such as transparent shared page detection [118, 124], are disabled because of their significant security risks in a multi-tenant cloud [86]. Cloud providers may use live migration to update host software [129], but this has significant performance impact and hot patching is often preferred [9, 79]. We will discuss this further in §3.4.

**Bare-metal clouds.** Although the bulk of IaaS cloud workloads run in virtual machines, there is also a sizable and growing market for bare-metal cloud servers that offer dedicated machines at a premium price. The three primary reasons for a customer to choose a bare-metal instance over a VM are: (a) to avoid the CPU overhead (“virtualization tax”) for memory-intensive workloads (described in §2.1), (b) a need for predictable performance without any possible contention from other co-located VMs (or “noisy neighbors”), or (c) security/compliance concerns arising from a shared hypervisor [92]. Customers that need to run their own hypervisor may also choose bare-metal servers to avoid the substantial performance overhead of nested virtualization [20, 70]. Core slicing seeks to offer similar features at flexible granularity and consequently lower cost.

## 2.5 Summary

We see that the bulk of IaaS VMs deployed in public clouds today run with a fixed allocation of memory and discrete cores, with I/O that is or soon will be fully offloaded, and have little to no use for features of virtual machines except for isolation. At the same time, CPU vendors are adding substantial complexity (not to mention, security risks and performance overhead) to their designs to support confidential VMs. We ask the question: *since the resources assigned to cloud VMs are effectively static slices of a machine, rather than relying on complex software to check the actions of a hypervisor that is not expected to do anything at VM runtime, why not enforce those partitions in hardware?*

## 3 Design

We describe the design of core slicing, starting with its overall architecture and threat model, before detailing our proposed hardware mechanisms, and how those mechanisms can be used by system software under the control of the host to securely partition hardware among untrusted guests.

Our design goals are as follows:

1. Partition shared hardware at natural boundaries, such

Figure 1: Core slicing system architecture.

as whole cores, while relying only on simple, easy-to-implement hardware mechanisms to ensure isolation.

2. Keep the trusted computing base small and simple, to permit a formally-verified implementation.
3. Support memory encryption and remote attestation features equivalent to confidential VMs.

### 3.1 Overview and terminology

Rather than VMs, we partition a machine into multiple guest *slices*, as shown in Figure 1 (denoted as *sliceU*). Each slice consists of a distinct set of named hardware resources: cores, memory ranges, and (virtual) I/O devices. Those resources are allocated exclusively to a slice for the duration of its execution. In the case of cores, this means that guest code runs in the highest privilege level (e.g., hypervisor mode), and controls every CPU cycle executed on that core until the slice is terminated. Like VMs, slices may start or stop at any time, and resources that were allocated together in one slice may later be partitioned among distinct slices after the first slice terminates. The key invariant is: *at any given time no two slices may share access to the same resource*. This avoids the need for any hypervisor-level mechanisms to share resources between guests, such as time-slicing VMs on a shared core or demand-paging overcommitted memory.

To allocate resources and manage the lifetime of guest slices, we rely on a distinguished control slice (termed *slice0*) running a *slice manager*. Somewhat like the host domain or root partition of a hypervisor, the slice manager is started at boot, and is responsible for creating and destroying user slices and determining their resource allocations. The slice manager runs on a core dedicated to that purpose, ideally a low-power management processor, potentially even on a separate chip as in Amazon’s Nitro system [7]. We do *not* assume that the slice manager shares memory cache-coherently with user cores, nor that it executes the same instruction set. The slice manager

software is further divided into a small, privileged portion, the *slicevisor*, that must be trusted by both cloud guests and the host, and a larger, unprivileged portion, that need not be trusted by guests. The unprivileged slice manager cannot interfere in the execution of a guest slice except for terminating it and resetting its cores. The slice manager maintains an *idle slice* to account for any unused resources. Cores in the idle slice do not execute, and merely wait to be assigned to a user slice.

To isolate resources, we rely on a new hardware mechanism, *lockable filter registers*, that restricts access to resources from a given core. Once configured and locked, these registers are read-only until the core is reset via another new mechanism, *core-local secure reset*. We require that it be restricted so that only the slicevisor can initiate a reset. A trusted loader, the *slicelocator*, is the first code to execute after a reset.

### 3.2 Security properties and threat model

Core slicing offers strong security, eliminating interference between all slices (including the control slice). Specifically:

1. The resources assigned to a slice are static from its creation until its termination.
2. A slice cannot access memory outside the slice, neither from cores nor via DMA.
3. A slice cannot interrupt cores outside the slice.
4. A slice cannot access I/O devices outside the slice.
5. Only *slice0* may terminate another slice or reset its cores.

The threat model for core slicing is comparable to other forms of trusted computing including confidential VMs and enclaves [29, 35, 64]. The host (cloud provider) and guests (cloud users) are mutually distrusting, with one caveat: a guest relies on the host to provide agreed resources (thus, denial of service is out of scope), but can check at runtime that sufficient resources (e.g., as many hardware cores as expected) are available. The cloud provider trusts the management stack executing in the control slice, which determines both which specific resources (CPU cores, memory, etc.) a guest is permitted to use, and for how long it executes.

Guests must trust only hardware, the slicevisor, and the slicelocator. The slicevisor ensures that resource allocations are disjoint (for example, that none of the memory allocated to a guest slice is ever shared with another slice) and configures hardware protection mechanisms accordingly. The slicevisor is also responsible for attesting guest slices, and forms part of the attestation root of trust. The slicelocator ensures that lockable filter registers are properly configured and locked before transitioning control to guest code on each core of a slice.

Core slicing provides substantially stronger protection from side-channel attacks than confidential VMs. Because slicing partitions a machine at core granularity, the only side channels possible are those that can be observed from another core; notably, side-channel leaks to sibling hardware threads or to a malicious hypervisor are impossible.

Hardware security features including memory encryption and cache partitioning are orthogonal to our design; if present, they allow us to strengthen the defenses against physical and cross-core side-channel attacks respectively.

### 3.3 Hardware support for core slicing

Recall that our goal is to partition shared hardware at core boundaries while relying only on simple hardware mechanisms to ensure isolation. To keep this hardware simple, a key choice we make is to *expose the underlying physical resources directly to guest software*. Specifically, a guest slice may not have access to all cores or physical memory of a machine, but the identifiers it uses (i.e., the processor IDs and physical addresses) for the resources to which it does have access are always those of the underlying hardware. The only role of our hardware extensions is to restrict the set of accessible resources on a per-core (and thus, per-slice) basis.

This design choice avoids the need for any additional translation layers (as in virtualization) but it does place some requirements on guest software (i.e., OSes or hypervisors). Specifically, guests must be able to run with non-contiguous processor IDs, and cannot assume that physical memory starts at any particular address (such as zero). Luckily, modern OSes already meet this requirement: the initial OS boot image is a position-independent binary that uses a well-specified data structure (either ACPI tables [109] or a devicetree blob [71]) to locate all accessible resources, including memory ranges and additional processors. As long as this boot-time data structure accurately describes the resources accessible to a slice, a correct guest will make no attempt to access other hardware, and it is sufficient to treat any illegal accesses as fatal.

We therefore require a hardware mechanism that can restrict access to named physical resources (physical addresses for memory and I/O, and processor IDs for inter-processor interrupts). However, by design, guest software running in a slice should be able to use the highest privilege level on those cores, which raises a conundrum: how can we configure these restrictions without a slice being able to change them?

Our solution borrows from a pattern seen in hardware support for trusted execution: we introduce *lockable filter registers* that restrict the accessible resources by *all* software (including the most privileged) running on a given core. Once configured and locked, these registers are read-only until a subsequent *core-local secure reset* regains control of the core from the slice. Similar lockable registers (sometimes referred to as “latches”) have been used to implement hardware security mechanisms such as secure boot and attestation for an

entire system [127]. To our knowledge, we are the first to propose such a technique at the granularity of a single core.

At a hardware level, our proposed secure reset mechanism is just a subset of the existing system-wide reset functionality, exposed separately at core granularity: it stops execution, resets the entire core to a well-defined architectural state (resetting locked registers), and causes the core to begin execution at a fixed address. The unique constraints we place on this mechanism are that (a) only the slicevisor running in the control slice’s privileged mode can initiate such a reset, and (b) the address of the jump target that receives control after reset remains inaccessible to any user slice. Here, we host the *slice-loader*, a small piece of trusted code similar to a secure bootloader that will reassign the core by programming and locking its filter registers before transferring control to untrusted user code, or taking it offline as part of the idle slice.

We next describe how hardware filters enable slicing of each distinct resource (memory, interrupts, cache, and I/O).

**Memory** To prevent a core from accessing any memory outside its slice, we rely on *lockable memory range registers* that restrict physical memory accesses by a core. Although we leave the precise semantics of these registers, such as the number of ranges and any alignment/size constraints, up to hardware designers, we assume that they can be configured in such a way as to restrict access to at least one contiguous range of RAM for a slice, as well as any virtual I/O devices (e.g., network and storage controllers) assigned to the slice, and any other memory-mapped registers (such as a local interrupt controller or timer) that are necessary. The minimum number of range registers is thus platform-specific, but we anticipate that around 10 ranges per core will generally suffice. More ranges will permit the slice manager greater flexibility in memory allocation, especially on multi-socket systems with non-uniform memory, but comes with a small but non-zero cost in additional hardware resources.

Range checks are trivially parallelizable and can be applied before installing a page translation in the TLB, thus having negligible runtime overhead. By contrast, virtualization relies on a nested page table which not only requires additional memory, it also increases page translation overhead and TLB pressure [3, 37, 88, 108]. However, because a slice is restricted to discrete physical ranges, its memory cannot be allocated in arbitrary pages, but instead must occupy a limited number of *contiguous* physical regions. We will evaluate the impact of this constraint on memory fragmentation in §6.4.

**Interrupts** We require hardware support to prevent a slice from sending inter-processor interrupts (IPIs) to cores outside its slice. Luckily, the address space of processor identifiers is substantially smaller than memory addresses, so we propose to use a *lockable IPI destination mask register* in preference to range checks. This register, which may in reality consist of a number of consecutive model-specific registers (e.g., four

64-bit registers for an 8-bit processor ID), permits a slice to run on any combination of cores. Of course, most workloads will benefit from adjacent cores (and caches).

**Cache** By design, any state internal to a core including the L1 cache is never shared across slices. However, shared L2 or L3 caches may raise performance interference and security concerns around cache-based side channels. To mitigate these, core slicing can make use of existing hardware support for cache partitioning [84], as long as the relevant configuration registers can also be locked or otherwise restricted.

**I/O devices** As described in §2.1–2.4, SR-IOV has been deployed by cloud providers to allow VMs to directly access networking, storage, GPUs, and more at no overhead. Just as the virtualization host OS assigns virtual functions to VMs, *slice0* configures and assigns virtual functions to slices.

I/O devices interact with software in three ways: memory-mapped registers, direct memory access, and interrupts; all three require a suitable access control mechanism. Access to memory-mapped I/O is restricted by the same range checks as regular memory, and we do not discuss it further here. However, we need a way to prevent a slice from initiating DMA transfers to any memory outside its slice. Such restrictions are typically implemented by an IOMMU [12, 49], and typical IOMMU functionality suffices for core slicing, as long as the IOMMU remains under the control of the slicevisor.

One simple approach is to configure the IOMMU to map accessible slice memory 1:1 for each virtual function belonging to a slice. Its main downside is security: all memory assigned to a slice is available for DMA. This does *not* compromise slice isolation, but, like a bare-metal system without an IOMMU, it may allow a buggy device driver to access the wrong guest memory. Rather than reprogramming the IOMMU at runtime to restrict DMA, recent work found that it is more efficient to simply allocate all I/O buffers from a dedicated pool of physical memory that remains mapped in the IOMMU [74]; this is naturally supported by core slicing, and avoids the need for runtime interaction with slicevisor to reprogram a slice’s IOMMU translations.

Besides DMA, an I/O device also sends interrupts. The interrupts of virtual functions are mapped and routed to host cores by the IOMMU, and the same mechanisms apply directly to core slicing. Since slice cores are statically assigned and there is no host hypervisor, direct interrupt mapping is substantially simpler than VMs [40].

One unique challenge of SR-IOV is that virtual functions do not implement normal PCI configuration space registers. Rather, a hypervisor typically emulates configuration space accesses for an assigned virtual function. For slices, we could rely either on an enlightened guest to avoid the need for such virtualization (as in our x86 prototype, see §5), or else on a custom PCI “card” [6, 36] to emulate a standard memory-mapped configuration space within its own device window.

### 3.4 Slice management

We now turn our attention to the *slice0* software stack responsible for resource allocation, slice lifetime, and a handful of runtime services. This may run on a dedicated host core, a low-power management core, or a separate SoC. We require only that it (a) has hardware privilege separation, (b) is able to trigger secure resets of guest cores, and (c) shares *some* memory, not necessarily cache-coherently, with those cores.

Recall that only the privileged portion of the slice manager, the slicevisor, is trusted by guest slices. The unprivileged slice manager has no access to guest slice memory or cores. The slicevisor implements all security-sensitive aspects of the process of creating, starting, stopping, and deleting a slice. Its primary role is to ensure that no resource is ever accessible to two slices at the same time; this includes checking that memory ranges assigned to slices are disjoint, and ensuring that all cores of an expired slice have been stopped via a secure reset prior to reassigning any resources of that slice.

To keep the slicevisor as simple as possible (and permit its eventual implementation in formally-verified code), it does not directly allocate resources, but merely checks the correctness of resource assignments provided by the unprivileged slice manager. This permits the unprivileged slice manager to implement flexible policies to choose the memory ranges and cores assigned to slices, without the need to trust them.

The only other code that must be trusted by guests is the *sliceloder* which is the first thing to run after a core is reset by the slicevisor. It is responsible for configuring and locking the per-core access filters, and then coordinating with other loaders of the slice to securely boot the guest OS. To do this, it relies on a *slice table* of configuration information maintained by the slicevisor (and inaccessible to untrusted software).

**Starting a guest** To create a slice, the unprivileged slice manager assigns available cores and memory, and determines the configuration of virtual I/O devices. Next, it invokes the slicevisor to create the slice, which rejects the request if the new slice includes any resource shared with another slice (including *slice0*), other than the idle slice. Otherwise, the slicevisor updates the slice table, programs devices to configure virtual functions, and updates IOMMU translations as described earlier. At this stage, the assigned cores remain idle.

To start the new slice, the slicevisor resets the relevant cores, which causes them to execute the *sliceloder* and follow a secure boot flow. After reading the relevant configuration from the slice table (recall that at this point the *sliceloder* is trusted and has unrestricted access to system memory), the loader determines whether the current core belongs to the idle slice or a new guest slice. It then programs and locks the core’s access filters for memory ranges and IPs, before synchronizing with the loaders (if any) for other cores in the slice. The rest of the boot process has no access to memory or cores of other slices. It zero-fills slice memory ranges, before

copying the guest's boot image and transferring control.

**Terminating a guest** Unless they are unresponsive, guest OSes will generally execute a controlled shutdown initiated via an out-of-band signal. To finally terminate a slice, the slice manager invokes the slicevisor which clears the relevant configuration in the slice table. Then, to stop the guest cores (which no longer have access to the slice table), the slicevisor reassigns them to the idle slice and resets them.

**Auxiliary services** At runtime, the slice manager exposes a simple shared memory device (much like a virtual I/O device) to guest slices, permitting an enlightened guest OS driver to initiate a shutdown or reset of the slice, or access slow-path emulated I/O devices (such as a virtual serial port and console) for which no offload device is warranted.

**Unsupported features** The functionality of a guest slice is similar to bare-metal clouds, and lacks advanced VM features such as live migration. This does not preclude a guest from implementing its own mechanisms (e.g., by running its own hypervisor, or doing so at process level [34]), but it does prevent a cloud provider from transparently migrating guests to implement software upgrades [129]. Since core slicing eschews the use of a hypervisor and runs the entire host stack on a dedicated management core, we do not anticipate that updates will require live migration. In particular, we expect that it will be possible to update the slice manager and slicevisor without any guest interruptions.

### 3.5 Attestation and memory encryption

We assume that hardware implements a root of trust for secure boot, permitting the initial bootloader and slicevisor to be cryptographically measured and attested. In turn, the slicevisor attests individual slices; this includes a measurement of slice configuration, the sliceloader code, and the guest image. Once booted, a guest can prove to a remote verifier that its slice is configured as expected and that its isolation is enforced by trusted slicevisor and sliceloader implementations.

As described earlier, slice memory is strongly isolated to defend against software attacks. To defend against physical attacks on memory, such as cold-boot and memory-bus attacks [43, 89], core slicing can leverage memory encryption hardware. The details of memory encryption are orthogonal to our design, and we expect to leverage existing platform mechanisms. In particular, because only trusted components (sliceloader, guest code, and I/O devices within DMA regions) can access slice memory, it is irrelevant to slice guests whether memory is encrypted by a random system-wide key (as in Intel SGX and Arm CCA), one of a set of random keys (as in Intel TDX), or a unique key for each guest (as in AMD SEV).

If per-slice memory encryption is nevertheless desired, we assume that the hardware will provide a suitable interface for

Figure 2: RISC-V prototype with the slice manager (upper left) and two Linux guest slices (lower terminals).

the slicevisor to configure a unique slice memory encryption key. In that case, when initializing a new slice, the sliceloader starts out in an unencrypted context before enabling encryption to load and boot the guest. Similarly to other confidential computing architectures [15, 54], once the guest boots, attested I/O devices may access the encrypted memory using the guest's encryption context.

## 4 RISC-V Prototype

We demonstrate the feasibility of our design with a RISC-V prototype. We chose RISC-V because an existing feature closely approximates the lockable filter registers required by core slicing. Our prototype runs in two environments: on a modified version of QEMU, and on an unmodified Microchip PolarFire Icicle board with a SiFive FU540-C000 SoC shown in Figure 2, the latter with some limitations due to partial support for our requirements. As the guest OS we run Linux.

Common RISC-V CPUs implement three privilege levels: machine (M) mode for firmware, supervisor (S) mode for an OS kernel, and user (U) mode for applications. Our SiFive SoC includes four general-purpose application cores and one less-powerful monitor core that implements a limited instruction set with only M and U modes. The monitor core is ideal for *slice0*, with the slicevisor running in privileged M-mode, and the rest of the slice manager in user mode. The remaining four application cores are available for guest slices in arbitrary combinations (i.e., up to four single-core guests).

**Memory** In addition to typical address translation mechanisms, RISC-V supports physical memory protection registers [93, §3.6] which can be programmed to restrict access to physical address ranges on a per-core basis. These registers are grouped into 8 or 16 PMP entries. Each PMP entry consists of a configuration register and an address register that specify the access permission (read/write/execute) to a particular region. Once programmed, PMP checks apply to all memory accesses from user and supervisor modes, and

Table 1: PMP permissions by physical region.

| Physical address range                     | <i>slice0</i> M-mode | <i>slice0</i> U-mode | <i>sliceU<sub>1</sub></i> |
|--------------------------------------------|----------------------|----------------------|---------------------------|
| <i>sliceU<sub>1</sub></i> RAM              | —                    | —                    | RWX                       |
| <i>slice0</i> trusted RAM                  | RWX                  | —                    | —                         |
| <i>slice0</i> untrusted RAM                | RWX                  | RWX                  | —                         |
| <i>sliceU<sub>1</sub></i> bus              | RW                   | —                    | RW                        |
| Other <i>sliceU</i> bus                    | RW                   | —                    | —                         |
| Cache controller                           | RW                   | —                    | —                         |
| Reset unit                                 | RW                   | —                    | —                         |
| Interrupts to <i>sliceU<sub>1</sub></i>    | —                    | —                    | RW                        |
| Interrupts to <i>slice0</i>                | RW                   | —                    | RW                        |
| Physical I/O devices*                      | RW                   | —                    | —                         |
| <i>sliceU<sub>1</sub></i> virtual devices* | —                    | —                    | RW                        |

\* Not implemented due to hardware limitations.

optionally from machine mode. Finally, as required by core slicing, PMP registers include a *lock* bit that, once set, prevents any subsequent modifications until a reset. Our prototype sliceloder configures and locks the PMP entries for each core in the slice before booting the OS. Thus, code in a slice cannot access physical addresses outside its slice, even from the most privileged machine mode.

Besides memory, other locked PMPs grant access to a slice’s hardware resources (described below), and enforce privilege separation between the slice manager and slicevisor on the monitor core. Table 1 summarizes their configuration.

**Interrupts** Recall that our design calls for lockable mask registers restricting the destinations for inter-processor interrupts. We found that although RISC-V lacks such a feature, the careful use of PMPs permits an equivalent mechanism. To send an IPI on the SiFive SoC, the source core writes to a memory-mapped register of the destination’s “core-local interruptor” [102]. Because the register’s address is unique for every destination, we can use the source core’s PMPs to restrict the addressable (and thus interruptible) destination cores. Access to core-local timers is restricted similarly.

**I/O devices** Our board includes several I/O controllers, and our prototype grants access to slices using PMPs and routes interrupts accordingly. We were unable to prototype SR-IOV support due to a lack of suitable hardware, such as an IOMMU. The RISC-V community has proposed PMP-like mechanisms to restrict DMA [103], but these are not yet available.

**Cache partitioning** The SiFive SoC includes a 2 MiB shared L2 cache that supports *way masking*, allowing each cache master to be restricted to a subset of the 16 total ways. Since each core’s L1 I- and D-cache act as separate masters for the L2 cache, we can flexibly partition it by enabling distinct way sets for each slice. Our implementation scales the size of a slice’s cache partition with the number of cores in that slice (i.e., four ways per core); thus, larger slices enjoy a

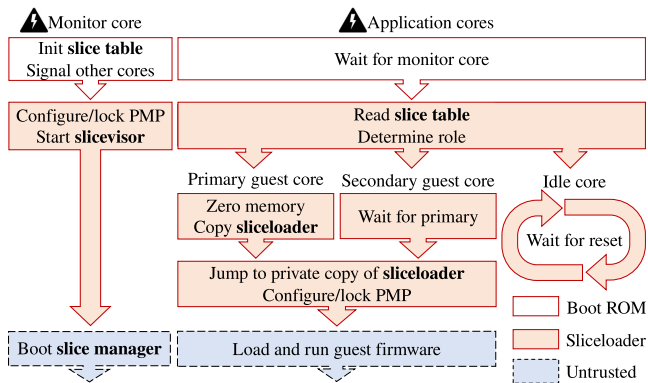

Figure 3: Boot flow for each core after reset.

larger share of the cache. Untrusted code cannot change the cache configuration because the cache control registers are enabled only in the monitor core’s M-mode PMP registers.

**Core reset** Recall that our design relies on a secure core-local reset to re-establish trusted control of a core from a user slice. Unfortunately, our board does not expose per-core reset signals, requiring a full system reset that reboots the entire board to clear any PMP lock bits. We have taken a number of approaches, with different trade-offs, to avoid this limitation.

First, we modified QEMU to implement a new device that exposes per-core reset registers; our prototype slicevisor uses these to reassign cores.

Second, we modified the slicevisor to create slices at boot time using a pre-determined configuration. On our board, such slices cannot be destroyed without a whole-system reset because their PMPs are locked. However, despite the loss of flexibility, this provides a strong security guarantee.

Finally, to test our ability to destroy and create slices on hardware, we implemented an insecure slice manager with an alternative software-based reset mechanism. In this version, PMP lock bits are not set. This provides no meaningful security (a malicious slice could reconfigure PMPs), but permits a cooperative slice to emulate a “secure” reset upon receipt of an IPI by clearing PMPs and jumping to the sliceloder.

**Sliceloder and guest firmware** As shown in Figure 3, the actions of the sliceloder vary depending on the slice to which the running core is assigned. When booting a guest, the sliceloder copies itself to private slice memory before setting PMPs, because doing so makes the main copy inaccessible.

When Linux boots, it infers the system configuration from a devicetree blob [71] provided by the firmware. This describes the available memory, cores, and devices on a given platform. To allow Linux to boot in a slice, we enlightened the OpenSBI bootloader [94] to run as untrusted code inside a newly-created slice. It constructs a devicetree describing the slice configuration before booting Linux. Given an appropri-

ate devicetree, Linux itself required no modifications to run with arbitrary physical memory ranges or core IDs.

**Slice communication** To enable communication between the slice manager and guests, we implemented a *slice bus* message transport, using a region of shared memory between each guest slice and *slice0*, with IPIs for signaling.

**Attestation** To prove that a guest slice runs only the image expected on a trusted platform, we implemented *measured boot* in the sliceloader and *attestation* in the slicevisor. When creating a slice, the sliceloader measures guest code and stores its hash in *slice0* trusted memory. To attest, slicevisor generates an attestation report including the guest measurement and user-provided data, signed by a slicevisor-held key derived from a hardware root of trust. A remote party can verify the attestation using the device public key and the TCB report.

**Limitations** Due to hardware limitations, our prototype lacks support for memory encryption. We do not yet implement virtual serial ports, but assign a UART to each slice.

## 5 x86 Prototype

We also implemented an x86 prototype. This lacks security isolation, but permits us to experiment with SR-IOV devices and compare performance to the state-of-the-art in hardware virtualization. We discuss ideas for actual hardware support on x86 platforms later, in §7.

Since there is no security, we simplified our management stack by building on top of Linux. Specifically, we run Linux on the bootstrap core, using kernel parameters that restrict Linux to a single core and a minimal amount of physical memory. Non-boot cores remain idle, in the *wait-for-startup-IPI* state. A privileged process is later responsible for configuring and booting slices with a user-specified set of cores, range of physical memory, and set of PCI devices.

**Booting a slice** To boot a slice, we load the guest kernel into the chosen physical memory range (accessed via `/dev/mem`), construct ACPI and E820 tables describing resources available to the slice, and then send a startup IPI to the slice’s first core. This runs a tiny (48-instruction) real-mode bootloader that constructs a page table, switches to 64-bit mode, and enters the slice kernel, which then boots as usual, sending further startup IPIs to other cores.

**Guest enlightenments** Because all the host hardware remains accessible, the Linux guest needed a few modifications. We disabled the `CONFIG_DMI` and `CONFIG_X86_MPPARSE` build options to prevent the slice kernel discovering these legacy firmware tables (and hardware they

Figure 4: RISC-V CoreMark results (lower is better).

describe) in the system BIOS. We fixed a bug that unconditionally enabled interrupts from the legacy PIC despite ACPI flagging it as absent. Finally, we added 283 lines of code to (a) use an SR-IOV virtual function without a virtual configuration space, and (b) enable only a subset of PCI devices. These enlightenments would be irrelevant to a hardware implementation. In particular, host firmware and devices would be inaccessible to slices, and (as described in §3.3) an I/O device could emulate standard PCI configuration space.

## 6 Evaluation

This evaluation seeks to answer the following questions:

- What is the performance overhead of core slicing? (§6.1)
- How does the design of core slicing translate into concrete security benefits for guest slices? (§6.2)
- What is core slicing’s hardware complexity? (§6.3)
- Does the need for contiguous physical memory lead to slice allocation failures due to fragmentation? (§6.4)

### 6.1 Performance

Our experiments run on the RISC-V board described in §4 with a 16-way 2 MiB L2 cache and 1 GiB of DRAM, and on an HP Z8 workstation with two Intel Xeon 4214 12-core CPUs (HyperThreading disabled), 64 GiB of RAM, a Mellanox ConnectX-4 25GbE NIC, and a Samsung PM1735 NVMe SSD. Another HP Z8 with two Xeon 4108 CPUs and the same NIC serves as a client.

**RISC-V** We run CoreMark PRO [33] and focus on two questions: (a) does a slice achieve bare-metal performance, and (b) what is the impact of a “noisy neighbor” slice?

For the native baseline, we enable two application cores and 512 MiB memory. This allows a fair comparison with the slice measurements, in which we launch two guests, *sliceU<sub>1</sub>* and *sliceU<sub>2</sub>*, each with two cores and 512 MiB memory. As shown by the *shared* results, performance in a slice exactly matches

Figure 5: x86 CloudSuite results (higher is better).

bare-metal execution. To determine the impact of cache contention, we run a workload in *sliceU<sub>2</sub>* as a noisy neighbor (denoted by ‘noise’) that repeatedly accesses a 2 MiB array (the same size as the L2 cache). Unsurprisingly, the average runtimes (denoted by *shared+noise*) increase depending on the given workload’s cache intensity. Specifically, *radix2* suffers the most (almost 50% overhead) since it operates on a 512 KiB array and suffers frequent cache misses. As demonstrated by *private+noise*, when the cache is partitioned, a noisy neighbor has a substantially smaller impact, with all workloads achieving stable performance, and outperforming the *shared+noise* configuration. The runtimes in *private+noise* increase slightly (< 5%) with noise compared to *private*, due to contention for the memory controller.

**x86** We compare slice performance to equivalent VMs using CloudSuite 3.0 [87]. Both slice and VM guests have 8 cores and 16 GiB of RAM (allocated on the same NUMA node), with NIC and NVMe virtual functions for I/O. We run VMs under KVM using full hardware acceleration including virtual APICs, and confirm via performance counters that the only significant source of VM exits is to service and emulate timer interrupts. To minimize memory management overhead we use pre-allocated and locked huge-pages (2 MiB and 1 GiB).

The results in Figure 5 are scaled to a native baseline with the same cores/memory. *Graph analytics*, which uses Apache Spark and GraphX to run PageRank on a large Twitter dataset, runs 10% slower in a VM. *Data caching* models a Twitter cache server with Memcached. Despite sustaining a similar peak throughput, the VMs have higher jitter and thus perform up to 8% worse while meeting the published QoS target of 10 ms p95 latency. This appears to be due to the extra TLB pressure of nested paging: DTLB misses are more than 3× native for 1 GiB pages, and 5× for 2 MiB pages. Finally, *Data serving* runs Apache Cassandra with 10M records of YCSB workload A and incurs a 12% throughput penalty in a VM.

**Summary** Core slicing achieves bare-metal performance without the overhead of virtualization, which remains significant for memory-intensive workloads, even with huge pages.

Table 2: Size of software TCB.

|             | Source lines <sup>a</sup> | Executable code <sup>b</sup> |
|-------------|---------------------------|------------------------------|
| slicevisor  | 3,609                     | 18 KiB                       |
| sliceloader | 3,607                     | 11 KiB                       |
| Total       | 4,826 <sup>c</sup>        | 29 KiB                       |

<sup>a</sup> Non-header lines, counted by `clloc` [30]. <sup>b</sup> Size of text section, from `binutils size`. <sup>c</sup> A library common to both is counted once.

Furthermore, hardware cache partitioning (as on RISC-V) not only lessens the impact of a noisy neighbor, it can also eliminate both cache contention and cache-based side channels.

## 6.2 Security

**Size of trusted computing base** Although no guarantee of security, a small TCB helps make formal verification tractable. Table 2 reports the executable source and binary sizes of our prototype. These are comparable to the firmware for Arm CCA (4.3 kLOC [69]), although we note that core slicing’s TCB eschews runtime interaction with a running guest, and thus its attack surface is drastically simpler.

**Side channels** By partitioning a machine at core granularity and without a trusted hypervisor, core slicing avoids either the host or another guest running concurrently on a core. This is inherently more secure than either reducing the hypervisor’s size [99, 100] or de-privileging it [13, 17, 53]. We also gain a systematic defense from a wide variety of CPU side-channel attacks. Following our threat model (§3.2), we consider two classes of attacker: guest attackers who may run arbitrary code in a guest slice, and the host attacker who controls untrusted code in *slice0*. We describe the extent to which these may compromise a guest’s confidentiality.

**Cache side-channel attacks** are defeated by cache partitioning and memory isolation. Because slices never share memory, a guest attacker cannot steal secrets by analyzing whether a co-located tenant accesses shared memory addresses. Because caches are partitioned, the attacker cannot observe how many cache lines are used by the guest per cache set. *slice0* is similarly restricted. Thus, given suitable hardware support, core slicing eliminates cache-based side channels. It also defeats all side-channel attacks where the attacker executes on the victim core, including sibling threads [4, 98].

**Transient execution attacks** can leak secrets through the side effects of speculative memory accesses [62, 72], and can break isolation between hypervisors and VMs. Core slicing relies on lockable filter registers to restrict memory access. Because filters only perform a range comparison (with no memory-bound table walk), they derive no significant benefits from speculation; e.g., current RISC-V CPUs cache PMP range checks in the TLB along with address translations [83].

Cross-core transient execution leaks were recently observed on Intel CPUs [91]; although these remain a threat, we expect them to be drastically simpler for vendors to identify and fix in future CPUs, since few instructions access uncore state. Of note, the demonstrated attack relies on delaying a victim enclave’s execution with page faults and exceptions, which is impossible across a slice boundary.

**Page-fault-** and **page-table-based attacks** are highly exploitable on TEEs where an untrusted hypervisor manages guest memory using a nested page table. In these attacks, a host learns the guest’s secret-dependent memory access pattern via page faults, page table access/dirty bits, or even cache contention with hardware table walks. Core slicing prevents this by allocating physical memory directly to guests. In addition, memory encryption can suffer from **ciphertext-only attacks** (e.g., dictionary attacks) with weak encryption algorithms. In our design, lockable filter registers prevent access to guest memory, including ciphertext, even by the host.

Side channels in resources shared by multiple cores remain, including power [61], row-hammer [59], cold-boot [43], and memory bus [89] attacks. Those can be mitigated with additional orthogonal hardware support.

### 6.3 Hardware complexity

To estimate the hardware cost of supporting core slicing, we extended the default *tiny* configuration of the RISC-V Rocket Chip implementation [18]. To measure the overhead of adding lockable filter registers, we doubled the number of PMPs from 16 to 32 (as might be necessary when existing PMPs are required for other uses), resulting in only a 3% increase in total FPGA resources. We also added per-core resets and a reset device for the monitor core, for 1.7% extra resources. Since these results are for an embedded core, we expect the fraction of resources required on a server-grade CPU to be much smaller.

### 6.4 Impact of physical contiguity

Unlike VMs, slices require *contiguous* physical memory, and the memory assigned to a slice cannot be changed without terminating and restarting it. Thus, it is possible that the available memory on a node becomes fragmented over time, leading to a situation where sufficient free memory exists to support a new slice, but cannot be used as it is not contiguous. Whether this is a problem in practice depends on both the pattern of memory allocations (i.e., the order of slices created and destroyed) and the policy implemented by the memory allocator (i.e., which region of memory to allocate for any given request). In this section, we report the analysis of VM start/stop events on a public cloud workload, modeling the effects of memory allocation policy and hardware capabilities.

The trace we use is similar to the VM allocation trace of Hadary et al. [42]. It includes all VM start and stop events (in

Figure 6: Rate of slice allocation failures due to memory fragmentation over a 7-day moving window.

excess of 750k events) for an Azure cluster, and was gathered over two months in mid-2021. Each VM has a type [81] that defines its resource allocation, including its memory size (other resources are irrelevant to our analysis).

In this analysis we ask the question: *how often does fragmentation prevent the allocation of a slice on a node when a VM would have succeeded?* Thus, although it may be beneficial for the cloud scheduler to use node-level memory contiguity in its placement decisions (allocating slices on nodes to reduce fragmentation), we leave the mapping of VMs to nodes unchanged and model slices as a drop-in replacement. Since our focus is memory allocation, we model every VM as a slice with physically contiguous memory. In reality, we expect that some types (such as burstable VMs) would continue to run as VMs on the cloud provider’s hypervisor either within a slice of a larger machine, or using dedicated machines.

The results of our analysis are shown in Figure 6. We experimented with a variety of memory allocators, and found unsurprisingly that a best-fit policy (which places each new slice in the smallest free region of sufficient size) minimized fragmentation and thus allocation failures. Other policies, including a traditional buddy allocator, performed uniformly worse and are not shown on the figure. Calculating the best allocation will take slightly longer, but given the low rate of slice instantiations relative to traditional memory allocation workloads, this overhead is not expected to be significant.

As shown in the figure, the allocation failure rate for fully contiguous memory is less than 0.3% of VMs in the trace, representing less than 1% of the total requested memory (since larger VMs are more likely to fail allocation). We also modeled the effect of permitting multiple contiguous regions per slice. With hardware support for two memory regions per slice, the memory allocator is able to split large slices across two distinct allocations, and the failure rate drops further to

less than 0.1% (only 6 failures across the entire trace). With three regions per slice, there are no failures. Overall, we conclude that restricting slices to contiguous memory does not pose a significant constraint for cloud operators. A different analysis by Teabe et al. [108] reached the same conclusion.

## 7 Discussion: core slicing beyond RISC-V

For a prototype implementation of core slicing, RISC-V had several advantages; most significantly, the use of physical memory protection registers allowed us to implement the bulk of our design on unmodified hardware. However, our design does not depend on RISC-V, and we ultimately hope to see it adopted by the x86 and Arm architectures that dominate today's cloud. This section discusses some of the challenges in doing so, and offers guidance to hardware designers.

The obvious first step in adapting an existing architecture to support core slicing would be to implement our hardware requirements: lockable filter registers to restrict a core's ability to access memory and send inter-processor interrupts, and a secure core-local reset to regain control of it. Of course, the details matter, and thanks to the long evolution of these architectures, there are many interactions with existing architectural features that must be considered.

Recall that our design goal with core slicing is to give guest software unfettered bare-metal access to a single core (or set of cores). As a first rule of thumb, we propose that *resource restrictions imposed via filter registers should take priority over other core-level architectural features*. This implies that existing features granting privileged access to memory, such as hardware shadow stacks [52] or secure-world memory regions [16] must be constrained by lockable address filters.

Second, *any hardware resources that are shared by more than one core must be restricted*. This includes peripherals, memory and cache controller configurations, and power management registers, among others. In RISC-V systems, such registers are memory mapped and thus restricted by PMPs, but on x86 they are configured via model-specific registers (MSRs) that occupy a distinct address space accessible to privileged software on each core (Arm system registers are similar). The access restriction could be implemented via further filter registers, or as a simpler alternative, access to these resources could be limited to the management core running the sliceloader. For the specific case of x86 MSRs, we expect that the MSR bitmaps found in the VM control block will serve as a useful starting point in determining the appropriate policy. Finally, the x86 legacy I/O address space must be filtered or (for legacy-free guests) blocked outright.

Finally, *the platform must not depend on firmware running on guest cores*. Thus, the system design should avoid the need for platform firmware in x86 system management mode or Arm EL3 on general-purpose cores. The motivation for this requirement is the same as that of core slicing: to avoid relying on intra-core privilege separation due to its demonstrated

weakness. In our view, firmware tasks are better delegated to a dedicated management core (along with the slicevisor).

## 8 Related work

**Direct hardware assignment** We discussed secure hypervisors and confidential VMs in §2.2.

NoHype's [58, 107] central security goal is to protect a *trusted* cloud provider and its legitimate customers from rogue VMs that try to exploit vulnerabilities in the hypervisor or the associated virtualization stack. NoHype achieves this goal by removing all run-time interfaces that traditional hypervisors expose to traditional VMs. The security goals of core slicing reach significantly further and address threats that have emerged during the decade since NoHype was designed. In addition to protecting the cloud infrastructure from rogue guest VMs, core slicing protects guests from the *untrusted* cloud provider. This task is complicated by an ever-growing array of microarchitectural attacks that can leak information out of VMs. Therefore, core slicing does not allow any cloud provider code to run on a guest's processor cores. In contrast, NoHype requires a highly privileged "temporary hypervisor" on those cores.

Core slicing relies on simple lockable filter registers to confine guests which enjoy bare-metal control over cores, and may run their own hypervisor. NoHype relies on conventional processor privileges; guests thus lack access to virtualization extensions, must be modified to avoid VM exits (notably, they must not execute CPUID, including in user mode), and must ignore spurious interrupts from other guests (both a side channel and a denial-of-service attack).

TrustOSV [120] and Quest-V [123] minimize runtime guest-hypervisor interactions by statically assigning cores and memory. The core of TrustOSV is a *microhypervisor* that uses nested paging to constrain guest memory accesses. Quest-V replaces a global hypervisor by trusted per-core monitors that also run in host/root mode and use nested paging. TrustOSV reduces trust in the cloud provider by attesting the microhypervisor and exposing a limited management interface. In contrast to core slicing's use of I/O offload, TrustOSV exposes a virtual NIC which is also the basis of its storage.

**Space partitioning** The use of core-granularity spatial partitioning [47, 73] for resource and security isolation has been explored in the context of prior many-core systems including the Tiler TILE64 [122], Intel single-chip cloud computer [75] and M3 [19], and the core idea dates back at least as far as IBM's logical partitioning feature from the 1980s [21]. Core slicing builds on the same mechanism, but is unique in its adoption of the confidential computing threat model, with a clear separation of host and guest trusted computing base. This leads us to the use of a unique mechanism combining per-core secure reset with lockable filter registers to

enable attested boot while minimizing the guest TCB. Past designs, including those cited above, permit a guest's accessible resources to be reconfigured at runtime by a privileged management core, requiring substantially more trust by the guest in the host's resource manager.

**RISC-V security** Several systems use PMP hardware for different goals. Keystone [64] is a framework for trusted execution environments similar to Intel SGX [46]. The OpenSBI bootloader can partition a machine into static PMP-isolated domains at boot time [95]. MultiZone [45] isolates software components (e.g., core RTOS and communication stack).

## 9 Conclusion

VMs are the basis of cloud isolation, but relying on them for confidential computing carries a serious risk from side channels. Core slicing offers an attractive middle ground between bare-metal servers and confidential VMs. By partitioning hardware at natural boundaries (discrete cores and contiguous physical memory ranges), it enables VM-like functionality and bare-metal performance with strong isolation.

Our prototypes are available at <https://github.com/MSRSSP/core-slicing>.

## Acknowledgments

We thank Luke Marshall for help preparing the VM traces in §6.4. The detailed reviews we received from OSDI'22, ASPLOS'23 and OSDI'23 along with feedback from our shepherd Ed Bugnion helped us greatly improve the paper.

## Abstract

Given the fundamental tradeoff between run-time and recovery performance, current distributed systems often build application-specific recovery strategies to minimize overheads. However, it is increasingly common for different applications to be composed into heterogeneous pipelines. Implementing multiple interoperable recovery techniques in the same system is rare and difficult. Thus, today’s users must choose between: (1) building on a single system, and face a fixed choice of performance vs. recovery overheads, or (2) the challenging task of stitching together multiple systems that can offer application-specific tradeoffs.

We present ExoFlow, a *universal workflow* system that enables a flexible choice of recovery vs. performance tradeoffs, even within the same application. The key insight behind our solution is to *decouple execution from recovery* and provide exactly-once semantics as a separate layer from execution. For generality, workflow tasks can return *references* that capture arbitrary inter-task communication. To enable the workflow system and therefore the end user to take control of recovery, we design task annotations that specify execution semantics such as nondeterminism. ExoFlow generalizes recovery for existing workflow applications ranging from ETL pipelines to stateful serverless workflows, while enabling further optimizations in task communication and recovery.

## 1 Introduction

A key requirement for distributed applications is *fault tolerance*, i.e. the appearance of execution without failures even when failures occur. In general, there is a tradeoff between recovery and run-time overhead. For example, logging generally adds higher execution overhead but reduces recovery time by allowing the system to only re-execute computations that failed [23]. Meanwhile, checkpointing reduces execution overhead but can impose higher recovery overhead as the system must roll back additional computation after a failure.

Current distributed systems often choose different tradeoff points between recovery and performance based on the application. For example, Apache Spark uses lineage-based logging for batch processing [48], and Apache Flink uses checkpointing for stream processing [19].

However, it is becoming increasingly common for different applications to be composed into heterogeneous pipelines. For example, a machine learning pipeline might use batch ingest to build a training dataset, then stream the data to a

batch distributed training job to reduce latency and memory overhead. If we use a single recovery strategy for the entire pipeline, performance and recovery may be suboptimal because different recovery strategies are suited to different applications. Thus, to optimize end-to-end performance and recovery, we need to *compose different recovery strategies*.

Implementing multiple, interoperable recovery techniques within the same system, let alone a single one, is challenging. For example, Spark introduced “continuous processing” to reduce performance overheads for stream processing applications, but this mode does not yet provide exactly-once semantics during failures [10]. On the other hand, Flink has added a batch processing mode, but this required building an entirely separate recovery system from the streaming path [20].

Overall, these challenges have led to patchy support for applications that have diverse requirements in the recovery-performance tradeoff space. Users must choose between: (1) building on a single system, and face a fixed choice of performance vs. recovery overheads, or (2) stitching together multiple systems that offer different application-specific tradeoffs. The latter, however, is challenging and requires coordinating the flow of data, control, and recovery across disparate systems. This is true even in a single system, if using disparate execution modes such as batch vs. streaming.

In this paper, we propose a *universal workflow* system that enables a flexible choice of recovery vs. performance tradeoffs, even within the same application. A *workflow* is a directed acyclic graph (DAG) of *tasks*, where each task encapsulates a function call and edges between tasks represent data dependencies. Workflows are used to orchestrate execution across systems and thus prioritize generality. The DAG API is popular because it allows arbitrary application code in each task, from submitting a Spark job to invoking a microservice.

In contrast to other workflow systems, however, we *decouple the unit of execution from the unit of recovery*. In particular, ExoFlow guarantees fault tolerance by durably logging the workflow DAG and coordinating task checkpoint and recovery, while execution of the DAG is handled by a generic “backend”. This has three key benefits. First, it enables heterogeneous application pipelines that need multiple recovery strategies for performance. Second, it augments existing distributed execution frameworks that provide only at-most-once or at-least-once semantics with strong exactly-once semantics. Third, it disaggregates the execution backend from recovery, allowing independent deployment and scaling.

Previous workflow systems provide exactly-once semantics but with significant limitations. For generality, workflow systems such as Apache Airflow [3] assume that each task is nondeterministic and may have side effects on external systems that in general cannot be rolled back. Thus, each task must synchronously checkpoint its outputs *before* they can be made visible to any downstream tasks. Otherwise, the system may have to re-execute the task in case of a failure. If the re-execution produces a different result, this can cause an inconsistent view among downstream tasks and external systems.

Thus, by assuming the worst, the workflow system has only one option of ensuring fault tolerance: no task can start before its upstream tasks have finished checkpointing all of their outputs. This limits the workflow system’s ability to incorporate key optimizations often employed by application-specific frameworks that exploit the application’s semantics. For example, large datasets passed between tasks can often be deterministically regenerated, making checkpointing unnecessary. In addition, while some tasks may indeed have external effects, e.g., starting a transaction on an external database, some effects can also be rolled back, e.g., by aborting the transaction.

Our goal is to hand control over recovery to ExoFlow and ultimately the end user. Thus, we use two key interfaces to enable awareness of application semantics. First, we extend the typical workflow DAG API with pluggable *first-class references* to enable more flexible workflow-internal communication. A workflow task can return references to its outputs, which the workflow system then passes to downstream tasks. In contrast, current workflow systems require the application to pass data by explicitly copying and checkpointing, which can be expensive for large data, or implicitly through external storage, which makes it difficult to guarantee exactly-once semantics. By using references to capture arbitrary data movement between workflow tasks, ExoFlow leverages third-party systems’ existing communication and recovery mechanisms while retaining control over workflow-level recovery.

Second, we introduce user annotations that specify relevant task semantics, i.e. whether to checkpoint a task, whether the outputs are deterministic, and whether the task has externally visible outputs. Before execution, ExoFlow checks the safety of the user’s specification. During execution, ExoFlow synchronizes task execution and checkpointing. During recovery, ExoFlow coordinates *rollback*, e.g., deletion of outputs from a previous execution, and task replay. For example, before executing a task with an externally visible output, ExoFlow will first synchronize upstream checkpoints to *commit* any nondeterministic outputs, i.e. ensure they will never be rolled back. This allows the user to flexibly and safely optimize the recovery technique.

ExoFlow is built on Ray [37] and consists of a per-workflow centralized controller, a pluggable checkpoint storage, and a pluggable execution backend. Centralizing controller logic makes it simple to guarantee recovery correctness. Meanwhile, checkpointing and execution are fully disaggregated,

allowing these to be scaled independently of the controller.

We demonstrate the benefits of ExoFlow with two execution backends, the Ray framework and AWS Lambdas, both distributed frameworks that provide at-most-once or at-least-once tasks. We show that references can enable  $\sim 5\times$  speedup for Spark data processing workflows compared to Apache Airflow, while task annotations enable 51% lower latency for transactional serverless workflows compared to Beldi [49]. These optimizations are possible because correctness is ultimately guaranteed by ExoFlow. These results also demonstrate ExoFlow’s *universality*, as the system is not specific to data processing or serverless environments. In summary, our contributions are:

1. Decoupling execution from recovery to enable a flexible tradeoff between performance and fault tolerance.
2. Designing a universal workflow system that guarantees exactly-once DAG execution.
3. Demonstrating benefits for a diverse set of applications, including an ML pipeline, serverless transactions, and graph processing that mixes stream and batch execution.

## 2 Motivation

### 2.1 Overview of recovery strategies

We use *exactly-once semantics* as our correctness condition. This condition often implies application-specific correctness properties, such as global consistency in message-passing systems [23] or linearizability in storage systems [29].

More precisely, exactly-once semantics require all outputs to appear consistent with a physical execution where all inputs were processed without failures. In a workflow setting, the inputs are the DAG and the root task arguments. Outputs are values produced by a task that are viewed by others.

Output visibility can be *internal* or *external*. For example, values passed between tasks in Figure 1a are internal because they are viewed only by other tasks. Meanwhile, `(key, val)` is external because it is sent to a key-value store. Once outputs are made external, the workflow system no longer has control over how they will be used, e.g., via reads from external key-value store clients. Outputs can also be either *deterministically* or *nondeterministically* generated.

Output visibility and determinism are important because together they determine the recovery procedures that will guarantee exactly-once semantics (Figure 1b). For example, consider the cases if A is nondeterministic and we do not checkpoint `a_out` in Figure 1a. Suppose C views an initial value `a_out1` and produces `c_out1`, but we lose `a_out1` due to a failure. If we re-execute A to produce `a_out2` and pass this to B, the outputs of B and C will not be consistent with a failure-free execution. To handle this case, we also need to “rollback” `c_out1` and re-execute C on `a_out2`.

We encounter additional problems in the opposite case where B finishes and we then lose `a_out1`. B has already made `(key, val)` external and these values may depend on `a_out1`.

If we execute  $C$  on  $a\_out_2$ ,  $c\_out$  will be inconsistent with  $(key, val)$ . Thus, the only way to guarantee correctness in this case is to either: (1) “commit”  $a\_out_1$  before executing  $B$ , e.g., by checkpointing it, or (2) gain application semantics about how to roll back visibility of  $(key, val)$ .

Meanwhile, deterministic outputs are safe to view as long as the task can be replayed on its original inputs and recomputed outputs can be deduplicated. The external output in Figure 1a can for example be deduplicated by attaching a deterministic `req_id`.

**Solution space.** Handling nondeterministic outputs is generally done in two ways: (1) global checkpointing and rollback on failure, or (2) logging and deterministic replay on failure [23]. Both “commit” a prefix of a failure-free execution by saving the outputs of a task frontier, allowing recovery to resume execution from a consistent set of intermediate outputs. Global checkpointing advances this frontier several tasks at a time and upon failure, rolls back to the last frontier to undo partially visible nondeterministic outputs. For outputs that cannot be rolled back, however, upstream nondeterministic outputs must first be committed by taking a global checkpoint. Logging-based methods advance the frontier one task at a time by committing each nondeterministic output before making it visible, thus avoiding additional rollback on failure.

Note that rollback and durability options vary based on output visibility. External outputs may be impossible to roll back, e.g., a transaction commit cannot be undone, or make durable, as third-party system context is not always serializable.

Current workflow systems guarantee exactly-once semantics by: (1) durably checkpointing each internal output before making it visible, and (2) requiring the developer to make external outputs idempotent and durable. This one-size-fits-all approach does not leverage application-specific recovery methods (Figure 1b). Furthermore, existing workflow systems have fundamental limits on internal outputs, usually because they must be sent between tasks through the workflow controller. Apache Airflow uses a database to coordinate tasks, which imposes a maximum output size on the order of MBs [3], and direct task communication in FaaS is limited [24]. Together, these force developers to use external outputs for much of their task communication [24, 42].

Our goal is to support different recovery methods in a single workflow system and even within a single application. The key insight behind ExoFlow is that knowing the DAG structure makes it simple to identify a consistent execution frontier, allowing the recovery methods before and after the frontier to be decoupled. For example,  $a\_out$  is internal to the outlined sub-DAG in Figure 1a and thus its recovery method can be chosen flexibly as long as the inputs ( $args$ ) and outputs ( $b\_out, c\_out, key, val$ ) are consistent.

Thus, our solution consists of two parts. First, *references* enable ExoFlow to capture a broader range of inter-task communication as internal outputs, without being involved in the physical communication. This encourages recovery

(a) Workflow DAG

|                         | Internal                                                 | External                                                                              |
|-------------------------|----------------------------------------------------------|---------------------------------------------------------------------------------------|
| <b>Nondeterministic</b> | Commit output OR on failure, rollback visibility         | Commit output <i>before</i> visibility OR if possible, rollback visibility on failure |
| <b>Deterministic</b>    | Replay failed task(s) on previous inputs, dedupe outputs | Also dedupe external outputs                                                          |

(b) Recovery strategies for workflow DAGs

Figure 1: (a) An example workflow with internal outputs (e.g.,  $a\_out$ ) and external outputs (e.g., `put(key, val)`). (b) The most efficient recovery strategy depends on output visibility and nondeterminism.

flexibility within a sub-DAG and recovery independence across sub-DAGs. References enable efficient passing of task outputs of any size and location as well as outputs that may not be serializable.

Second, we support *annotations* to specify task semantics (checkpointing, nondeterminism, output visibility). These allow the system to determine recovery correctness before execution. The system “commits” the application to this specification by durably logging the DAG before execution, then coordinates and synchronizes task checkpoints during execution.

## 2.2 Applications

We use three representative applications to show the value of: (1) making workflow-internal outputs more flexible, and (2) exposing application semantics to the workflow controller:

1. Extract-transform-load (ETL) pipelines: Using references to pass large data as internal outputs.
2. Machine learning (ML) pipelines: Using references to pass large data and leveraging application semantics.
3. Serverless workflows: Leveraging application semantics to reduce recovery overheads, in a way that is agnostic to external systems.

**ETL pipelines.** Workflow systems such as Apache Airflow are commonly used to orchestrate extract-transform-load (ETL) pipelines composed of data processing jobs. Figure 2a shows an example in which a Spark job  $A$  performs batch data cleaning and writes the data to an external database, e.g., Delta Lake [11]. Jobs  $B$  and  $C$  then load the data for querying.

Current practice for exactly-once workflow execution requires all of  $A$ ’s outputs to be made durable *before* executing  $B$  and  $C$ . Synchronous checkpointing adds high overhead for large and distributed data. In addition,  $B$  and  $C$  must each reload the data, imposing an unnecessary memory copy. This is of course unnecessary if  $A$  is deterministic. Execution systems such as Spark leverage this property to natively support distributed in-memory caching. Ideally,  $A$  should pass its output as a cached RDD [48] to  $B$  and  $C$  (Figure 2b), avoiding the round trip to external storage, allowing  $B$  and  $C$  to share

Figure 2: (a) ETL workflow today, using external outputs for communication. (b) The same ETL workflow with internal outputs only. (c) ML training workflow today, with external outputs and manual orchestration within a task. (d) The same ML workflow with internal outputs only, and orchestration is handled by the workflow system. Third-party framework state (TF workers) can be passed between workflow tasks.

physical memory, and enabling asynchronous checkpointing.

Building such optimizations into a workflow system would enable orchestration of arbitrary DAGs and third-party frameworks. However, even with awareness of task determinism, current workflow systems cannot execute Figure 2b due to limitations in workflow-internal data passing.

**ML pipelines.** Machine learning (ML) pipelines are similar to ETL pipelines, but with an ML application as the end consumer. This requires composition of traditional ETL systems with distributed ML frameworks for training and inference. Figure 2c shows a typical ML training workflow, in which training data is extracted and transformed in the Ingest task, then consumed by a distributed training job. Loading data into the training job may itself require complex and possibly distributed data processing, with computations such as random transforms to augment datasets [40]. Furthermore, datasets are often large enough that preprocessing must be pipelined with training to maximize GPU utilization.

Current workflow systems cannot effectively orchestrate within the training task, as training data and worker state must be passed through distributed memory. Expanding workflow-internal outputs would enable workflows such as Figure 2d. To reduce the overhead of recovery, however, the workflow system also requires application semantics, such as whether dataset augmentation is deterministic. Also, the model output can be consumed in a variety of ways, from local one-off testing during development to deployment on an ML serving system during production. All of these factors affect the optimal correct recovery strategy.

**Serverless workflows.** In the functions-as-a-service (FaaS) model, the user breaks their application into small functions that can be transparently executed and scaled without explicit resource provisioning. Serverless functions have a limited lifetime, all local state is transient, and failure handling is usually limited to function retries. This makes it challenging to build fault-tolerant nontrivial applications directly on FaaS [28].

Recently, *serverless workflow* systems [16, 46, 49] have gained popularity as a solution, especially for stateful applications. A common strategy for guaranteeing exactly-once execution is to provide fault-tolerant APIs to capture external outputs. For example, Figure 3 shows an example of a trip reservation workflow [25] that places the order if and only if both the hotel and flight were successfully reserved. Systems such as Aft [46], Beldi [49], and Boki [32] guarantee exactly-

Figure 3: Serverless workflow systems [32, 46, 49] guarantee exactly-once semantics by interposing on all communication to external storage, e.g., through a transaction buffer, and explicitly managing visibility of these external effects.

once semantics by providing a transactional key-value store to manage external output visibility.

However, each system offers different isolation levels that require different recovery strategies. Aft buffers uncommitted writes, which are safe to rollback, while Beldi and Boki use write-ahead logging. Thus, each system implements their own recovery procedures, e.g., durability and task re-execution.

ExoFlow factors out workflow recovery to enable flexibility and optimizations. Instead of providing opinionated APIs for external outputs, we treat external systems such as the transaction buffer in Figure 3 as a black box. ExoFlow does not interpose on the communication to this external system and instead requires that the application can specify task semantics such as whether the external effect can be rolled back. These semantics can be specified by a particular transaction system, i.e. Aft or Beldi.

### 3 API

#### 3.1 Overview and requirements

ExoFlow is a general workflow layer that abstracts a workflow *backend*, i.e. a distributed framework providing at-least-once and/or at-most-once remote function invocation. We overview the application-facing API (Table 1) and requirements. The application must be able to: (1) differentiate deterministic tasks, and (2) for tasks with external outputs, ensure that the task is idempotent or specify an idempotent rollback function.

**DAG interface.** The application invokes workflow tasks and specifies arguments using `f.bind` (Table 1). The caller receives a `WorkflowDAG` that represents the task’s output and that can be passed to other tasks as dependencies. Workflow execution is *lazy*: to evaluate a `WorkflowDAG`, the developer must run it. This is to simplify recovery, as the workflow system can check DAG-level properties before executing it.

The workflow backend should implement an RPC-like inter-

| Workflow API                                                         | Semantics                                                                                                                                                                                                                                                                                  |
|----------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>f.options(Opts).bind(Value   WorkflowDAG) → WorkflowDAG</code> | Create a workflow task <code>f</code> . Creates and returns a <code>WorkflowDAG</code> , whose value is lazily evaluated. The caller may pass the <code>WorkflowDAG</code> to another task. The return value of <code>f</code> can be a <code>WorkflowDAG</code> , i.e. a nested workflow. |
| <code>run(WorkflowDAG w, str name) → Value</code>                    | Run the workflow <code>w</code> and return the result. Optionally take a string identifier for this workflow.                                                                                                                                                                              |
| <code>run_async(WorkflowDAG w, str name) → Fut</code>                | Run the workflow <code>w</code> asynchronously and return a future that can be used to retrieve the result.                                                                                                                                                                                |
| <code>Ref.get() → Value</code>                                       | Used by the application to dereference to a value. Ref construction is backend-specific.                                                                                                                                                                                                   |
| <code>bool Opts.checkpoint=True</code>                               | True if the task's output should be saved.                                                                                                                                                                                                                                                 |
| <code>bool Opts.deterministic=False</code>                           | True if outputs are deterministically generated.                                                                                                                                                                                                                                           |
| <code>bool Opts.can_rollback=False</code>                            | True if task has no external outputs, or if they can be rolled back. If False, the task must be idempotent.                                                                                                                                                                                |
| <code>Fn Opts.rollback=null</code>                                   | If external outputs can be rolled back, a function to do so. The function must be idempotent, and any <code>WorkflowDAG</code> arguments must be a subset of the original workflow task <code>f</code> 's arguments.                                                                       |
| <code>Ref._id() → ID</code>                                          | Used by the workflow system to compare equality.                                                                                                                                                                                                                                           |
| <code>Ref._checkpoint() → Fut[Value]</code>                          | Used by the workflow system to coordinate checkpointing. The <code>Value</code> is the checkpoint data or metadata.                                                                                                                                                                        |
| <code>Ref._restore(Value)</code>                                     | Used by the workflow system to reload from a saved checkpoint.                                                                                                                                                                                                                             |

Table 1: Workflow API. Top: API calls exposed to the application. Middle: Task annotations specified by application or third-party library. Bottom: ExoFlow-internal Ref API, pluggable by execution backend.

face. Within a task, the application can invoke arbitrary local or distributed execution. For greater generality, we also adopt the *dynamic* task model [39]: tasks can dynamically invoke exactly-once nested workflows by returning a `WorkflowDAG`.

**Task annotations.** The application specifies semantics relevant to recovery at task invocation time (Table 1). The workflow system uses these to ensure correctness of: (1) coordination of distributed workflow checkpoints during execution, and (2) output rollback and task re-execution upon failure.

First, the application specifies whether to skip checkpointing a task's output. Note that the workflow system guarantees correctness, so this can be considered an optimization hint, e.g., to avoid recomputation for long tasks,

Next, the application can specify whether a task's outputs (both internal and external) are deterministic. This allows the workflow system to minimize rollback during recovery.

Finally, the application specifies whether a task can be rolled back and if yes, how to do so. Tasks with no external outputs, such as the data processing tasks in Figure 2, should set `can_rollback=True`. Tasks that have external outputs that cannot be rolled back should set `can_rollback=False` and ensure idempotence, as recovery may require re-execution.

Non-idempotent tasks with external outputs that can be rolled back should set `can_rollback=True` and the `rollback` callback. On failure, ExoFlow executes these rollback "tasks" in reverse dependency order before resuming execution. The rollback task can take any arguments available to the original workflow task, but the application must additionally guarantee that the rollback task is idempotent. For example, to implement the transaction in Figure 3, rollback for the `beginTxn` and `reserve` tasks could simply abort.

On run, ExoFlow checks the `WorkflowDAG` for specification errors and throws an exception if any are found. In particular, correctness requires the application to set checkpoints between each nondeterministic task and each downstream task with external output. Section 3.3 makes this precise.

**Internal outputs.** Direct task outputs are subject to limits of the execution backend. For greater flexibility, ExoFlow

allows outputs to include `Refs` created by the task. `Refs` are (optionally) pluggable by the execution backend. They are intended to capture volatile outputs that would be expensive or complex to natively support in ExoFlow, e.g., large distributed data or third-party framework context. For an AWS Lambdas backend, for example, values can be stored in an external (volatile) key-value store and the key can be passed in a `Ref`. Other tasks can dynamically get the value, which can throw an error if the value is irretrievable due to failure.

`Refs` are uniquely identifiable objects typically containing backend-specific metadata. A task can only return `Refs` that it created or that were passed to it by an upstream task. Then, upon failure, ExoFlow can either restore the `Ref` from a checkpoint, or trace the DAG back to the creating task. On re-execution, the task need not return the same `Refs` as its original execution. For example, with the annotation `deterministic=True`, it is only necessary that the *value* of a returned `Ref` is deterministic; the `Ref` itself may have a nondeterministic ID. This is safe because ExoFlow simply cancels tasks using the previous `Refs` and re-executes with the new `Refs`.

By default, `Ref` values are *immutable*. This improves recovery efficiency, as it simplifies checkpointing and minimizes task rollback. To capture task outputs that are expensive or impossible to materialize, we also support *stateful* references, i.e. *actors* [30]. An `ActorRef` extends `Refs` with application-defined methods that execute on the actor's state (Listing 1). However, mutable state is more complex to recover efficiently and correctly. Thus, compared to `Refs`, we limit how `ActorRefs` can be passed between workflow tasks (Section 3.4).

## 3.2 Model

We present a formal model of workflows to more precisely capture the API and assumptions. A *workflow*  $G = (V, E)$  is a directed acyclic graph with vertices  $V$  and edges  $E$ . Each vertex  $v_i$  has an associated function  $F_i$ , a function  $\mathcal{N}_i$  representing a (potential) source of nondeterminism, a nullable rollback function  $\mathcal{R}_i$ , and the annotations described in Table 1.

A workflow execution produces one internal and one

Figure 4: (a) Task annotations. Edge cuts represent `checkpoint=True`. (b) Passing references (small boxes) in an ML workflow. Blue Refs are actors that wrap TensorFlow worker state. (c) Passing an ActorRef in an ETL workflow. B and C call read-only methods on the Spark context actor.

external output per vertex, both nullable. For brevity, we do not consider tasks with multiple outputs. We denote an execution’s outputs by  $(O_{Int}, O_{Ext})$ , both mappings from vertex to a single output  $o_{Int}$  or  $o_{Ext}$ .  $F_i$  outputs  $o_{Ext}$  by adding it to a global set  $\mathcal{W}$ , which can be read by other tasks and external processes. Each  $F_i$  takes as inputs:

- $I_{Int}$ : Internal outputs of vertices with an edge to  $v_i$ .
- $w_i$ : A read of  $\mathcal{W}$ , i.e. the external outputs so far.
- $n_i$ : A nondeterministic value returned by  $\mathcal{N}_i$ .

In other words, an edge  $(v_i, v_j)$  indicates that  $v_i$ ’s internal output is passed to task  $v_j$ . Internal outputs passed between vertices are analogous to messages passed between processes in a message-passing model [23], except that the application must declare the “messages” (dependencies) before execution.

$\mathcal{N}_i$  captures nondeterministic inputs. For example, if  $F_i$  depends on the current time, then  $\mathcal{N}_i$  returns the current time. We assume that if  $\mathcal{N}_i$  reads some external state, the external state will not be rolled back (unless  $F_i$  is also rolled back via  $\mathcal{R}_i$ ).

The correctness condition relates outputs to a failure-free execution.  $W$  denotes all possible sequences of reads of  $\mathcal{W}$  by an external process.

**Definition 1** (Consistency).  $O_{Int}, O_{Ext}$  are consistent with a workflow  $G = (V, E)$  if  $W$  is monotonic and  $\forall w \in W$ :

$$o_{Ext} \in w \Rightarrow \exists i, O_{Ext}[i] = o_{Ext} \bigwedge (O_{Int}[i], o_{Ext}) = F_i([O_{Int}[j] \mid (v_j, v_i) \in E], \{O_{Ext}[j] \mid v_j <_G v_i\}, \mathcal{N}_i()) \bigwedge \{O_{Ext}[j] \mid v_j <_G v_i\} \subseteq w$$

More simply, from an external process’s perspective, if it sees an external output, then: (1) the same output was seen in all previous reads, (2) it must correspond to one invocation of some  $F_i$ , and (3) it also sees the external outputs of all predecessors of  $v_i$ . This is analogous to *global consistency* in message-passing [23], i.e. that every visible output has a corresponding task that created it. The goal is to provide a consistent execution under a crash failure model.

The application assumptions are as follows. For each  $v_i$ :

1. If  $v_j$  is concurrent with  $v_i$  ( $v_i \not\prec_G v_j$  and  $v_j \not\prec_G v_i$ ), then  $F_i(I_{Int}, w_i, n_i) = F_i(I_{Int}, w_i \setminus \{O_{Ext}[j]\}, n_i)$ .
2. If `deterministic=True`, then  $\{O_{Ext}[j] \mid v_j <_G v_i\} \subseteq w_i, w'_i \Rightarrow F_i(I_{Int}, w_i, n_i) = F_i(I_{Int}, w'_i, n'_i)$ .
3. If the  $o_{Ext}$  returned by  $F_i$  is not null, then either `can_rollback=False` or  $\mathcal{R}_i$  is not null.

- (a) If `can_rollback=False`, then  $F_i$  is idempotent. That is, if  $(o_{Int}, o_{Ext}) = F_i(I_{Int}, w, n_i)$  and  $(o'_{Int}, o'_{Ext}) = F_i(I_{Int}, w', n'_i)$ , then  $o_{Ext} = o'_{Ext}$ .
- (b) If  $\mathcal{R}_i$  is provided, then it is a deterministic and idempotent function of the task’s internal inputs. If  $(o_{Int}, o_{Ext}) = F_i(I_{Int}, w, n_i)$ , then  $\mathcal{R}_i(I_{Int})$  removes  $o_{Ext}$  from all past reads of  $\mathcal{W}$ .

(1) means that we do not consider cases in which a task  $v_i$  depends on a task  $v_j$ ’s external output, where  $v_i, v_j$  cannot be ordered in  $G$ . To ensure consistency,  $v_j$ ’s external output should be considered part of  $v_i$ ’s nondeterministic input, and  $v_j$  must set `can_rollback=False`. Regarding (3b), note that the meaning of removing  $o_{Ext}$  from past reads is application-dependent. For example, suppose  $F_i$  executes a transaction and  $\mathcal{R}_i$  aborts the transaction; if uncommitted reads are allowed, then  $\mathcal{R}_i$  does not need to roll back the reader.

**Nested tasks and references.** While not explicitly captured in the above model, nested tasks can be thought of as tasks that expand into a sub-workflow. Refs and ActorRefs are native data types that can be returned in a function’s internal output. Because actors are mutable, ActorRefs are versioned: if a caller writes to an actor by calling a method on its ActorRef, the caller’s resulting ActorRef is of a different version. This becomes relevant in Section 3.4, which discusses the rules that the application must follow to ensure exactly-once semantics when ActorRefs are passed between workflow tasks.

### 3.3 Guaranteeing exactly-once execution

Task annotations simplify the decision of when to commit task outputs. To illustrate this, we use Figure 4a, a modified version of the workflow described in Figure 3. We show the annotations for a workflow using an external two-phase locking (2PL) transaction system. `beginTxn` generates a transaction context with a random `txn_id`. The `acquire` tasks each attempt to acquire a lock on an external table row. If this is successful, we attempt to reserve the flight and hotel if available, then finally commit the transaction and place the order if both succeed. The cuts in Figure 4a indicate `checkpoint=True`.

As an example, we first consider the `acquire` and `commitOrAbort` tasks. `acquire` tasks are nondeterministic because they depend on the run-time state of the external table. `commitOrAbort` has `can_rollback=False` because it is impossible to abort a committed transaction and vice versa. Although `ac-`

quire can be rolled back (e.g., by aborting the transaction and releasing the lock), once we have started the `commitOrAbort` task, it is no longer safe to do so because the transaction may already be committed. Thus, we must ensure that both acquire outputs are saved before `commitOrAbort` starts. We can generalize this rule for the application as follows:

**Invariant 1** (External output commit). *For each workflow task  $v_i$  with `deterministic=False`, let  $G$  be the minimal subgraph that contains  $v_i$  and all downstream tasks (tasks for which there is a path from  $v_i$ ). Then, for each workflow task  $v_j$  with `can_rollback=False` in  $G$ , there must exist a vertex cut that partitions  $v_i$  from  $v_j$  such that all tasks in the cut have `checkpoint=True`.*

Intuitively the vertex cut of the sub-DAG defines a commit point for the nondeterministic output of  $v_i$ . There may exist multiple such cuts. For example, another acceptable specification in Figure 4a is to instead checkpoint the reserve outputs.

ExoFlow guarantees that at least one task frontier is fully checkpointed by the time `commitOrAbort` ( $v_j$ ) starts. Interestingly, this also tells us that we do not need to commit the acquire outputs synchronously. In particular, the reserve tasks in this case are deterministic, as their outputs depend only on whether the lock was acquired and the value stored in the external table, which cannot be modified while locked. Furthermore, their external outputs are not visible while the lock is held. Thus, in this case, it is safe to annotate the reserve tasks with `deterministic=True` and `can_rollback=True`. Together, these annotations allow ExoFlow to *overlap* the checkpoint of acquire’s outputs with execution of the reserve tasks, as long as the checkpoints are synchronized before `commitOrAbort`.

There is a similar requirement for rollback tasks. The rollback tasks in Figure 4a are conditionally invoked by the workflow system to undo external outputs of the acquire tasks. We must ensure that all inputs to the original acquire task are recoverable *before* execution. Otherwise, if the rollback task and its inputs fail simultaneously, it will be impossible to finish rollback. Thus, in Figure 4a, the application must set `checkpoint=True` for `beginTxn`, and ExoFlow synchronizes this checkpoint before executing the acquire tasks.

**Invariant 2** (Rollback durability). *For each path beginning at a task  $v_i$  with `deterministic=False` and ending at a task  $v_j$  that has a rollback function  $R_j$ , there must exist at least one vertex along the path with `checkpoint=True`.*

Unlike Invariant 1, here we only require checkpointing a single task to handle nondeterminism, as the availability of a rollback function  $R_j$  means that we do not need to commit to the original output. The checkpointed task can also be a task other than  $v_i$  or  $v_j$ . For example, if there were additional deterministic tasks between `beginTxn` ( $T$ ) and `rollback_acquire` ( $R$ ), then checkpointing any is sufficient.

Both invariants can be easily checked by walking the DAG passed to run. If an invariant is not met, the system throws an exception to the user. Annotations do therefore require user

```
@ray.remote
class SparkActor:
    def __init__(self):
        self.spark_context = connect(); self.df = None
    def generate_df(self):
        self.df = generate_df(self.spark_context).cache()
    @const
    def exec(self, seed: int) -> int:
        return exec(self.df, seed=seed).count()
    def _checkpoint(self):
        return self.spark_context.save(self.df)
    def _restore(self, path):
        self.df = self.spark_context.load_df(path)
```

Listing 1: Pseudocode for passing a Spark DataFrame by actor. The execution backend implements the actor. Public methods are user-defined. Methods prepended by `_` are called internally by ExoFlow.

cooperation, but note that a user with minimal performance needs can use the defaults in Table 1. This specification trivially satisfies the invariants and indeed corresponds to current workflow systems that commit all task outputs. Section 4 describes how ExoFlow leverages the invariants to improve run-time performance for more sophisticated specifications.

Note that the system will not durably record a nested workflow returned by a task with `checkpoint=False`. To simplify recovery, we disallow sub-tasks with `checkpoint=True`, as we may lose all references to these checkpoints upon failure. We also disallow `can_rollback=False` and `rollback`, as these are challenging to recover without workflow durability.

### 3.4 References

Immutable Refs enable efficient passing of large and distributed data between workflow tasks. For example, Figure 4b shows how the `Ingest` task from Figure 2d can use Refs to return distributed in-memory data. ExoFlow tracks inter-task Ref dependencies for recovery purposes, while the execution backend handles intra-task execution (e.g., `get`).

Some cases require stateful actors for performance. For example, the blue boxes passed between train tasks in Figure 4b are ActorRefs representing a training worker’s state, e.g., a Distributed TensorFlow session. This helps avoid expensive materialization, such as the worker’s local model copy.

Guaranteeing exactly-once semantics for state is challenging. If one task writes the ActorRef’s state, the output is visible to any other task holding a reference to the same actor. This can cause cascading rollbacks on failure depending on how ActorRefs are passed. Furthermore, checkpointing is more challenging if multiple tasks write concurrently to the actor, as the system must ensure that the actor checkpoint is consistent.

To simplify recovery, we limit ActorRef passing to two patterns, analogous to a read-write lock. By default, the ActorRef is in “write” mode. In this mode, only one workflow task may have a reference to the actor at a time. That task can call any actor methods as long as they finish before the task returns. For example, in Figure 4b, only one train task refers

to each actor at a time. ExoFlow can then checkpoint the actors' state between tasks, and on failure, roll back the actors with the workflow. This pattern is useful for abstracting and checkpointing distributed workers in third-party frameworks such as Distributed TensorFlow [9] and Flink [20].

If there are multiple concurrent workflow tasks with a reference to the same actor, however, the tasks are restricted to read-only methods annotated by the user, as shown in Listing 1. Figure 4c shows an expanded Figure 2b in which we use an ActorRef to capture a Spark DataFrame. Initially, A has the only ActorRef, so it can write to the actor's state (`generate_df`). B and C share the actor concurrently, however, and so they are limited to read-only methods (`exec`). Invoking a write method such as `generate_df` would throw a run-time error.

Similar to a read-write lock, ExoFlow can only provide correctness if the application respects certain conditions. In particular, the workflow tasks must explicitly pass ActorRefs through their outputs and arguments. Any other ActorRefs cannot be tracked by ExoFlow and exactly-once semantics is not guaranteed, similar to reading a variable without holding the lock. Also, while methods may be called asynchronously on an ActorRef, a workflow task must synchronize any outstanding calls to an actor before returning.

## 4 Architecture

We describe the ExoFlow design and the requirements of the pluggable execution backend and persistent storage. The workflow controller is a long-running service that can be sharded by workflow (Figure 5). Persistent storage can be implemented by any durable blob storage supporting puts and gets with read-after-write consistency, such as Amazon S3. The execution backend should implement a *remote function invocation* interface, used by the controller to scale checkpointing and task execution. The backend should provide: (1) ability to detect and report task and Ref failures, and (2) guarantee no resource leaks for failed task execution and Refs.

The controller runs as an event loop with the following events: task or checkpoint completes, and task or checkpoint failed. All critical workflow state, such as the workflow DAG, is cached by the workflow controller and written-through to persistent storage, making it simple to also recover the workflow controller. On restart, the controller simply scans the storage for any unfinished workflows, and re-runs to completion.

### 4.1 Workflow execution

The workflow control layer is implemented using the system Ray [37]. Ray provides remote task invocation, distributed immutable memory, and distributed actors. However, Ray only provides at-most-once or at-least-once guarantees and lacks built-in persistence for memory and actors. Thus, Ray tasks and actors are distinct from workflow tasks and actors, which execute exactly-once and can be natively checkpointed.

We use Ray actors to implement the workflow controller and task executors (Figure 5). The controller uses Ray's

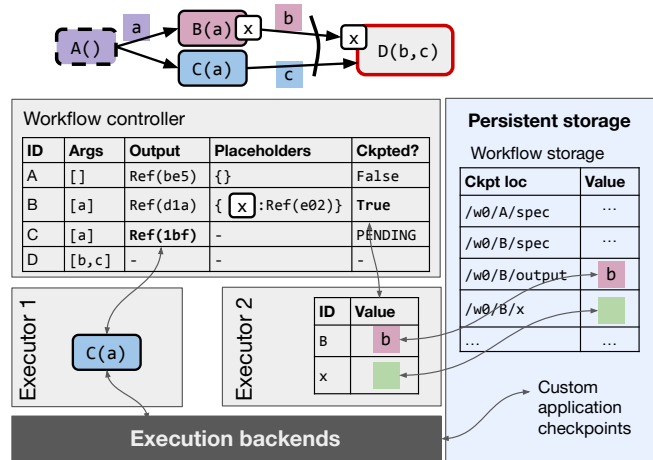

Figure 5: Workflow architecture. The controller and executors are RPC-like services built using Ray actors. Each invocation on these services returns a distributed future (system-internal Refs).

*distributed futures* [47] to coordinate task execution and checkpointing. Distributed futures are an asynchronous extension of RPC where each invocation returns a future pointing to the eventual and possibly remote return value. Ray actors and distributed futures also directly implement application-facing references (Section 3).

We build on Ray for three reasons: (1) futures make it simple for the controller to manage concurrent task execution and checkpointing, (2) passing remote values by reference avoids bottlenecks from large task outputs being passed directly through the centralized controller, and (3) the RPC-like interface straightforwardly and efficiently wraps other execution backends. For example, the Lambdas backend is implemented by wrapping a synchronous Lambda invocation in a Ray task.

The controller is a state machine where the state describes the current execution status of a workflow DAG and is persisted in storage. On run, the controller logs the workflow DAG specification (arguments, opts, etc.) to durable storage and triggers execution. On each iteration of the event loop, the controller may select a workflow task whose inputs are ready and submit the task to an executor. For example, in Figure 5, the controller submits C to executor 1 and immediately receives back the distributed future `Ref(1bf)`. The controller uses this system-internal Ref to wait for task completion, and then passes it to downstream workflow tasks (e.g., D).

Checkpointing is carried out asynchronously by background threads on the executors, enabling parallel and distributed checkpoints that are not bottlenecked by the centralized controller. To checkpoint an output, the executor asynchronously writes a copy to a deterministic storage location (e.g., `w0/B/output` in Figure 5). The controller considers the checkpoint done once it is fully written. For convenience, the controller can also synchronize the checkpoint by requesting a signal from the executor (controller to executor 2 in Figure 5).

Checkpoint synchronization is required: (1) at the end

of a workflow, (2) before executing a task with `can_rollback=False`, and (3) before executing a task with a `rollback` option. Section 6 evaluates a simple policy that synchronizes all pending checkpoints for a workflow in any of these cases and shows that this provides sufficient performance for key applications. A more sophisticated policy may synchronize only the minimum necessary.

ExoFlow handles passing and checkpointing application references (Section 3.4). When a task finishes, the executor replaces any `Refs` and `ActorRefs` appearing in the task’s output with placeholders, e.g., `x` in Figure 5. When passing the output to another task, the controller also passes a list of concrete references (`Ref(e02)` for `x`) used by the executor to fill the placeholders. Task checkpoints include a list of `Ref` checkpoint locations, which are written in parallel and distributed fashion. The controller restores and swaps `Refs` after a failure.

If a workflow task returns a `WorkflowDAG` as its output, the controller simply records the sub-workflow (if `checkpoint=True`), points the output of the parent task to the output of the sub-workflow, then resumes execution.

## 4.2 Workflow recovery

The controller handles task and checkpoint failures. In both cases, the protocol rolls back any previous outputs as needed, then rolls “forward” by re-executing workflow tasks.

The first step is to determine the re-execution task frontier. For example, suppose `C` in Figure 5 fails because we lost `A`’s cached output `Ref(be5)`. Then, we walk the DAG backwards from `C` and add each visited task node to the re-execution set. For each task, we check argument availability, i.e. whether the value has a checkpoint or a live `Ref`. If all arguments are available, then we terminate. Else, we add the tasks that create the arguments (`A`) to the re-execution set. If a visited task has `deterministic=False`, then we also add all tasks downstream to the re-execution set. Thus, if `C` fails and we need to re-execute `A`, we also re-execute `B`, even though it has a checkpoint.

From the re-execution task set, we carry out rollback. In reverse-topological order of the re-execution set, we first clear any cached output `Refs` and output checkpoints, e.g., `/w0/B/output` and `/w0/B/x` for `B`. If it has a `rollback` task, then we re-execute this task, using the same protocol as normal task execution. Finally, we resume workflow execution as normal, starting from the earliest task frontier of the re-execution set.

Critical controller state is persisted, so recovering from controller failure is straightforward. On failure, all in-memory controller state (the table in Figure 5) is wiped, including any `Refs`. On restart, the controller simply scans persistent storage for incomplete workflows, rebuilds its in-memory table, then re-executes them using the described protocol.

**Correctness.** We provide informal proofs that the final outputs are consistent (Definition 1). During normal execution, this follows from the execution protocol: starting from a consistent prefix of outputs, executing a task will produce another consistent prefix.

For recovery, we first consider reconstruction of internal outputs, i.e. values returned by workflow tasks. If the task is deterministic, then the reconstructed output will match the original. If the task is nondeterministic, then the described rollback procedure returns execution to a consistent prefix that does not include any results downstream to the original output.

Next, we consider external outputs: tasks with `can_rollback=False` or `rollback` defined. For a task `T` with `can_rollback=False`, the application guarantees idempotence, so it is enough to show that once `T` begins, the failure-free execution will include the same inputs for `T`. To show this, we rely on Invariant 1 (Section 3.3) and checkpoint synchronization (Section 4.1). The system synchronizes the partition provided by Invariant 1 before submitting `T`; thus once `T` begins, any future recovery procedure will never add `T` to the rollback set.

If `T` instead has `rollback` defined, we must show that if `T` fails, `rollback` will complete with the same view of inputs as `T`’s previous execution, before re-executing `T`. Invariant 2 and checkpoint synchronization guarantee that we can deterministically and idempotently recreate `rollback`’s original inputs.

Correctness also requires preventing conflicts between different executions of the same task. For task checkpoints, if the backend’s failure detection for executors is reliable, then by the time we re-execute `T`, we can be sure that there is no concurrent checkpoint in progress. Under unreliable failure detection, the ExoFlow controller assigns unique checkpoint locations to prevent races between concurrent executions. This requires one extra durable write before each task execution to record the expected checkpoint location.

For a task that returns `Refs` or `ActorRefs`, the execution backend can provide reliable failure detection for references by killing all copies of a `Ref` before reporting failure to ExoFlow. Alternatively, a safe and efficient method that works for both crash and fail-stop failures is to generate unique references for each execution.

## 4.3 Execution backends

**Integration.** ExoFlow references are compatible with existing third-party mechanisms for task communication and recovery. For example, Ray does not provide exactly-once semantics, but it does automatically reconstruct `Refs` created by deterministic (at-least-once) tasks [47]. ExoFlow encourages hierarchical recovery, wherein the execution backend can attempt to handle `Ref` failures first, then throw unrecoverable errors up to the workflow controller.

ExoFlow is compatible with backends that use logging and checkpointing. In general, log-based tasks would use `deterministic=True` and `can_rollback=False` annotations, while checkpoint-based tasks would use `deterministic=False` and `can_rollback=True`. The backend can also directly leverage ExoFlow for checkpointing instead of supplying a user-defined `rollback` function; this shifts the responsibility of checkpoint coordination to ExoFlow and automatically enables optimizations such as overlapping with execution.

**Preventing leaks.** The workflow layer ensures that previous Refs and pending checkpoints do not leak; invalid Refs and checkpoints are dropped during rollback. The execution backend must additionally prevent resource leaks for dead Refs. Dead Refs can be deleted via reference counting (the controller calls back to the backend once a Ref goes out of scope) or garbage collection (the backend scans the controller’s in-memory state for dead Refs).

## 5 Implementation

ExoFlow is built on Ray v2.0.1, which uses gRPC [6] for tasks and actors and a custom shared-memory object store for Ref storage [37]. ExoFlow is implemented as a Ray Python program in 4k LoC.

We implemented two execution backends for ExoFlow: Ray itself (“ExoFlow-Ray”) and the serverless FaaS offering AWS Lambdas (“ExoFlow-Lambdas”). In each case, a typical deployment would use one Ray node to host the ExoFlow controller. In ExoFlow-Lambdas, the controller node takes the place of the gateway provided by AWS for their proprietary serverless workflow offering (Step Functions).

We chose to implement ExoFlow on Ray for three reasons:

1. Support for first-class references to immutable data, which we use to implement Refs.
2. Support for actors (stateful workers), which we use to implement ActorRefs.
3. Low task and actor overhead, similar to pure RPC.

We also use Ray actors to implement executors. Workflow tasks are stateless, but we use actors to store execution state about checkpoints that are pending after task completion.

To build ExoFlow on another actor system such as Akka [2] or Orleans [13], we must implement Refs. This is straightforward for workloads that only pass small data. For data-intensive workflows, one can build a custom in-memory store that is tightly coupled to executors, as in Ray, or use an external key-value store. The latter requires low implementation effort, but may result in poor locality. It is ideal if the execution backend cannot be modified, e.g., to support values larger than the Lambdas response size in ExoFlow-Lambdas.

## 6 Evaluation

Our evaluation covers the following questions:

1. What overheads does ExoFlow add to at-least-once or at-most-once execution backends?
2. How can applications leverage first-class references and task annotations to have greater flexibility in recovery?
3. How does this flexibility in recovery strategy affect performance during execution and recovery?

We compare primarily against these baselines: (1) exactly-once workflow systems: Airflow [3], “standard mode” AWS Step Functions [14], and the serverless workflow system Beldi [49]; and (2) at-least-once distributed DAG systems: “express mode” AWS Step Functions [14] and Ray [37].

Given the high execution overheads of exactly-once workflow systems such as Airflow (Section 6.4), to fairly address questions (1) and (3), we also compare against the following ExoFlow modes:

1. SyncCkpt: Task outputs are synchronized before executing downstream tasks. This is used to simulate the recovery strategy of exactly-once workflow systems such as Airflow.
2. NoCkpt: All task outputs except the final are skipped. This is used to simulate the recovery strategy of an at-least-once or at-most-once system. The application must guarantee that all tasks are deterministic and idempotent to achieve exactly-once semantics.
3. AsyncCkpt: The default mode of ExoFlow. Task outputs are only synchronized where necessary, to provide exactly-once semantics.

We conduct all of the experiments using the AWS cloud, specifically in the us-east-1 region. ExoFlow and execution backends are hosted on EC2 and use Amazon S3 (or EFS in Section 6.2) for persistent storage.

### 6.1 ML training pipelines

We show how ExoFlow enables a flexible recovery-performance tradeoffs for the workflow in Figure 2d. We use an image classification example adapted from Azure MLOps [4]. An ETL Ingest task (1 r3.2xlarge node) downloads the compressed data from S3. “1×” in Figure 6 indicates one data copy with 569 raw image files and total size 225MB. The task loads the images into memory, and performs data cleaning and normalization with at-least-once parallel Ray tasks. The dataset (1.4GB of memory per data copy) is partitioned and passed using Refs to the dataset augmentation tasks, via Ray’s shared-memory object store. Dataset augmentation again uses Ray at-least-once tasks to apply random cropping, flipping, and color adjustments to the base dataset, once per epoch. Dataset augmentation requires repeatedly processing the same dataset in a tight loop with training. Therefore, the dataset augmentation stage accumulates a total intermediate and checkpoint size of 67GB and 18GB respectively, per data copy. Training tasks are colocated and pipelined with dataset augmentation (1 g4dn.12xlarge node, 4 NVIDIA T4 GPUs). We use PyTorch data-parallel distributed training and the ConvNeXt Tiny (28.6M parameters) model. PyTorch workers are passed using ActorRefs.

Figure 6L shows end-to-end duration of 25 epochs without failures of different ExoFlow recovery modes, as a function of dataset size. Here, we also include Selective AsyncCkpt (skip checkpointing dataset augmentation outputs) and Workflow Tasks (include at-least-once Ray tasks for data processing in the workflow DAG instead of passing volatile Refs).

Duration predictably grows approximately linearly with the dataset size for all strategies. The overhead of Workflow Tasks is high because each data processing task is durably (and unnecessarily) logged as part of the workflow. For the same

Figure 6: End-to-end duration for the ML workflow application shown in Figures 2d and 4b. **Left:** End-to-end duration without failure. **Right:** End-to-end duration with different failure types. The shadow represents the execution time without failure.

workflow graph, the overhead for larger data varies depending on the recovery strategy. NoCkpt represents the best possible performance, where only the final model is checkpointed. SyncCkpt represents existing workflow systems (Figure 2c) and its overhead grows the most because checkpointing overhead grows faster than computation overhead. AsyncCkpt’s overhead grows less because checkpointing of augmented datasets is overlapped with training tasks. Selective AsyncCkpt has nearly identical duration as NoCkpt because the Ingest checkpoint is perfectly overlapped with training tasks.

Meanwhile, Figure 6R shows end-to-end duration in different failure scenarios compared to normal run-time execution (dark): whole cluster failure (including the ExoFlow controller); in-memory ingest data lost; PyTorch worker actor lost; augmentation task lost; and in-memory augmented data lost. Here, we see the tradeoff between recovery and performance. SyncCkpt has similar or better recovery time overhead than NoCkpt for cluster and ingest data failures because it avoids re-executing the Ingest task, but overall it does worse because of high normal run-time overhead. Selective AsyncCkpt checkpoints the Ingest data asynchronously, so recovering from cluster and ingest data failures is fast because it simply restores the Refs from the checkpoint. Together, Figure 6L and R demonstrate how *the developer can flexibly choose the best recovery strategy*.

Figure 6R also demonstrates ExoFlow’s *broad failure coverage and ability to integrate with Ray’s built-in recovery*: Ray automatically reconstructs deterministic data processing results but does not handle persistence or actor recovery [47]. Thus, ExoFlow handles the first four failures, while Ray handles the last. Recovery for the last two failures is fast because rollback and checkpoint restore are unnecessary.

## 6.2 Stateful serverless workflows

We compare ExoFlow on a travel reservation benchmark [26] to Beldi [49], a recent system for fault-tolerant and transactional stateful serverless workflows that uses *intent logging* to ensure exactly-once semantics. Our implementation uses Beldi’s APIs for reading and writing state but the ExoFlow controller with an AWS Lambdas backend for workflow execution and recovery. We use a single m5.16xlarge instance to host ExoFlow and EFS for persistent storage, which

provides lower latency than S3. The benchmark procedure follows [49], and we report response latency in Figure 7a.

ExoFlow achieves about 51% lower p50 latency than Beldi for request rates up to 400, despite using the same execution system (AWS Lambdas) and state APIs (Beldi). This is because most of the workflows have deterministic computation and no external effects (i.e. read-only), so the additional logging used by Beldi is unnecessary for correctness. Furthermore, Beldi schedules an additional Lambda function to orchestrate others, while ExoFlow directly schedules Lambdas. When requests/s is higher than 700, ExoFlow’s median latency is greater than Beldi’s. This is due to the Lambdas invocation bottleneck at the ExoFlow controller node and can be easily removed through sharding across workflows. The Lambdas gateway used in Beldi is likely sharded internally.

The use of ExoFlow as a Lambdas gateway has benefits in recovery time. Figure 7a also shows latency with a 10% failure rate for all Lambdas. ExoFlow directly invokes Lambdas, so it can detect failures and recover virtually instantaneously, resulting in 0-31% extra overhead in p99 latency. In contrast, Beldi is fully decentralized and relies on timeouts for recovery correctness. Thus, although Beldi-style logging may reduce re-execution on recovery, the actual recovery time would be lower-bounded by a timeout ([49] evaluates 1min as a possible lower bound).

Figure 7b further demonstrates the performance benefit of exposing application semantics to the workflow system. We report latency of the most complex workflow in the benchmark, the trip reservation request described in Figure 3. Beldi implements the transaction using two-phase locking (2PL). We demonstrate progressive improvement over the original solution by varying the execution and recovery strategy. First, we eliminate Beldi logs for dynamic task invocation, as the DAG can be easily specified upfront, reducing p50 and p99 latency by 17% and 25% respectively (-wal). Next, we parallelize the hotel and flight reservation tasks, further reducing p50 and p99 latency by 17% and 15% respectively (+parallel). Beldi executes these tasks sequentially because asynchronous invocation does not allow retrieval of the reply. Finally, we split each reservation task into two steps: lock acquisition and reservation, as seen in Figure 4a. -async shows that with synchronous checkpoints,

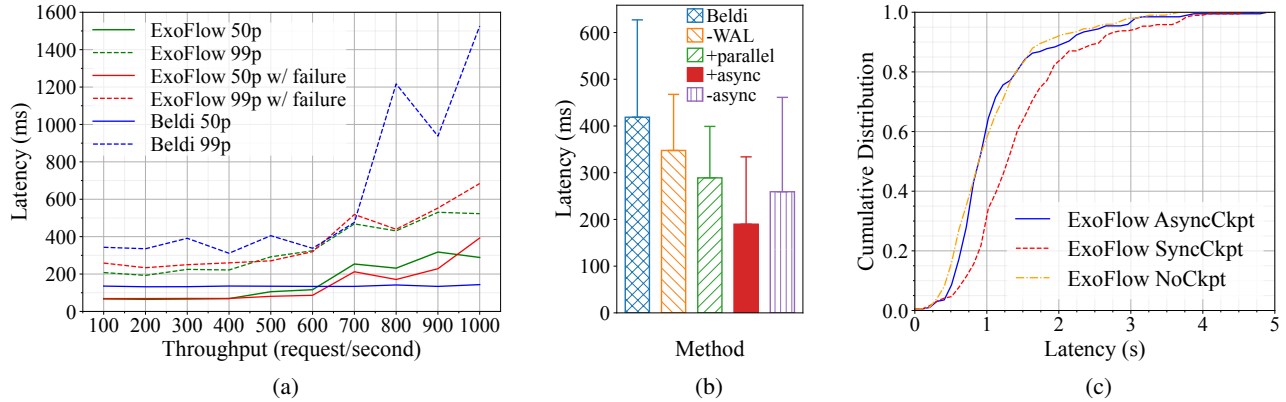

Figure 7: (a) Response latency percentile for a serverless travel reservation benchmark [25]. (b) Median latency of the trip reservation request from the travel reservation benchmark. Error bar represents 99-percentile latency. (c) Latency CDF of online-offline graph processing.

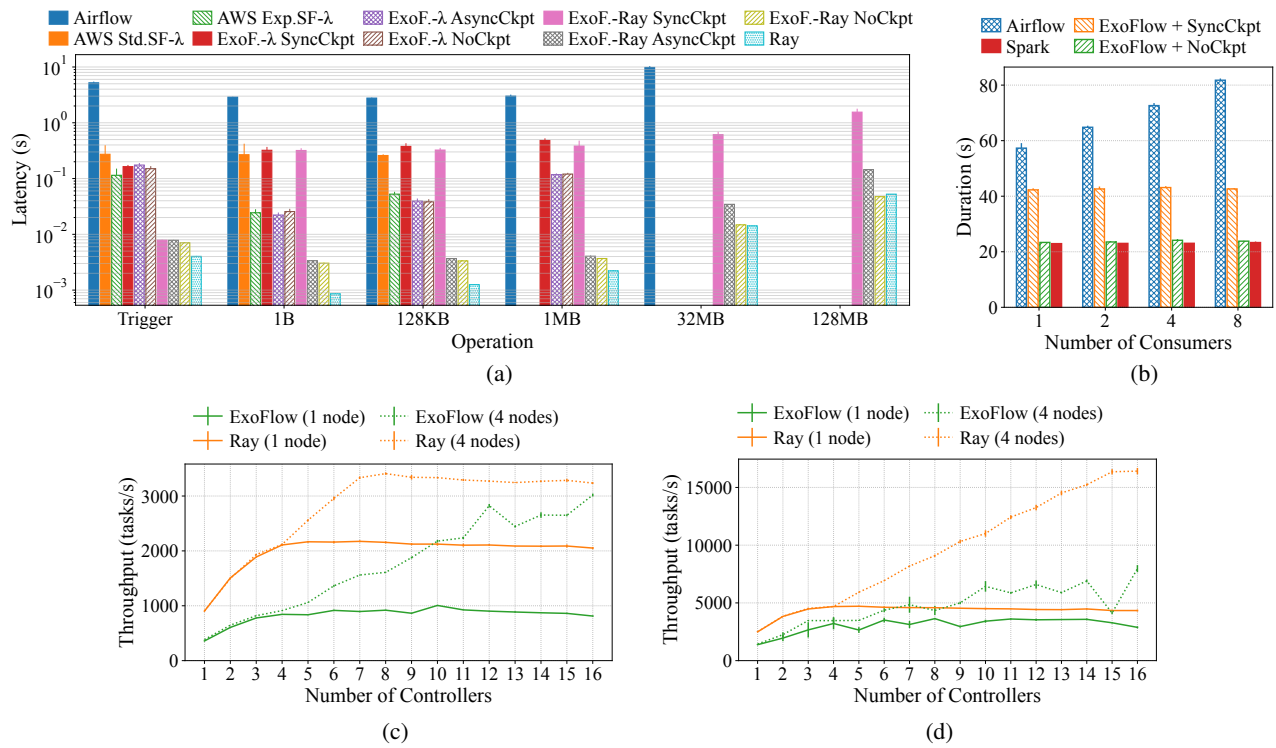

Figure 8: Microbenchmarks. (a) Triggering and data passing latency of ExoFlow and other workflow systems, using AWS Lambda ( $\lambda$ ) and Ray as execution backends. Missing bars indicate limitations in inter-task communication. (b) End-to-end run time for the ETL workflow shown in Figures 2b and 4c, compared with Airflow and native Spark. (c, d) Maximum task throughput (c: 1 task/DAG; d: 100 tasks/DAG) of 10k tasks, compared against Ray as an optimal baseline, on 1 node and 4 nodes.

this actually increases latency due to the added task. However, +async shows that by overlapping checkpointing with execution, we can further reduce p50 and p99 latency by 34% and 16% respectively, without compromising correctness.

### 6.3 Online-offline graph processing

Distributed graph processing systems can be generally divided into stream vs. batch processing [36]. Streaming systems can handle continuous updates and produce timely results, but may not offer the same precision as batch systems.

We use references in ExoFlow to link stream and batch

graph processing, producing a single application that can both handle online queries and produce periodic exact results. We use Ray actors to implement a version of Kineograph [21], a streaming graph processing system that uses distributed snapshots for consistency. Each workflow task ingests one epoch of incoming graph updates to compute a graph snapshot and an online approximate result, and we periodically pass the snapshot in-memory to another workflow task that uses Spark to compute the full result.

We evaluate on the SNAP Twitter follower network

dataset [33] (41M nodes and 1.5B edges), with each input record representing an edge insert event. We run the push-model TunkRank algorithm used by Kineograph to compute Twitter user influences on a 3-node r3.8xlarge cluster, 1 for streaming and 2 for the Spark cluster. We use two Ray actors to process the input stream and use ExoFlow to checkpoint and pass the ActorRefs between streaming tasks. Each streaming task represents a 10-second epoch and also returns 4 Refs that represent the partitioned graph snapshot. These Refs are passed to a Spark task every 20 epochs. Latency is reported for 200 epochs, after an initial warmup of 150 epochs. The average digestion rate is 44.94k tweets per second with our dataset. Kineograph achieves about 40k tweets per second with 2 ingest node + 48 graph nodes with a similar setting. We outperform Kineograph likely because we utilize shared memory for data passing, with more powerful hardware, which significantly reduces overhead of data pushing.

Figure 7c shows a CDF for latency from input event to the earliest time that the event is reflected in a streaming task’s output (although inconsistent results can be returned earlier by querying the ingest actors directly). AsyncCkpt allows the snapshot to be viewed before it is checkpointed. NoCkpt has impractical recovery overhead, but we use it as a performance baseline. AsyncCkpt achieves similar latency as NoCkpt, meaning that checkpointing overhead remains stable as the graph grows larger; this is because streaming tasks pass through previous Refs that are already checkpointed, so ExoFlow only checkpoints new data on each epoch. SyncCkpt is similar to Kineograph, checkpointing the snapshot before making it visible, and adds less than 1s latency. Finally, the error rate of the online results and the batch processing task duration both grow linearly over time, confirming the tradeoffs between batch vs. stream processing.

## 6.4 Microbenchmarks

**Latency.** With equivalent backends, ExoFlow matches or reduces execution overheads of existing workflow systems while enabling more flexible inter-task communication. Figure 8a (1 m5.8xlarge instance) shows the latency of workflow execution (“Trigger”) and task execution with different size arguments. We use exactly-once systems (Airflow [3], AWS Standard Step Function [14]) and at-least-once systems (AWS Express Step Function [14], Ray [37]) as baselines. Airflow is an industrial custom-built workflow system while Step Functions are the AWS-native workflow offering for Lambdas.

First, with the Lambdas backend, ExoFlow has similar trigger latency as AWS Standard Step Function. Airflow has generally high overhead due to coordinating execution through a database, which can easily lead to inefficient scans.

“1B” in Figure 8a compares minimum task execution latency. ExoFlow-Lambdas achieves comparable latency as AWS Step Functions, as the primary overheads for exactly-once and at-least-once execution come from durability and Lambdas invocation, respectively. ExoFlow-Ray improves

upon the latter as it uses Ray for execution.

Finally, we compare the ability to pass large data between tasks. AWS Step Functions limit data passing to 256KB, but plain Lambdas have a size limit of 6MB. Thus, ExoFlow-Lambdas can actually support larger data sizes. This could be improved further with Refs, e.g., with Redis [44] for distributed memory. Airflow’s XCom [1] can support slightly larger data but is fundamentally limited by its database-centric design. Meanwhile, ExoFlow-Ray uses Ray Refs for efficient data passing. The gap between AsyncCkpt and NoCkpt latency is small but grows with data size; although the checkpoint is asynchronous, ExoFlow synchronously copies the data to guard against concurrent writes.

In summary, ExoFlow’s low execution overheads make it a practical replacement for existing workflow systems, and it enables greater flexibility in task communication and recovery.

**Data sharing for ETL.** We evaluate ExoFlow against Airflow for a Spark workflow similar to Figure 2b (1 m5.8xlarge instance, 4GB Spark memory). Figure 8b measures total run time for a workflow that uses Spark to generate a 1GB random dataset, followed by multiple downstream tasks that consume the data with data sampling Spark jobs. Such a workflow requires orchestration across Spark jobs, which Spark does not provide, and is therefore often run on a workflow orchestrator such as Airflow.

Airflow run time grows proportionately with the number of consumers because they cannot share data in-memory. Meanwhile, ExoFlow scales well even with synchronous checkpointing because consumers share data via Spark’s native cache. Furthermore, ExoFlow runs as fast as native Spark alone, while facilitating composition with other systems as well.

**Throughput and Scalability.** We measure maximum throughput with varying numbers of controllers, (AWS m5.2xlarge) nodes, and tasks per DAG. We use Ray as the optimal baseline, as Ray is also the execution backend.

Figure 8c (1 task/DAG) shows that ExoFlow and Ray both reach saturation after 4 controllers on one node. With 4 nodes, scalability continues, and the gap between ExoFlow and Ray narrows at around 16 controllers. Figure 8d (100 parallel tasks/DAG) shows that throughput overall improves via task batching. Again, with four nodes, both ExoFlow and Ray scale linearly with the number of controllers. ExoFlow achieved roughly 50% of Ray’s throughput, due to additional overhead from workflow orchestration and ensuring exactly-once semantics.

## 7 Related Work

**Workflow systems.** Industry workflow systems [3, 5, 7, 14] orchestrate execution and recovery for distributed applications by durably logging the workflow, checkpointing task outputs and replaying failed tasks. However, they require external outputs to be idempotent and significantly limit how tasks can pass data to each other (Section 2).

Many workflow systems for FaaS focus on stateful serverless workflows. Several provide a fault-tolerant transactional key-value store interface [45, 46, 49]. ExoFlow is agnostic to external state APIs and implementation and factors out execution and recovery orchestration from such systems.

Some stateful workflow systems offer a fault-tolerant actor programming model [8, 15, 16]. A common recovery technique is *event sourcing*, i.e. durably logging nondeterministic events. However, this requires the developer to use special APIs for nondeterministic code and can add higher overheads than necessary when deterministic replay is not required for application correctness [23, 38]. ExoFlow also supports pluggable actors but only with coarse-grained logging (i.e. recording the workflow DAG) and checkpoint-based recovery (Section 3.4). This is intentionally minimal, as it enables composition of both log- and checkpoint-based actor implementations.

ExoFlow is similar to DARQ [35]: both use composable atomic steps (tasks) and asynchronous checkpointing. Unlike DARQ, ExoFlow exposes references and annotations to avoid materializing and/or persisting outputs where possible.

**Dataflow systems.** Many dataflow systems use the DAG model [22, 31, 48]. Several use *lineage reconstruction* for recovery, a form of logging that records the DAG but not the data, to reduce run-time overhead. CIEL [39, 41] also introduces *dynamic tasks*, which we adopt. However, these systems target data processing applications in which all tasks are stateless and deterministic. Ray proposes a unified API for DAGs and actors [37], which we also adopt, but cannot support exactly-once semantics or persistence [47]. Tachyon [34] proposes a method of optimizing checkpoints for lineage-based systems; this could be applied to a future version of ExoFlow.

Other systems such as Naiad [38], Apache Flink [18] and Canary [43] implement both batch and streaming dataflow with message passing and global checkpoints at run time for recovery. This produces lower latency but requires more rollback on failure; it can also add more overhead for applications with frequent external outputs [23]. ExoFlow augments log- and checkpoint-based systems by orchestrating recovery across systems with different internal strategies (Section 6.3).

Falkirk Wheel [27] targets efficient and flexible recovery for batch *and* streaming. It uses logical message timestamps to transparently determine the minimum to roll back on failure. ExoFlow provides practical recovery for black-box functions (tasks) by asking semantics from the developer through references and task annotations.

**Actor systems.** The actor model is a distributed programming model where processes communicate through asynchronous method calls [30]. Most systems do not guarantee exactly-once semantics [2, 12, 17, 47]. ExoFlow provides a limited exactly-once actor model to support workflows that pass actors between tasks. Meanwhile, the application has full flexibility of existing actor systems within a task.

**Message-passing systems.** Message-passing systems are a generalization of actors in which processes communicate

through message sends and receives. There is a large body of work on recovery for message passing, primarily focusing on logging vs. checkpointing [23]. Our work adapts these techniques to the distributed workflow setting and aims to compose log- and checkpoint-based applications.

## 8 Discussion

**References for framework interoperability.** Like other dataflow systems, ExoFlow captures the *logical* data movement in an application. ExoFlow also aims to enable *interoperability* across distributed execution frameworks, unlike abstractions such as RDDs [48] or timely dataflow [38] that are tightly coupled to a specific framework. This motivates some of the differences between Refs and ActorRefs vs. other dataflow abstractions: they can be used to capture third-party data and context, they are serializable, and they do not impose a particular model of parallelism.

**Limitations.** Using ExoFlow effectively requires developer effort. ExoFlow offers recovery flexibility but the developer must choose the right tradeoff for their application. For example, the developer must decide how large a workflow task should be, and whether checkpointing the output is desirable. Currently task annotations are also very coarse-grained, which makes the system general-purpose but also makes it more challenging for an application to achieve optimal performance and recovery overheads.

There are a number of future directions towards improving ExoFlow's interfacing with external systems. First, while Refs allow the application to efficiently pass data between workflow tasks, reading and writing a Ref's data may still require data movement to or from an external framework. Second, currently ExoFlow does not support transactions, i.e. there is no way to specify that a task should be rolled back if another task fails. In this case, the developer must manually roll back the effects of both tasks, e.g., in a final `commitOrAbort` task. Finally, for cases where tasks read and write external state, capturing more fine-grained semantics could reduce developer burden and improve performance. For example, native support for popular types of external state (e.g., a database) could be added.

## 9 Conclusion

Many existing distributed systems provide specialized, efficient, and transparent recovery for specific application domains. ExoFlow has an orthogonal and complementary goal. To unify heterogeneous applications, we must provide *general* and *interoperable* recovery methods. The greatest challenge is to gain sufficient application semantics without sacrificing flexibility. ExoFlow presents one approach that strikes a balance between usability (minimal annotations, compile-time safety checks) and functionality (flexible Refs, automatic recovery). In doing so, we hope to provide universal recovery that matches a universal API: the workflow DAG.

## Acknowledgement

We thank the OSDI reviewers and our shepherd, Steven Hand, for their valuable feedback. We also thank Haoran Zhang and Vincent Liu for their insightful discussions and help with Beldi. ## A Artifact Appendix

### Abstract

Our artifact includes a comprehensive guide and the source code of the project that allows the evaluators to validate the claims made in ExoFlow. Our artifact runs on Amazon AWS without additional requirements or dependencies. Deploying the code, performing the measurements, generating the plots, and running the benchmarks depend on some third-party frameworks including Anaconda, awscli, and Ray. Please refer to our Github repository <https://github.com/suquark/ExoFlow> for the latest instructions on reproducing the results.

### Scope

The artifact allows the evaluators to validate the claims made in the ExoFlow paper (mostly in the figures) and provides a means to replicate the experiments described. The artifact can be used to set up the necessary environment, execute the main results, and perform microbenchmarks, thus providing a comprehensive understanding of ExoFlow's capabilities.

### Contents

Our artifact includes a comprehensive guide designed to assist the evaluator in setting up and running experiments for the ExoFlow paper. It is organized into three primary sections: Local Setup, Main Results, and Microbenchmarks.

The Local Setup section provides instructions to set up an initial AWS EC2 instance. All subsequent experiments will be conducted within that instance.

The Main Results section contains instructions to reproduce the main experiments (ML training pipelines, Stateful serverless workflows, Online-offline graph processing) presented in our paper. These experiments may take a significant amount of time to run (>30 hours) for evaluation. Therefore, we provide options for both batch running experiments and testing individual data points.

The Microbenchmarks section includes instructions for running microbenchmarks, which take a shorter time to complete.

### Hosting

You can obtain our artifacts from GitHub: <https://github.com/suquark/ExoFlow>. The Github repository may be updated later, but we will maintain clear and accessible instructions about our artifacts in an easily identifiable "README" file.

### Requirements

ExoFlow is developed and tested on AWS, and we use some AWS services as the baseline. Thus, an AWS account and quota for certain experiments are required.

# Hyrax: Fail-in-Place Server Operation in Cloud Platforms

## Abstract

Today’s cloud platforms handle server hardware failures by shutting down the affected server and only turning it back online once it has been repaired by a technician. At cloud scale, this all-or-nothing operating model is becoming increasingly unsustainable. This model is also at odds with technology trends, such as the need for new cooling technology.

This paper introduces Hyrax, a datacenter stack that enables compute servers with failed components to continue hosting VMs while hiding the underlying degraded capacity and performance. A key enabler of Hyrax is a novel model of changes in memory interleaving when deactivating faulty memory modules. Experiments on cloud production servers show that Hyrax overcomes common hardware failures without impacting peak VM performance. In large-scale simulations with production traces, Hyrax reduces server repair requirements by 50-60% without impacting VM scheduling.

## 1 Introduction

Server hardware failures are quite frequent in cloud platforms. For example, a typical cloud server relies on at least 24 DIMMs, six SSDs, six fans, and two CPU sockets [48]. Even assuming optimistic annual failure rates<sup>1</sup> of 0.1% per DIMM and 0.2% per SSD, 22% of servers will have at least one failure during the typical 6-year lifetime of a cluster. In practice, repair rates are typically even higher.

The common approach to dealing with hardware failures in today’s cloud platforms is to evict all virtual machines (VMs) and stop using the affected server. The server goes back into production only once a technician has replaced all faulty components. This maintains server homogeneity, which simplifies scheduling and operation [4, 24, 32, 41, 42, 46, 61, 64, 69]. We call this the “all-or-nothing” operating model.

Recent technology trends make all-or-nothing operations increasingly unsustainable in cloud platforms. First, server power consumption increasingly requires liquid cooling, which offers performance, efficiency, and sustainability benefits [33, 63, 72]. Liquid cooling significantly increases the time and effort required to repair servers. Second, the share

of total costs that are due to repairs are increasing (§2). This is in part due to servers staying in datacenters for longer<sup>2</sup>. Third, all-or-nothing requires a continuous supply of spare components, which is increasingly hard to procure. Component supply chains have emerged as a barrier to further extending server lifetimes and reducing carbon emissions [7]. Fourth, the human repair process can cause interruptions to nearby servers [32], which is becoming an obstacle in cloud provider’s pursuit to improve the availability of their servers.

This paper advocates that cloud providers should move toward a fail-in-place paradigm where servers with faulted components continue to host VMs without requiring repairs. Fail-in-place operation would significantly reduce repair needs, improving costs, carbon emissions, and availability. However, fail-in-place faces multidimensional challenges in practice. First, it requires a form of graceful degradation where individual faulty components are deactivated instead of decommissioning the entire server. Unfortunately, we find that mechanisms to deactivate components are largely undocumented. Furthermore, deactivating the right component requires accurate fault diagnostics and it is unclear whether this can be achieved in practice. Second, deactivating common components such as DIMMs can significantly impact server performance due to reduced memory interleaving. This performance loss should not be exposed to VM customers. Third, the cloud platform must be able to actually use the capacity on servers with deactivated components. This requires algorithmic changes in VM scheduling and changes to adopt the cloud control plane to support heterogeneous servers.

We introduce Hyrax—the first implementation of the fail-in-place paradigm for cloud compute servers. In a multi-year study of component failures across five server generations, we find that sufficient redundancy in existing servers can overcome the most common memory and SSD device failures. While existing diagnostics can only identify a subset of component types, we empirically find that they are 95% accurate. We identify hooks in deployed firmware that enable deactivating components in ways that overcome many failure possibilities (e.g., dirty or corroded connectors or chip failures). Finally, Hyrax adds a *degraded* server state and corresponding scheduling rules to a production control plane to

\*Formerly at Microsoft Azure

<sup>1</sup>Prior work reported 0.09% [58, 59], 0.12% [12], and 1.6% [57, 66] for DIMMs and 0.22% [43, 44] to 1.2% [3, 54] for SSDs.

<sup>2</sup>Major cloud providers have moved to a minimum server lifetime of six years [7, 26, 53] for cost and sustainability reasons.

**Figure 1:** Hyrax dominates all-or-nothing (AoN) operations along the entire trade-off spectrum between available resources (core hours) and the number of required server repairs (repair tickets). Different points on the trade-off spectrum are generated by varying the repair schedule, ranging from immediate repairs (IR) to performing repairs in batches at periodic intervals ranging from 1-12 months long. All numbers are normalized to those for AoN with immediate repairs, which is the common approach in today’s cloud platforms.

support servers with deactivated components.

Hyrax overcomes the reduced performance of degraded servers by exploiting existing heterogeneity in VM sizes and configurations. Specifically, we find that the peak performance expectation of small and old VM types matches the performance offered by degraded servers. Further, we find that there are sufficiently many small and old VM types to effectively utilize the capacity of degraded servers. Hyrax also introduces scheduling optimizations for efficiency at scale.

Hyrax has been deployed for a few months on a subset of Azure clusters and a small set of component types. We report on its effectiveness on real failures and use microbenchmarks and large-scale trace-driven simulations to extrapolate a full deployment over six years. Our experience demonstrates that the fail-in-place paradigm is practical under real-world platform constraints.

To evaluate the benefits of at-scale deployment, we simulate 66 compute clusters from two geographic regions over a period of six years. Overall, Hyrax reduces the number of server repairs in a region by 50-60% depending on the region (Figure 1), while offering the same resource availability and scheduling the same VMs as today’s all-or-nothing operation. Figure 1 also shows that Hyrax’s benefits carry over to different repair schedules, including Azure’s existing repair schedule (immediate repairs) as well as previously-suggested batching of repairs [4, 5], where repairs are scheduled at periodic intervals (e.g. once per year). Furthermore, Hyrax reduces replacement rates by 40% for fans, 50% for SSDs, and 75% for memory, which enables extending server lifetimes for multiple years to amortize server costs and carbon emissions.

We hope that, by sharing our journey towards the fail-in-place paradigm, we motivate the community to invest in future cross-stack systems research to make degraded mode and fail-in-place operation significantly more efficient.

**Contributions:**

- The first description of design goals and constraints for

**Figure 2:** At Azure, servers are either online and serving VMs, or offline and being repaired. Repairs take between 3 and 190 days at the 50-th and 99-th percentile, respectively.

fail-in-place and feasibility analysis of degraded mode operation at a large public cloud platform (§3).

- The design and implementation of Hyrax, the first fail-in-place system at a cloud provider. Hyrax’s implementation includes novel mechanisms to deactivate component pathways and a novel model of memory interleaving when memory modules are deactivated (§4, §5, and §6).
- Experimental results that show Hyrax’s effectiveness, performance, and cost impacts (§7).
- A discussion of deployment experience, broader impacts, and research avenues (§9).

**Limitations.** Hyrax is not applicable to all repair operations. The following assumptions underpin our work.

- Hyrax focuses on server repairs, which account for the majority of technician hours in Azure datacenters. Hyrax does not reduce other technician duties, such as power, network, and cooling maintenance.
- Hyrax focuses on compute servers, where degraded operation is challenging. Storage servers often already implement variants of degraded mode (§8).

**2 Background**

This section reviews repair workflows and costs, typical server configurations, and cloud workloads.

**Repair workflow.** A software agent called Server Health Monitor (SHM) checks server error logs and component types, counts, and capacity for deviations from the expected (homogeneous) configuration. If the SHM suspects any kind of fault, the server is marked as “offline”, which signals the VM scheduler to filter out this server (Figure 2). VMs are migrated away or gracefully evicted. The server is then rebooted into a diagnostics environment. If diagnostics finds a hardware problem, it immediately creates a *repair ticket* [4, 32, 41, 66].

Repair tickets can point to a specific component pathway (like DIMM #4, Figure 3a) or require a manual diagnosis. After a technician resolves a ticket, e.g., by reseating connectors or swapping out components, the server is tested again to certify reliability (certification step). A reliable server is marked “online” and again becomes a candidate for hosting VMs.

**Impact of all-or-nothing repairs on TCO.** Server repairs are a significant component of total cost of ownership (TCO). The main components of TCO are CapEx (capital expendi-

**Figure 3:** A component can appear faulty due to other component faults along the path between a core and the actual component. We call this a *pathway* that typically spans the socket and pins, printed circuit board (PCB), and slots/risers to the actual component like the NVMe SSD or memory DIMM.

ture for the purchase of servers, networking, cooling, and power infrastructure) and operational costs due to energy and power (estimated at 6% of CapEx per year [19, 20, 62]), and maintenance (estimated at 5% of CapEx per year for each server [4, 66]). Maintenance costs are largely made up by technician salaries and cover maintenance of all datacenter components. At Azure, server repairs account for about half of technician work hours in the all-or-nothing operating model. Server repairs thus account for 9% and 12% of total cost (TCO) for server lifetimes of 6 and 10 years [7], respectively.<sup>3</sup>

Repairs are also known to be slow [69]. At Azure, 2% of servers are waiting for repairs at any given time in the all-or-nothing operating model.

**Server hardware.** Figure 4 shows a typical cloud server configuration [48]. Variants of this base architecture include one or two NICs and 24-32 DIMMs; most servers use a single NIC. We note that the component count for some component types is larger than one (marked in green in Figure 4). We refer to these as *degradable* components as they do not represent a single point of failure.

We note that hardware components internally contain redundancy, such as spare blocks in SSDs [8, 25, 34, 44, 52, 55, 67, 68]. Moreover, the operating system and hypervisor at Azure employ an aggressive policy for offlining memory pages to mask faulty cachelines. A repair ticket is generated for a component only when the above mechanisms cannot resolve the problem.

**Cloud workload.** All workloads run within virtual machines (VMs) for security and ease of management. Resources for each VM are typically preallocated at its start time to improve performance and facilitate the use of virtualization accelerators [2, 39, 60, 70, 71]. VMs come in hundreds of different types with many combinations of the number of virtual cores, memory capacity, local and remote storage options, NIC and GPU configurations.

The cloud provider has no introspection into the workloads that a customer is running inside their VMs and does not know their performance requirements. Hence, performance goals

<sup>3</sup>We calculate TCO based on the three dominant cost factors: Deployment years ( $y$ ), CapEx ( $C$ ), Maintenance ( $y \times C \times 5\%$ ), and Energy/Power ( $y \times C \times 6\%$ ). This leads to  $TCO(y) = C + y \times 5\% \times C + y \times 6\% \times C = C(1 + 0.11 \times y)$ .

**Figure 4:** A typical cloud server configuration and its component counts. We refer to the component types marked in green as *degradable*, as their component count is large enough that they are not a single point of failure.

are defined in terms of peak performance, e.g., bandwidth and latency for memory and IOPS and bandwidth for SSDs. For older VM types that are scheduled on newer servers, their performance goals are defined for the server generation they were originally introduced on.

Azure’s distributed VM scheduler is called Protean [1, 9, 22, 37, 61]. Protean first forwards VM requests to a compute cluster within the specified region based on hardware requirements and available capacity. At the cluster level, Protean places VMs following a series of rules that balance tightly packing resources with spreading workloads across racks for high availability. Filter rules select which servers are considered candidates for placing each VM. They ensure that only servers are considered that can ensure the SLAs associated with the requested VM type. Preference rules rank these candidates to find the best placement. Similar to other schedulers [4, 22, 24, 32, 41, 42, 46, 61, 64, 69], Protean assumes identical hardware configurations for all servers within a cluster.

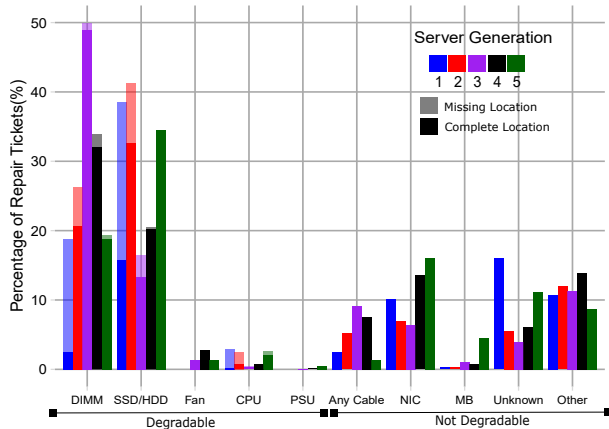

### 3 Fail in Place

The “all-or-nothing” operating model and the associated high repair frequency is costly and at odds with multiple server and data center trends. This paper pursues an alternative paradigm, which we term Fail-in-Place (FIP). In FIP, servers are allowed to exist with failed components for prolonged periods of time, sometimes forever. The main goal of FIP is to *reduce repair tickets* while continuing to offer the same user experience to VMs and minimal impact on cluster capacity and scheduling.

FIP is motivated by our observation that the majority of hardware repair tickets are due to the failure of *degradable* components. Consider Figure 5, which breaks down repair tickets at Azure into the component type that triggered them. We see that, for example, in Generation 3 clusters<sup>4</sup> more than 65% of tickets are due to degradable components. Recall from Section 2 that degradable components do not represent a single point of failure as their component count per server is larger than one.

<sup>4</sup>Higher server generations reflect newer server and component architectures. Generation 3 is a currently highly utilized hardware generation.

**Figure 5:** Breakdown of repair tickets at Azure into the component type responsible for the ticket. The repair tickets were recorded on dozens of production clusters spanning regions across two continents and clusters from five different hardware generations, which have been deployed between 2018 to 2022. Most repair tickets in server generations later than 2 are for degradable components and diagnostics indicates a specific pathway.

For degradable component types, Figure 5 further marks in a darker shade the share of tickets that also identify a specific pathway, rather than just the component type. For example, for DIMMs, these tickets would include the specific DIMM slot (recall Figure 3a). We observe that for generations above 2, almost all repair tickets among degradable components also indicate the specific pathway.

The key idea behind FIP is to avoid repair tickets by deactivating (rather than repairing) a faulty degradable component and allowing the server to continue to host customer VMs, albeit with reduced capacity. We refer to this new server state as *degraded* servers.

While Figure 5 illustrates FIP’s potential to reduce repair tickets, a real FIP implementation must also satisfy the following constraints.

- $C_{\text{Performance}}$  VMs placed on degraded servers must still be able to achieve the same peak performance (e.g. memory bandwidth) expected for this VM type (§2).
- $C_{\text{Efficiency}}$  A FIP system must be able to effectively use the capacity on degraded servers. For example, it must not strand one resource (e.g., CPUs) because another resource is degraded (e.g., memory).
- $C_{\text{Capacity}}$  A FIP system must continue to be able to satisfy a region’s demand for VM resources. In particular, VMs must not be turned away from a region because of server degradation or disrepair.

For cloud platforms, FIP system design can be guided by the following observations based on real-world cloud workloads and failure patterns.

First, a majority of VMs that customers are running belong to smaller VM types that can be accommodated on a degraded

| Requested Cores | Core-hours v3 | Core-hours pre-v3 |
|-----------------|---------------|-------------------|
| $\leq 2$        | 27.7%         | 26.9%             |
| (2,4]           | 26.8%         | 16.9%             |
| (4,8]           | 21.5%         | 18.9%             |
| (8,16]          | 10.6%         | 16.6%             |
| $>16$           | 13.4%         | 20.7%             |

**Table 1:** Core counts for VMs introduced with 3rd-generation servers (v3) and with previous-generation servers (pre-v3).

mode server without impacting their performance. For example, Table 1 shows a breakdown of core hours by VM type at Azure. VMs with four or fewer cores account for 40-50% of all core hours and are small enough that they require only a small fraction of a server’s full capacity to achieve their expected performance.

Second, our study of server repair tickets at Azure reveals that the number of component failures per server is typically small compared to a server’s total component count. For example, for servers in Generation 3, 90% of servers that develop SSD and/or DIMM failures in a one-year period exhibit two or fewer failures. The most common failure patterns among those servers are one failed DIMM (36.5%) followed by one failed SSD (10.3%). Hence for the bulk of servers with failures, deactivating the affected components would reduce the server’s capacity by only a small fraction (recall that typical server configurations include 24-32 DIMMs and 6 SSDs) and not cause a significant amount of resource fragmentation. We note however that over long time periods, more than a few components will fail. To prevent resource stranding, any FIP system must thus control how many components can be deactivated in any degraded server.

Third, we find that FIP systems will still have to accommodate some repairs (albeit at a greatly reduced frequency) in order to satisfy capacity requirements. While servers with failures of degradable components are returned to online status, the capacity loss due to servers with failures of undegradable components (which will stay offline in the absence of repairs) is not acceptable.

The design and implementation of a complete FIP system pose multiple open challenges not captured in the simple vision above. For example, FIP requires accurate diagnostics, mechanisms to deactivate component pathways, a detailed understanding of how component deactivation impacts performance, policies to determine when to degrade (versus repair) a server, and a control plane that supports FIP (including the VM scheduler and automated diagnostics).

## 4 Hyrax System Design

Hyrax is a concrete implementation of the FIP idea and the first FIP system at a cloud provider. Hyrax implements a new “degraded” online server state on servers and in the control plane and changes multiple aspects of the offline workflow at Azure. Currently, Hyrax supports three degradable component

Figure 6: Server states in Hyrax.

types: memory, SSDs, and fans.

Figure 6 provides an overview of server states in Hyrax. After a server is marked as suspect, results from Diagnostics are used by the Hyrax Policy (Ⓜ) to decide whether to degrade or repair. This policy applies first filters for degradable component types. Second, it verifies that diagnostics points to a specific pathway within this component type. Third, it applies a threshold on how many components of each type can be degraded. Degraded servers are created by deactivating the faulty component pathway (⚙️, §5.1). Repairs are scheduled for undegradable component types, when diagnostics cannot identify the faulty component pathway, or if deactivation would cross the policy’s threshold. Degraded and repaired servers are subject to extensive testing (called Certification in §2 and Figure 2) before becoming available for hosting VMs (online).

Hyrax achieves  $C_{\text{Efficiency}}$  via the policy’s thresholds. Currently, we never deactivate more than two components of any type. Empirically, we find that this is sufficient to prevent resource stranding. We provide a detailed sensitivity analysis in Section 7.4.

Hyrax achieves  $C_{\text{Performance}}$  by characterizing how deactivating components affects VM performance for different VM types. This allows Hyrax to decide whether the remaining healthy components are sufficient for the server to continue serving VMs and which VM types it can serve without impacting user experience. Hyrax modifies the VM scheduler such that *only the VM types whose performance requirements can be met* are scheduled on the degraded server.

Hyrax minimizes repair tickets because many servers that are degraded instead of repaired will not encounter another fault during their deployed period. If degraded servers encounter another fault that cannot be degraded, Hyrax issues a single repair ticket and technicians repair all faults on the server at once. We call this technique “*mini-batching*”. Mini-batching effectively amortizes technician work like the journey to the server’s rack, identifying and opening the server, manual diagnosis, and record keeping.

Hyrax achieves  $C_{\text{Capacity}}$  in two ways. First, the capacity an individual degraded server can lose is limited via the policy’s thresholds. Second, undegradable servers are not permanently left offline without repairs. We consider a range of different repair schedules (§7).

We discuss technical details of the Hyrax server design in Section 5 and the Hyrax policy and control plane in Section 6.

(a) Deactivating a failed memory component pathway.

(b) Deactivated SSD component pathway.

Figure 7: Component deactivation takes care of entire paths of error sources, such as memory controller, DDR phy, PCB, connector, and DIMM itself. This has the potential to improve over repairs where reseating or exchanging the DIMM often does not resolve the problem.

## 5 Hyrax Servers

Hyrax seeks to convert an offline server with one or multiple faulty component pathways into a degraded server that can host VMs. Hyrax focuses on memory, SSD, and fans as the most common degradable components (§3). This section describes how to deactivate these three component pathways and associated performance implications.

### 5.1 Component Pathway Deactivation (⚙️)

The key challenge is making component deactivation comprehensive enough so that faults are effectively hidden. Hyrax achieves this by deactivating components using combined firmware and software mechanisms.

**Memory pathway.** Hyrax targets memory errors that cannot be resolved by existing, fine-grained mitigations [8, 13, 35, 55, 67]. Common causes are uncorrectable errors across a DIMM’s banks/ranks, connector problems, or too many faulty rows. Hyrax exploits a rarely-documented firmware (BIOS) feature, called Rank Enable BitMask. On Azure servers, this setting offers a bitmask for each channel, on each memory controller (MC), and on each socket. Each bitmask controls which of the DIMM’s ranks on this channel are included in memory interleaving. Azure diagnostics currently only provides DIMM-level information, so Hyrax deactivation always excludes all ranks on a DIMM. Excluding an entire DIMM means that this DIMM’s memory is not assigned an address. Furthermore, the MC will not attempt to control or refresh any data on that DIMM’s memory chips. Figure 7a shows examples of deactivating one DIMM (0x3) as well as the whole memory pathway (0x0).

Hyrax has two ways to set the Rank Enable BitMask. If the server is able to boot a minimal OS, Hyrax software directly sets the bitmask in the BIOS configuration flash. If the server does not boot, Hyrax can set the bitmask via the Baseboard Management Controller (BMC) on the management network.

**Figure 8:** Peak memory bandwidth of a naïve implementation of Hyrax as measured from VMs on servers with all DIMMs enabled, one DIMM or two DIMMs deactivated, respectively.

**SSD pathway.** Server-local storage for VMs is striped across six NVMe drives. This configuration improves peak performance for IO-intensive VM types and facilitates bin packing hundreds of VM types with server-local storage. We modify the striping software module to read a list of serial numbers to include into the stripe. To deactivate an SSD pathway, Hyrax deletes the drive’s serial number from the striping configuration file. Additionally, we deactivate the SSD component pathways in the BIOS using an option called PCIe Port Config (Figure 7b).

**Fan pathway.** No explicit deactivation is needed for fans. They are monitored by the BMC which emits frequent error messages in case of faults (e.g., zero or low RPM). Hyrax changes BMC firmware to filter out fan error messages for deactivated fan slots.

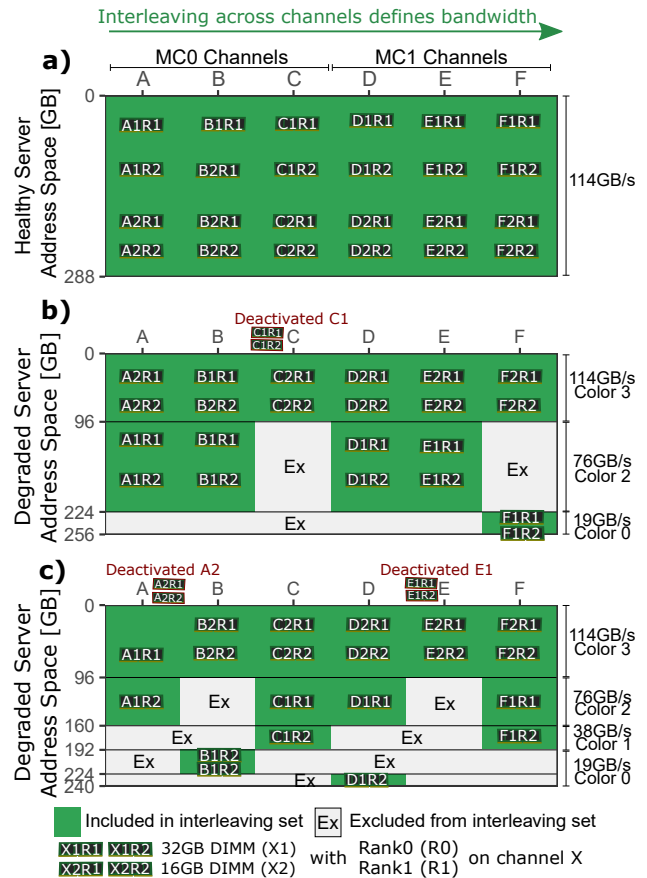

## 5.2 Achieving High Performance on FIP Servers

We describe performance challenges when deactivating memory and SSD pathways and how Hyrax overcomes them.

**Memory pathway.** Cloud servers maximize achievable memory bandwidth by interleaving cachelines across DIMM ranks on all memory channels on the same socket. Deactivating a DIMM limits the processor’s interleaving options and can significantly reduce VM memory bandwidth. Unfortunately, the resulting configuration is almost always outside CPU specifications, known as DIMM population rules [11, 31, 38].

To understand the performance impact of undocumented interleaving from deactivating DIMMs, we experiment with a common production server configuration. This server has two memory controllers per socket (MC0 and MC1), three memory channels per controller (A-C on MC0 and D-F on MC1), and two DIMMs per channel (e.g., A1, A2).

Figure 8 shows memory bandwidth for this server configuration measured in four scenarios: all DIMMs enabled, only DIMM A1 deactivated, only DIMM A2 deactivated, or DIMM A1 and A2 deactivated. We measure the memory bandwidth with a Memory Latency Checker (MLC) [30] for VMs ranging from 4-32 cores and show averages across 10 runs for each VM size. Error bars indicate the worst-performing run

**Figure 9:** Channel interleaving with deactivated DIMMs. The top image shows interleaving for a healthy server, the middle image with DIMM C1 deactivated and the bottom image with two DIMMs (A2, E1) deactivated. Under degraded mode different regions of the address space experience different memory bandwidths, ranging from 19GB/s to 114GB/s.

for each VM size. We observe mean bandwidth loss between 0 to 36% depending on which and how many DIMMs are deactivated. Additionally, we observe that even for the same configuration, there is a significant variance between runs with worst case bandwidth loss up to 82%. Such outliers are not acceptable for deployment. We next explain the underlying reasons and then explain our mitigation.

We find that the inflexibility inherent in channel interleaving is the reason for the bandwidth loss. While a server can have multiple interleaving configurations for different ranks (called sets), each set must either alternate between MCs or just focus on a single MC. Consequently, cross-MC-interleaving requires the same capacity in participating channels on both MCs. To better understand the subtleties involved in interleaving we use a custom firmware debug mode that prints interleaving sets and participating channels. Figure 9 compares the interleaving we observe on healthy versus degraded servers for a single CPU socket on a common platform.

Figure 9a shows interleaving for a healthy server, which

contains a 32GB and a 16GB DIMM per channel<sup>5</sup>. For example, channel A on MC0 contains the 32GB DIMM A1 with ranks A1R1 and A1R2 and a 16GB DIMM A2. Cachelines are interleaved across all six 32GB DIMMs and across all six 16GB DIMMs. Interleaving across all channels creates a uniform address space with 114GB/s, i.e., a sixfold increase over a single channel (19GB/s).

Figure 9b shows a degraded server with C1 (32GB) deactivated. Since symmetry is required within an interleaving set, both C1 and F1 are removed from the first set and as a result, the server interleaves only across the four remaining 32 GB DIMMS. On the other hand, since all 6 16GB DIMMs are still active, the processor continues to interleave across all 6 DIMMs achieving the full 114 GB/s for their part of the address space (note that the 16GB DIMMs now make up the top part of the address space). As F1 is active, but not part of any set so far its capacity remains as non-interleaved (19GB/s). This creates a non-uniform address space with 38% of pages at 114GB/s, 50% at 76GB/s, and 12% at 19GB/s.

A degraded server with two deactivated DIMMs further complicates interleaving sets. Figure 9c shows the interleaving that results when A2 (16GB) and E1 (32GB) are deactivated. With deactivated DIMMs having different sizes, the resulting interleaving sets do not align with full DIMMs and instead use individual ranks (1/2 of a DIMM). The first interleaving set uses A1's first rank (A1R1) and five 16GB DIMMs (B2-F2) achieving the full 114GB/s. The second set uses A1's second rank (A1R2) and the first ranks from DIMMs C1, D1, F1 achieving 76GB/s. The third set uses the second rank from C1 and F1. Two final sets interleave across only a single channel using both ranks from B1 and D1's second rank. This results in an address space with 40% of pages at 114GB/s, 27% at 76GB/s, 13% at 38GB/s, and 20% at 19GB/s.

The main problem with varying peak bandwidth in different address ranges is that it makes VM memory performance on these servers unpredictable. As the OS and hypervisor are unaware of bandwidth differences across the address space the performance of a VM will vary depending on where in the address space its memory gets allocated. A naïve implementation of Hyrax would allocate VMs with a mix of pages leading to low-bandwidth outliers as shown in Figure 8.

To mitigate bandwidth variance on a degraded server, we must know the exact address map that maps address ranges to their achievable peak bandwidth. Unfortunately, reading the interleaving configuration usually requires debugging output that is typically not available. While we can test the memory bandwidth of the entire address space, we found this to be slow and inaccurate. Instead, we conceptually group different deactivation scenarios into equivalence classes, where scenar-

ios in the same class result in the same address map, and store the resulting address map in a distributed database (§6). For example, deactivating a single DIMM leads to two equivalence classes depending on the DIMM size of the deactivated DIMM: The first class includes all scenarios where any one of the 32GB DIMMS fails (and the resulting map would be the image in Figure 9b) and the second class includes all scenarios where one of the 16GB DIMMs fails. Deactivating two DIMMs leads to ten equivalence classes, in addition to two DIMM sizes, interleaving changes with the two DIMMs being on the same channel, within the same MC, in a symmetric or asymmetric position on another MC.

Note that our discussion above focused on only one socket. Since interleaving on different (cache-coherent) CPU sockets happens independently, it is sufficient to characterize one socket. We validated equivalence classes by testing almost all 276 possible combinations. Deactivating three DIMMs leads to 2024 combinations and a multitude of equivalence classes — Hyrax thus deactivates at most two DIMMs and repairs three or more DIMM failures. A sensitivity analysis in § 7.4 will show that disabling larger numbers of DIMMs does also not provide significant gains in terms of repair savings.

Once we know the address map, we employ *page coloring* in the OS/hypervisor memory manager (MM) to assign the same color to pages that are in address regions with equal bandwidth. For example, in Figure 9 we assign colors 0, 1, 2, 3 to pages within a 19, 38, 76, 114 GB/s region, respectively. Each VM type comes with a preferred page color, which is set based on core count. Figure 8 shows that color 0 is sufficient for 2-core VMs. Color 1 is sufficient for 4-6 cores, color 2 for 8-12 cores, and color 3 for above 16 cores. Older generations of VMs sometimes run on new servers, while originally being created for servers with a lower per-channel bandwidth and four (instead of six) channels. Thus, old VM types do not even require color 3 and often use colors 0 and 1.

One could use this coloring scheme to guarantee performance at all times by exposing the amount of available memory for each color to the scheduler. However, to reduce coupling between control plane services, we do not expose this level of detail to the VM scheduler. So, large VMs may be allocated using colors below their bandwidth expectation if no higher colors are currently available on the server. Thus, Hyrax offers only a best-effort guarantee. Empirically, we find that this is sufficient since these cases are exceedingly rare (§7).

**SSD pathway.** The SSD pathway is simple compared to memory. In a fully healthy server, local VM storage is striped across six NVMe drives. VM types are capacity and rate limited (IOPS and bandwidth). When deactivating one NVMe drive, aggregate throughput remains sufficient for even the largest VM type. Deactivating two NVMe drives leads to sufficient throughput for all except the largest VM type. Hyrax thus never schedules this VM type on degraded servers with only four active NVMe drives. Hyrax never deactivates more

<sup>5</sup>The combination of 32GB and 16GB DIMM within one channel is a common configuration to reach target memory-to-core ratios in cloud compute servers of recent years. We discuss this configuration since our experiments with custom firmware happened to run on it. Interleaving on a 32GB/32GB server behaves similarly.

than two NVMe drives and this failure case is rare.

**Fan pathway.** Due to cooling overprovisioning, deactivating up to two fans leads to no performance loss.

## 6 Hyrax Control Plane

The Hyrax control plane consists of two new distributed services that implement the Hyrax policy and many changes to existing control plane services, including the VM scheduler.

### 6.1 Hyrax Policy (🔧)

The Hyrax Policy has two roles (recall Figure 6). First, it interprets diagnostics and sets constraints on which components are degradable. Second, it ensures that degraded servers meet  $C_{Capacity}$ .

To perform the first role, the Hyrax Policy specifies for each server type how many component pathways of each type can be deactivated at once. While Hyrax can adapt to a wide range of thresholds, for our purposes we use two DIMMs, two SSDs, and two fans. These thresholds are guided by common failure scenarios (Section 3) and performance observations (Section 5). Hyrax schedules repairs for any server with more than two faulty component pathways of the same type or any other failure diagnosis. The Policy also includes an extensive mapping list of diagnostic results to valid component pathways. For example, SSD pathways can appear as IO errors, timeouts, and PCIe errors. Diagnostics for SSD failures can sometimes point to PCIe ports and slots that have different (non-SSD) devices or even no device — for these the Hyrax Policy would just schedule the server for repair.

To ensure  $C_{Performance}$ , the Hyrax Policy maps every degraded server configuration to a capacity and performance profile (CPP). The CPP defines the exact server capacity and performance equivalence class (§5). Based on the CPP, Hyrax defines the set of allowable VM types that can run on a degraded server and still meet their SLAs. For example, servers with two DIMMs deactivated on the same channel do not have any page of color 3. This server thus cannot host latest-generation VMs with more than 16 cores. A server with two deactivated SSDs cannot host the largest VM type.

### 6.2 Control Plane

Deactivating component pathways leads to heterogeneous server configurations within a cluster. This requires changes across service and team boundaries. Figure 10 shows a simplified view of Azure’s control plane. We change three and add two new control plane systems.

Let’s consider a server that starts in healthy state and encounters an SSD failure. (1) The Server Health Monitor (SHM) detects NVMe read errors and follows the offlining workflow (§2). (2) Diagnostics reports the SSD component

Figure 10: Simplified overview of Hyrax’s control plane.

pathway to the Hyrax Policy (🔧). (3) The policy decides to start the deactivation workflow and communicates with a server-local daemon to deactivate that SSD (⚙️). The deactivated SSD’s serial number is also passed to the new Hyrax Inventory system. (4) After deactivation, the server is tested in the certification step. In the rare event that diagnostics leads Hyrax to deactivate the wrong pathway (§3), it would be detected in this step, e.g., during load testing. After passing certification, the server is onlined. As multiple control plane services might cache the server’s capacity, onlining requires Hyrax to invalidate caches throughout the control plane including the VM scheduler. (5) The Hyrax Inventory shares the server’s capacity and performance profile (CPP) with the VM scheduler (§6.3). Internally, our inventory tracks server state as a delta to the existing Datacenter Inventory. The delta consists of the serial numbers and slots of deactivated components, which remains small enough to fit into a single inventory server’s memory. (6) The Hyrax Inventory sends active serial numbers and slots to the SHM. The SHM only checks for these active components, which prevents the SHM from triggering warnings over missing components which have been deactivated.

There are additional changes in downstream services not shown here. For example, it was previously uncommon for servers to have multiple concurrent failures, so repair tickets used to be issued only for a single component type. With Hyrax, it is common for repair tickets to include multiple different component types. For example, there are no tickets for a server with two DIMM failures. However, if the two DIMM failures are later followed by any failures for an undegradable component (e.g., the NIC) the repair ticket will involve two different component types. To minimize repair tickets, Hyrax changed the ticket workflow and retrained technicians to repair multiple different component types at once, with a single ticket (mini-batching).

### 6.3 VM scheduling policy

Hyrax requires three changes to VM scheduling and an optional optimization. First, the VM scheduler consumes Hyrax Inventory to calculate hardware resources for individual servers instead of a single lookup to obtain a cluster’s homogeneous server type. The overhead of this lookup is negligible as servers moving from offline to online state is

| All Tickets (100%)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |                       |                            |                           |
|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------|----------------------------|---------------------------|
| Diag says undegradable (27%)                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |                       | Diag says degradable (73%) |                           |
| Diag in-accurate (2.7%)                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | Accurate Diag (24.3%) | Diag in-accurate (0.9%)    | Accurate Diag (72.1%)     |

**Figure 11:** Accuracy of automated fault diagnostics at Azure and their impact on Hyrax.

rare compared to VM scheduling events.

Second, we extend filter rules (§2) to enforce Hyrax’s CPP, i.e., which VM types can be placed on every server.

Third, we change the definition of a cluster’s “*capacity reserve*”. The capacity reserve exists for multiple reasons, including to have a target to migrate VMs to when a server shows signs of failing soon. A key component of the capacity reserve is to have some healthy empty servers (HES) that are able to host any kind of VM, including full-server VMs that use all of a server’s capacity. Degraded servers are not able to host all full-server VMs. We thus exclude them from being counted as HES.

Finally, we change a preference rule to optimize scheduling. Since degraded servers cannot be counted as HES, we prefer fully-healthy servers to become empty and stay empty. Our change updates rules to prefer placing VMs on degraded servers over healthy servers, provided no other rule takes precedence. By doing this we increase HES counts which allows placing more VMs into clusters.

## 6.4 Hyrax Diagnostics

Hyrax builds on an existing automated monitoring and diagnostics system. This system’s output is targeted at humans and includes information on which component type is faulty and its location. To use this system, we add an interpreter that maps diagnostic results to valid Hyrax component pathways. As part of this design, we analyzed four years of repair ticket logs at Azure. This analysis shows the *accuracy* of the diagnostic system and how Hyrax handles inaccurate or incomplete diagnoses. Specifically, we rely on notes from human technicians, who worked on the tickets in our history of repair logs. These notes indicate whether the diagnosis was correct, including whether the right component was identified.

At a high level, we find that diagnostic accuracy is high. For example, across all tickets in 2021, 96.4% accurately identify the component type at fault. For a more detailed view, Figure 11 shows a breakdown of all diagnoses made in 2021, outlining the different scenarios that arise and how they

impact Hyrax’s operation.

We make two interesting observations: First, diagnostic accuracy is lower for diagnoses pointing to an *undegradable* component: 10% of tickets labelled with an undegradable component are inaccurate (accounting for 2.7% of *all* tickets). Fortunately, this type of misdiagnosis is relatively benign. Hyrax will take the server offline (for potential later repair), which is the intended behavior if the actual faulty component is indeed undegradable. It is however a *missed opportunity* to keep the server running in degraded mode if the true fault is in a degradable component.

Second, diagnostic accuracy is very high for diagnoses pointing to a degradable component: 98.8% of tickets labelled as degradable do accurately identify the component type at fault. Within these, some diagnoses are *incomplete*, where the correct component type is specified, but location information is missing (e.g. the diagnosis indicates a DIMM problem, but does not specify a DIMM slot). More precisely, 3.8% of the accurately diagnosed degradable tickets (corresponding to 2.8% of *all* tickets) are missing location information which leads Hyrax to offline the server despite the fact that the faulty component is degradable. These tickets thus also represent a *missed opportunity* for degraded mode operation.

The last scenario we need to consider is the 1.2% of degradable tickets that contain an inaccurate diagnosis pointing to the wrong component type. These make up only 0.9% of all tickets, but their impact on Hyrax is less obvious. In the best case, Hyrax will try to deactivate the specified pathway and certification testing (recall §4) fails since this is not the faulty component. Failing certification testing with any degraded component automatically triggers an investigation both by a technician and by the Hyrax on-call team. In the worst case, the server passes certification testing and returns to serve customer VMs despite the fact that the true faulty component has not been degraded or repaired. This can lead to negative user experience as VMs may be scheduled on the server and they may get interrupted if the server is offlined again. Such repeat offlining of the same server also happens for technician repairs. In fact, our preliminary data indicates that the rate at which repaired servers are offlined again is comparable to such inaccurate decisions by Hyrax. This is likely because technicians rely on the same automated diagnostics and certification process as Hyrax.

We conclude by noting that diagnostic accuracy has continuously improved over the past years. Figure 12 shows the breakdown of repair tickets for three different hardware generations (Gen 2-4) by year since deployment. We observe that accuracy has improved from generation to generation, and also that accuracy improves over time within a particular hardware generation. Both the fraction of tickets with missing location and tickets with inaccurate fault code have decreased over the years. The reason is a concerted effort by the diagnostic team at Azure to add more coverage of various fault codes as well as improvements based on technician feedback.

**Figure 12:** The progression of the breakdown of repair tickets at Azure by deployment year for three generations of servers.

## 7 Evaluation

### 7.1 Evaluation Setup

We use two types of setups in our evaluation of Hyrax. First, we evaluate Hyrax on production servers to characterize its performance and ability to mitigate faulty components. Our evaluation focuses on 3rd-generation servers which have been deployed for 2-3 years. Second, to measure cluster-level impacts on repairs and VM scheduling over six years, we use trace-driven large-scale cluster-level simulations.

#### 7.1.1 Server experiments

We use production server hardware and *synthetically inject failures* using a commercial memory error injector (MEI) that interposes on the DDR memory bus [29]. We also perform *real failure* tests by intercepting nodes after Diagnostics flags a memory fault, but before a repair ticket is issued (§4).

We measure latency and bandwidth with Intel MLC [30] from inside VMs on healthy and degraded servers. MLC characterizes worst-case performance as it is more sensitive to deteriorated latency and bandwidth than any real-world application we’ve tested. We compare three implementations.

- **Hyrax:** Coloring approach based on 1GB hypervisor page table entries (§4)
- **Naïve:** Hypervisor randomly allocates VM memory among free pages
- **Interleaving:** 4kB-interleaving in hypervisor page tables

Our tests cover Intel servers from generations 3-5 and a subsequent (not yet deployed) generation. We report measurements from the 3rd generation as results from other generations are qualitatively the same. A typical 3rd-generation server uses two Intel Skylake processors (96 threads total). Each socket is equipped with six DDR4 channels with a 32GB and a 16GB DIMM per channel. Memory interleaving is enabled across all ranks on the same socket; thus, the

OS/hypervisor sees two NUMA nodes. There are six data SSDs using 960GB NVMe drives. The server runs Azure’s production-grade hypervisor and software stack. VMs are allocated with a 1GB page size.

#### 7.1.2 Large-scale simulations

We replay VM, failure and repair ticket traces in a simulated environment, using the Azure production VM scheduler code base. The traces span 66 clusters that host general-purpose VMs from regions in the US and Europe. With only 2-3 years of real failure traces for 3rd-generation servers, we model future failures with the help of 1st and 2nd-generation failure traces. The simulator models Hyrax’s control plane components (Figure 10) including Hyrax and all server states (Figure 6).

We compare two designs.

- **Hyrax:** Hyrax enables degraded server states and repairs servers with undegradable components and above thresholds (§4).
- **AoN:** All-or-Nothing repairs all hardware faults.

We simulate four possible repair schedules: issuing an immediate repair ticket (**IR**) and scheduling batch repairs every 3, 6, or 12 months (**3m**, **6m**, **12m**). For IR, we sample actual repair delays from Azure production datacenters. For batch repairs, we assume a hypothetical schedule where repairs are immediately effective at 3, 6, or 12 months. This batch repair schedule is unlikely how batch repairs would actually be implemented in practice. Instead, its purpose is to show a hypothetical and simplified schedule that could also reduce repair work, to highlight the impact of degraded mode operation. For each repair schedule, we compare the number of repair tickets, repair trips, resource availability and impact on arriving VMs under Hyrax and AoN.

We cross-validate the simulator for AoN relative to real-world clusters with the same failures and VM workloads. Due to the inherent randomness in placement decisions, repeated runs have small deviations. Across runs on 10 clusters, simulation of AoN and real-world metrics are within 0.25%. Overall, our simulations required more than 80,000 CPU hours.

### 7.2 Correctness

In this section, we use production server measurements to demonstrate that Hyrax can correctly deactivate component paths and thereby avoid future faults on a path. Due to space constraints, we focus on memory faults and omit qualitatively-similar SSD experiments.

**Synthetic failures.** We measure memory error rates with the MEI placed on a given DIMM slot and either activate all ranks (no-Hyrax) or deactivate the corresponding slot (Hyrax). We target the MEI to corrupt bits matching a single row address and start a VM on the same CPU socket. The VM runs MLC in the peak bandwidth setting. Under no-Hyrax, we observe

**Figure 13:** Peak memory bandwidth of a healthy server, a Hyrax server with page coloring, and a naïve implementation of degraded servers with two DIMMs deactivated.

a high rate of correctable memory errors. There are bursts of uncorrectable errors that lead to both VM and host crashing within minutes. With Hyrax, there are no memory errors throughout the duration of a 48 hour test; the VMs and the host run without errors or crashes.

**Real-world failures.** We identify a server in a test cluster that was diagnosed with a high rate of uncorrectable memory errors on one DIMM. Diagnostics is able to boot its minimal OS and reproduce these memory errors. Hyrax recognizes that this server can be degraded and deactivates the correct DIMM. Certification testing does not find any memory errors and issues a “pass” that qualifies this server for hosting VMs.

### 7.3 Performance

In this section, we demonstrate that Hyrax can successfully mitigate any VM performance impact of degraded mode operation. For space reasons, we focus on the more complex case of memory performance (memory latency and bandwidth).

**Server-level experiments.** Figure 13 compares VM memory bandwidth of Hyrax and Naïve on a degraded server to a healthy server. The degraded server has A1 and A2 deactivated. Hyrax allocates the VM using colors 0-3, depending on VM core count (§4). We find that memory bandwidth under Hyrax is within 1% of the healthy server. In contrast, Naïve’s performance is highly variable with mean bandwidth up to 36% lower and worst-case bandwidth up to 82% lower than on the healthy server.

We also tested memory latency. In all three systems, and across all experiments, the unloaded memory latency reported by MLC for the degraded server remains within 5% of the healthy server.

**Large-scale page coloring simulations.** The previous experiment focused on a single VM in isolation for one particular failure pattern. For a more complete view of VM performance under Hyrax we use simulations that are driven by actual traces of VM arrivals and departures to capture the effect of VM churn and also simulate component deactivation based on real failure traces to capture the rich set of failure patterns

**Figure 14:** Hyrax almost always achieves the same VM memory bandwidth on degraded nodes as VMs would on healthy servers.

that arises in practice. (The traces come from our cluster simulations in §7.4). We play back these VM events in server-level simulations of the three memory allocation policies: Hyrax page coloring, page interleaving, and Naïve.

Figure 14 shows the percentage of VMs with less than 95% and 99% of the bandwidth of a healthy server, both for VM aggregate bandwidth (left) and bandwidth of the VM’s *worst* page (right). With Hyrax, fewer than 0.16% of VMs see bandwidth on their worst page that is lower than 99% of the worst-page bandwidth achieved on a healthy server. VM *aggregate* bandwidth under Hyrax is even closer to that of a healthy server.

Page interleaving also results in a low percentage of VMs that achieve less than 95-99% of the aggregate memory bandwidth of a healthy server. However, more than half of VMs include at least one memory page with significantly lower bandwidth. We also note that page interleaving increases a VM’s page table by orders of magnitude. This leads to a high rate of TLB misses and increased memory access latency. In practice, we know that memory access latency is even more important than bandwidth — internal production workloads lose 5-15% of performance for small page sizes. Thus, interleaving is not practical.

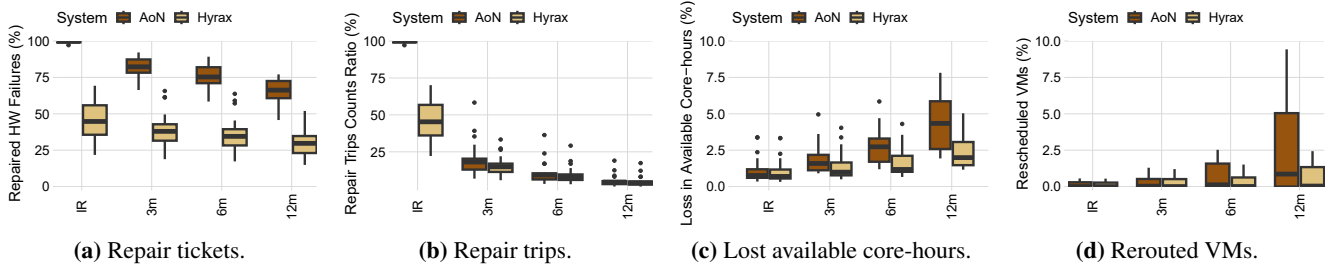

Naïve is compatible with large page sizes but more than 2% of VMs achieve less than 95% of the aggregate bandwidth goal. This grows to 3.5% for a goal of 99% and above 50% when considering the worst page in a VM. While Naïve performs well on average, tail performance matters at scale.

### 7.4 Large-scale Cluster Simulations

We turn to large-scale cluster simulations to characterize Hyrax’s impact on repair tickets, repair trips, cluster resource availability and user impact. We consider four different repair modes: Azure’s process of immediately scheduling a repair ticket (IR) and hypothetical repair batching policies with three different intervals (3 months, 6 months, 12 months).

**Repair tickets.** We begin by measuring for each repair mode the percentage of all hardware failures that result in a repair ticket, i.e. the failures that require a technician to perform

**Figure 15:** Results from a simulated deployment of Hyrax across two regions with 66 compute clusters and four repair schedules: immediate repair tickets (IR) and batch repairs (3m, 6m, 12m). The figures compare key metrics under Hyrax with all-or-nothing server operation (AoN).

**Figure 16:** Ratio between Hyrax and AoN for different threshold settings with fixed batch repair interval (3m). Stranded availability is not included when computing core-hours and memory-hours availability.

physical examinations and repairs. Figure 15a shows the results for Hyrax and AoN using boxplots, where each data point in the distribution represented by the boxplot corresponds to one of the 66 clusters.

We observe that Hyrax reduces the number of repair tickets by more than a factor of 2 across all repair modes. Both mean and median are consistently around 55% lower under Hyrax than under AoN. A significant contributor to Hyrax’s effectiveness is mini-batching. Specifically, under Hyrax, we find that 56% of repair tickets contain more than one component, compared to single-digit fractions for AoN.

**Repair trips.** We compare the number of repair trips required under Hyrax and AoN, i.e. the number of times when a technician needs to travel to a cluster. Figure 15b shows the number of repair trips normalized by the number of hardware failures.

We observe that Hyrax significantly reduces repair trips under immediate repairs (IR). While under AoN every hardware failure results in a repair trip, under Hyrax, on average 55% of these repair trips can be avoided by deactivating the affected component.

Under batch repairs, the number of repair trips to a cluster is upper-bounded to once every  $x$  months, where  $x$  is the repair interval. Interestingly, Hyrax still provides improvements over AoN, albeit smaller than for IR. For example, for a batch repair interval of 3 months Hyrax reduces repair trips by around 20% (mean and median across clusters). Every saved repair trip results from a 3 month interval in which Hyrax was able to

handle all failures with component deactivation.

**Lost available core-hours.** This metric quantifies the impact of the repair operating model on the availability of cluster hardware resources. In particular, we consider the percentage of a cluster’s total core-hours (i.e. number of cores in the cluster multiplied by cluster lifetime) that are *lost*, i.e., a core physically exists in the cluster, but is not available to run VMs due to one of two reasons: (1) A server is offline for repairs; (2) Due to resource fragmentation some of a server’s cores cannot be allocated to VMs because of limited availability of another resource (DIMMs or SSDs) [40]. Hyrax might exacerbate resource fragmentation as it might deactivate multiple components of one type, making it harder to utilize the remaining components.

Figure 15c shows that under a batch repair schedule Hyrax significantly reduces the loss of available core-hours. Hyrax keeps servers running (albeit with reduced capacity) after degradable component failures, rather than taking the entire server offline until the next scheduled batch repair. The improvement in the median lost core-hours of Hyrax over AoN ranges from 38% for a 3m interval to 55% for a 12m interval.

Interestingly, we observe that Hyrax improves loss in available core-hours even in the IR repair schedule. The median loss in core-hours is 9% lower under Hyrax than AoN. The reason is that immediate repairs are not truly immediate - typical repair times are on the order of days, but can sometimes take much longer, depending on component availability. In

contrast, deactivating components is consistently fast.

**Rerouting of VMs.** When a cluster’s available resources are insufficient to host an arriving VM, the VM is rerouted to a different cluster. Rerouting of VMs can negatively impact user experience as it increases the time until a VM gets started. Figure 15d shows the percentage of arriving VMs that are being rerouted under Hyrax versus AoN.

Under IR, the fraction of VMs that get rerouted is very small for both Hyrax and AoN. While it is identical (zero) in the median for both policies, the mean is slightly lower (4% reduction) under Hyrax as it decreases lost core hours in some clusters with many failures.

When moving to batch repair schedules, Hyrax provides clear improvements over AoN, ranging from an average 38% reduction in rerouted VMs for 3 month batch repairs to an average 64% reduction for 12 month batch repairs. These improvements are a direct consequence of the reduced loss in system capacity (core-hours) under Hyrax compared to AoN.

**TCO impacts.** Server repairs account for 9 to 12% of TCO (§2), and Hyrax reduces repair tickets by an average of 55% across the simulated clusters (§7.4). However, repairs frequently involve multiple components as well as undiagnosed failures, which extends repair times by about 15%. Thus, Hyrax reduces technician time by about 48%, which translates to a 4.5 to 6% reduction in TCO.

**Sensitivity to Hyrax’s deactivation thresholds.** Our implementation of Hyrax chooses its deactivation threshold of two per component type to reduce complexity. Figure 16 shows how different choices of thresholds impact available core hours, available memory hours, repair tickets and rerouted VMs. The numbers in the figure represent the ratio of Hyrax to AoN for a batch interval of 3m. Darker color shading corresponds to better results.

We observe that available system capacity (core-hours as well as memory hours) does not improve/change significantly beyond a threshold of one DIMM and one SSD. The reduction in number of repair tickets and rerouted VMs under Hyrax continues to increase as thresholds increase, however, returns are diminishing past a threshold of two DIMMs and two SSDs. One of the reasons is that it is very rare that more than two DIMMs and/or more than two SSDs fail in the same server, so these scenarios have little impact on key metrics.

In conclusion, increasing the thresholds beyond two per component type provides very limited gains while increasing system complexity, e.g. in handling servers with very low performance due to a large number of degraded components.

**Sensitivity to different regions.** Figure 1 shows that Hyrax performs similarly across the US and EU region.

**Sensitivity to server generation.** We also simulated a full deployment of Hyrax on 4th-generation servers. Figure 12 shows that this generation has an overall lower percentage of degradable components. Hyrax’s benefits are thus slightly less pronounced on this server generation. However, as diagnostics

has improved over time for 2nd and 3rd-generation servers, 4th-generation servers may also improve in the future.

## 8 Related Work

Our work is the first work to explore degraded mode operation in the context of VM compute servers and at the scale of a cloud platform.

**Datacenters that fail-in-place.** Related to our work are the general efforts toward lights-out data centers such as containerized datacenters [23, 65], underwater datacenters [10], and zero-maintenance storage systems [49, 50]. In our evaluation, AoN with high batch repair intervals (12m) represents these approaches. Unfortunately, the loss in availability or cost (hardware, power, space) to make up for this loss is prohibitive without degraded mode.

**Mechanisms to implement fail-in-place.** We borrowed the term degraded mode from RAID systems [51], where upon failure of a drive, the system seamlessly continues to operate until the failed drive is replaced, however at *reduced capacity and reduced performance*.

There are many existing fault-tolerance approaches that use component-internal redundancy [8, 25, 34, 44, 52, 55, 67, 68]. Hyrax targets the left-over failures not already covered by these approaches. It can be viewed as taking degraded mode to the extreme and applied to even combinations across different devices. As such, Hyrax has different requirements that raises novel challenges (§4).

**Improving repairs and redundancy.** Recent efforts for reducing the reliance on human technicians in lights-out datacenters explore the use of robots to replace hardware components [56]. Currently, this technology is not sufficiently capable, versatile and economical to be employed at scale. Our work presents a solution that can be deployed immediately in today’s systems.

Finally, systems that require no or minimal repairs throughout their lifetime are common in the context of embedded systems, for example, as part of autonomous vehicles, airplanes or satellites [6, 14, 47, 73]. However, these are special purpose systems with specialized components and significant redundancy. In contrast, we are exploring whether a cluster based on commodity data center components can operate with no or minimal repair throughout its lifetime through the use of fail-in-place.

## 9 Deployment Experience and Discussion

Hyrax reduces repair tickets while maintaining cluster capacity, VM scheduling, and VM performance. We discuss deployment experience and broader issues.

**Deploying incrementally.** Hyrax requires changes across teams that have not previously interfaced, including hypervi-

sor software engineers, hardware validation teams, and data-center staffing. Such a large project requires years to achieve visibility and alignment. During this process, we developed variants of Hyrax that could be deployed incrementally and fly largely under the radar. Our first increment focused on deactivating a single SSD in clusters without impacts on VM scheduling due to spare capacity and bandwidth. Further, we shortcut offline state changes as we could pinpoint some SSD failures without diagnostics. Our shortcut quickly migrated VMs away, rebooted the server, and deactivated the faulty SSD without leaving the online server state. Building in increments increased visibility and buy-in across Azure which facilitated far-reaching changes to VM scheduling and offline server workflows. Overall, Hyrax demonstrates the feasibility of overcoming ossification in large software stacks.

#### **Reduced benefits due to non-optimized software paths.**

The server state diagram in Figure 6 and the control plane overview in Figure 10 are vastly simplified. In principle, a degradable server should be able to return online within half an hour (after a reboot). However, before Hyrax, repairs took multiple days and sometimes even weeks, e.g., due to supply chain issues. Thus, the duration of offline states and transitions did not matter. Under Hyrax, returning to online has to wait for these states, which takes multiple hours in production.

An early variant shortcuts the offline state and returned servers to online within minutes. Unfortunately, the deployment scale of this variant is limited as few faults can be recognized as degradable without deep diagnosis. The limited scale of the shortcut variant and the slowness of Hyrax's offline implementation currently limits Hyrax's ability to improve cluster capacity. This is reflected in our simulations (§7).

**The usefulness of simulations and quantitative data.** We tested significant parts of the production code for inventory and state management in a mocked-up environment driven by simulated failures. Our large-scale simulations also helped convince engineering teams to help with large-scale changes. For example, we initially faced significant skepticism towards mini-batching. This was partly due to multiple past efforts that had tried and failed to implement mini-batching. These past efforts had cemented the idea that multiple components failing at once is a very rare occurrence. Simulations showed that Hyrax led to a high occurrence of mini-batched tickets.

**Tailoring automated diagnostics for FIP.** While our work shows that FIP can work with existing diagnostics systems, there is still room for improvement, including fine-grained diagnostics to find individual faulty cores and to improve locating other component paths (§6.4). We also find subtle shortcomings in diagnostics systems due to their focus on technician repairs. For example, current diagnostics systems prefer not to issue a ticket when they cannot reproduce a failure and pinpoint a specific repair action. This is required due to the high cost of false positives, i.e., calling a technician and replacing a component when the underlying component

was not actually faulty. The flip side is a higher rate of false negatives, which we observe as repeated failures on the same server. Hyrax's automation may open up a path towards improving cloud reliability and availability. Specifically, a FIP system could tolerate a higher rate of false positives (as they lead to a negligible capacity impact), and in exchange achieve lower false negative rates.

**Interaction with class failures.** An early practical concern at Azure was how Hyrax interacts with the occurrence of class failures, which is a recall of a large set of components of similar types from the same manufacturing period. Over three years, we found class failures affecting multiple PSU, DIMM, and CPU models, and one SSD model. Class failures often lead to an expectation of increased failure rates which may affect availability. Thus, associated components are typically proactively swapped out for new components. While class failures cause only about 5% of repair tickets, they often affect a large percentage of servers in the same cluster at once. If the number of affected components in a server is below Hyrax's thresholds, degraded mode can be an effective mitigation. However, deactivating many components at once may negatively affect VM scheduling. Thus, when we look back at three years of class failures, Hyrax would have only been effective in mitigating one out of about a dozen of class failures.

**Implications for new datacenter environments.** Our findings affect how one might design a future datacenter. In short, Hyrax reduces repair needs but does not obviate the need for repairs entirely. Specifically, the capacity loss after 6 to 10 years of deployment without repairs exceeds the cost savings of most new datacenter designs. We thus expect to see continued need for individual component replacement.

Hyrax's reduction in the number of repairs may be sufficient to offset the additional repair time introduced by some designs, such as new cooling techniques [33, 72]. Specifically, we find that Hyrax enables datacenter designs that result in repairs that take about twice as long. When repair times take much longer, TCO will increase even with Hyrax. This might be the case for some server and datacenter designs including extremely dense servers [15–18, 21, 27, 28, 36], connector-less server designs with soldered-on components [45], or datacenters in hard-to-reach locations, such as sealed containers on the ocean floor [10].

## **Acknowledgments**

We thank our shepherd, Daniel Peek, and the anonymous OSDI '23 reviewers for their great comments. We thank our many partner teams within Microsoft including Dirk Hofmann, Saptadeep Chanda, and Tom Harpel for their continued support on understanding technician training, workflows, and staffing; Rama Bhimanadhuni for his help on firmware; and Manish Dalal for early feedback on interpreting diagnostics.

# NCC: Natural Concurrency Control for Strictly Serializable Datastores by Avoiding the Timestamp-Inversion Pitfall

## Abstract

Strictly serializable datastores greatly simplify application development. However, existing techniques pay unnecessary costs for naturally consistent transactions, which arrive at servers in an order that is already strictly serializable. We exploit this natural arrival order by executing transactions with minimal costs while optimistically assuming they are naturally consistent, and then leverage a timestamp-based technique to efficiently verify if the execution is indeed consistent. In the process of this design, we identify a fundamental pitfall in relying on timestamps to provide strict serializability and name it the timestamp-inversion pitfall. We show that timestamp inversion has affected several existing systems.

We present Natural Concurrency Control (NCC), a new concurrency control technique that guarantees strict serializability and ensures minimal costs—i.e., one-round latency, lock-free, and non-blocking execution—in the common case by leveraging natural consistency. NCC is enabled by three components: non-blocking execution, decoupled response management, and timestamp-based consistency checking. NCC avoids the timestamp-inversion pitfall with response timing control and proposes two optimization techniques, asynchrony-aware timestamps and smart retry, to reduce false aborts. Moreover, NCC designs a specialized protocol for read-only transactions, which is the first to achieve optimal best-case performance while guaranteeing strict serializability without relying on synchronized clocks. Our evaluation shows NCC outperforms state-of-the-art strictly serializable solutions by an order of magnitude on many workloads.

## 1 Introduction

Strictly serializable datastores have been advocated by much recent work [12, 18, 19, 33, 52, 58, 68] because they provide the powerful abstraction of programming in a single-threaded, transactionally isolated environment, which greatly simplifies application development and prevents consistency anomalies [8]. However, only a few concurrency control techniques provide strict serializability and they are expensive.

Common techniques include distributed optimistic concurrency control (dOCC), distributed two-phase locking (d2PL), and transaction reordering (TR). They incur high overheads which manifest in extra rounds of messages, distributed lock management, blocking, and excessive aborts. The validation round in dOCC, required lock management in d2PL, blocking

during the exchange of ordering information in TR, and aborts due to conflicts in dOCC and d2PL are examples of these four overheads, respectively. These costs are paid to enforce the two requirements of strict serializability: (1) ensuring there is a total order by avoiding interleaving transactions, and (2) ensuring the *real-time ordering* i.e., later-issued transactions take effect after previously-finished ones. However, we find these costs are unnecessary for many *datacenter workloads* where transactions are executed within a datacenter and then replicated within or across datacenters.

Many datacenter transactions do not interleave: e.g., many of them are dominated by reads [12], and the interleaving of reads returning the same value does not affect correctness. Many of them are short [24, 27, 40, 52, 64, 71], and short lifetimes reduce the likelihood of interleaving. Advances in datacenter networking also reduce variance in delivery times of concurrent requests [5, 14, 22], resulting in less interleaving.

In addition, many datacenter transactions arrive at servers in an order that trivially satisfies their real-time order requirement. That is, a transaction arrives at all participant servers after all previously committed transactions.

Because many transactions do not interleave and their arrival order satisfies the real-time order constraints, intuitively, simply executing their requests in the order servers receive them (i.e., treating them as if they were non-transactional simple operations) will naturally satisfy strict serializability. We call these transactions *naturally consistent*.

Ideally, naturally consistent transactions can be safely executed without any concurrency control, incurring zero costs. However, existing techniques pay unnecessary overheads. For instance, dOCC still requires extra rounds of messages for validation, d2PL still acquires locks, and TR still blocks transactions to exchange ordering information, even if validation always succeeds, locks are always available, and nothing needs to be reordered. Therefore, this paper strives to make naturally consistent transactions as cheap as possible.

In this paper, we present Natural Concurrency Control (NCC), a new concurrency control technique that guarantees strict serializability and ensures minimal costs—i.e., one-round latency, lock-free, and non-blocking execution—in the common case. NCC’s design insight is to execute naturally consistent transactions in the order they arrive, as if they were non-transactional operations, while guaranteeing correctness without interfering with transaction execution.

NCC is enabled by three components. *Non-blocking execution* ensures that servers execute transactions in a way that is similar to executing non-transactional operations. *Decoupled response management* separates the execution of requests from the sending of their responses, ensuring that only correct results are returned. *Timestamp-based consistency checking* uses timestamps to verify transactions' results, without interfering with execution.

While designing the consistency-checking component, we identified a correctness pitfall in timestamp-based, strictly serializable techniques. Specifically, these techniques sometimes fail to guard against an execution order that is total but incorrectly inverts the real-time ordering between transactions, thus violating strict serializability. We call this the *timestamp-inversion* pitfall. Timestamp inversion is subtle because it can happen only if a transaction interleaves with a set of *non-conflicting* transactions that have real-time order relationships. The pitfall is fundamental as we find it affects multiple prior systems (TAPIR [71] and DrTM [66]), which, as a result, do not provide strict serializability as claimed.

NCC handles timestamp inversion through response timing control (RTC), an integral part of decoupled response management, without interfering with non-blocking execution or relying on synchronized clocks. NCC proposes two timestamp optimization techniques, asynchrony-aware timestamps and smart retry, to reduce false aborts. Moreover, NCC designs a specialized protocol for read-only transactions, which, to the best of our knowledge, is the first to achieve optimal performance [40] in the best case while ensuring strict serializability, without relying on synchronized clocks.

We compare NCC with common strictly serializable techniques: dOCC, d2PL, and TR, and two serializable protocols, TAPIR [71] and MVTO [55]. We use three workloads: Google-F1, Facebook-TAO, and TPC-C (§6). The Google-F1 and Facebook-TAO workloads synthesize production-like workloads for Google's Spanner [12, 59] and Facebook's TAO [10], respectively. Both workloads are read-dominated. TPC-C [63] consists of few-shot transactions that are write-intensive. We further explore the workload space by varying the write fractions in Google-F1. NCC significantly outperforms dOCC, d2PL, and TR with 2–10× lower latency and 2–20× higher throughput. NCC outperforms TAPIR with 2× higher throughput and 2× lower latency, and closely matches the performance of MVTO.

In summary, this work makes the following contributions:

- Identifies timestamp inversion, a fundamental correctness pitfall in timestamp-based, strictly serializable concurrency control techniques.
- Proposes NCC, a new concurrency control technique that provides strict serializability and achieves minimal overhead in the common case by exploiting natural consistency in datacenter workloads.
- A strictly serializable read-only protocol with optimal best-

case performance that does not rely on synchronized clocks.

- An implementation and evaluation that shows NCC outperforms existing strictly serializable systems by an order of magnitude and closely matches the performance of systems that provide weaker consistency.

## 2 Background

This section provides the necessary background on transactional datastores, strict serializability, and general techniques for providing strict serializability.

### 2.1 Transactional Datastores

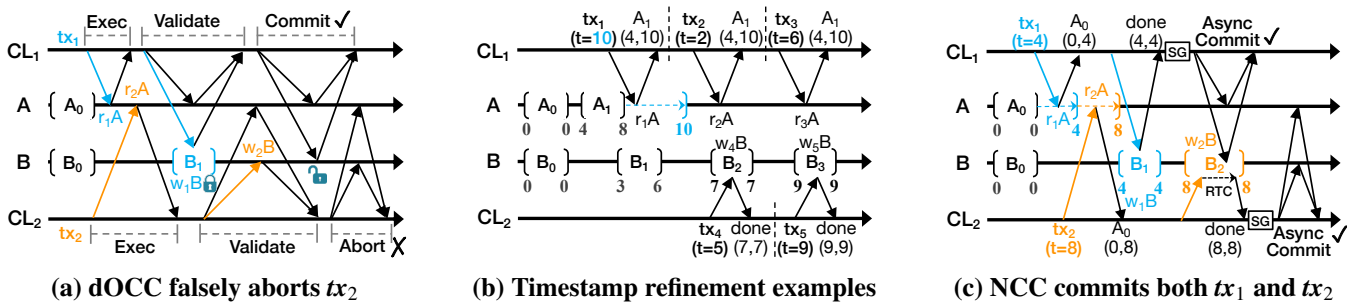

Transactional datastores are the back-end workhorse of many web applications. They typically consist of two types of machines. Front-end *client* machines receive users' requests, e.g., managing a web page, and execute these requests on behalf of users by issuing transactions to the storage *servers* that store the data. Servers are fault-tolerant, e.g., the system state is made persistent on disks and replicated via replicated state machines (RSM), like Paxos [30].

Transactions are managed by coordinators, which can be co-located either with a server or the client. This paper adopts the latter approach to avoid the delays caused by shipping the transaction from the client to a server, while explicitly handling client failures. The coordinator issues read/write operations to relevant servers, called *participants*, following the transaction's logic, which can be *one-shot*, i.e., it knows a priori which data to read/write and can send all requests in one step, or *multi-shot*, i.e., it takes multiple steps as the data read in one step determines which data to read/write in later steps. The system executes transactions following a concurrency control protocol, which ensures that transactions appear to take effect in an order that satisfies the system's consistency requirements. The stronger the consistency provided by the system, the easier it is to develop correct applications.

### 2.2 Strict Serializability

*Strict serializability* [23, 53], also known as external consistency [21], is often considered the strongest consistency model. It requires that (1) there exists a *total order* of transactions, and (2) the total order must respect the *real-time order*, which means if transaction  $tx_1$  ends before  $tx_2$  starts, then  $tx_1$  must appear before  $tx_2$  in the total order. As a result, transactions appear to take effect one at a time in the order the system receives them.

**Formal definition.** We use Real-time Serialization Graphs (RSG) [1] to formalize the total order and real-time order requirements. An RSG is a directed graph that captures the order in which transactions take effect. Specifically, two requests from different transactions have an *execution edge*  $req_1 \xrightarrow{\text{exe}} req_2$  if any of the following happens:  $req_1$  creates some data version  $v_i$  and  $req_2$  reads  $v_i$ ;  $req_1$  reads some data version  $v_j$  and  $req_2$  creates  $v_j$ 's next version that is after  $v_j$ ; or

**Figure 1:**  $tx_1$  and  $tx_2$  are naturally consistent. dOCC incurs unnecessary validation costs, and  $tx_2$  could be falsely aborted due to lock unavailability. NCC can commit both transactions with timestamp pre-assignment, refinement, and the safeguard check (denoted by SG). These techniques are detailed in Section 5.1. Each version in NCC has a  $(t_w, t_r)$  pair which is included in server responses. RTC means response timing control, detailed in Section 5.2.

$req_1$  creates some data version  $v_k$  and  $req_2$  creates  $v$ 's next version that is after  $v_k$ . Two transactions have an execution edge  $tx_1 \xrightarrow{\text{exe}} tx_2$  if there exist  $req_1$  and  $req_2$  from  $tx_1$  and  $tx_2$ , respectively, such that  $req_1 \xrightarrow{\text{exe}} req_2$ . A chain of execution edges constructs a directed path between two transactions (requests), denoted by  $tx_1 \xrightarrow{\text{exe}} tx_2$  ( $req_1 \xrightarrow{\text{exe}} req_2$ ), meaning that  $tx_1$  ( $req_1$ ) “transitively” affects  $tx_2$  ( $req_2$ ) through some intermediary transactions (requests). Two transactions have a *real-time edge*  $tx_1 \xrightarrow{\text{rto}} tx_2$  if there is a real-time ordering between  $tx_1$  and  $tx_2$ , meaning that  $tx_1$  commits before  $tx_2$ 's client issues  $tx_2$ 's first request. In an RSG, vertices are committed transactions, connected by execution and real-time edges.

There exists a total order if and only if transactions do not circularly affect each other. That is, the subgraph that comprises all vertices and only execution edges is acyclic, meaning that the following invariant holds:

**Invariant 1:**  $\forall tx_1, tx_2 (tx_1 \xrightarrow{\text{exe}} tx_2 \implies \neg(tx_2 \xrightarrow{\text{exe}} tx_1))$

The (total) execution order respects the real-time order if and only if the execution edges (paths) do not *invert* the real-time edges, meaning that the following invariant holds:

**Invariant 2:**  $\forall tx_1, tx_2 (tx_1 \xrightarrow{\text{rto}} tx_2 \implies \neg(tx_2 \xrightarrow{\text{exe}} tx_1))$

These invariants correspond to the total order and real-time order requirements, respectively. Therefore, a system is strictly serializable if and only if for any execution it allows, both invariants hold.

By enforcing a total order and the real-time order, strictly serializable systems provide application programmers with the powerful abstraction of programming in a single-threaded, transactionally isolated environment, and thus they greatly simplify application development and eliminate consistency anomalies. For example, if an admin removes Alice from a shared album and then notifies Bob of the change (via a channel external to the system, e.g., a phone call), who then uploads a photo he does not want Alice to see, then Alice must not see Bob's photo, since *remove\_Alice*  $\xrightarrow{\text{rto}}$  *new\_photo*. Such guarantees cannot be enforced by weaker consistency models, e.g., serializability, because they do not enforce the real-time order that is external to the system.

## 2.3 dOCC, d2PL, & Transaction Reordering

Only a few techniques provide strict serializability. The common ones are dOCC, d2PL, and transaction reordering (TR). dOCC and d2PL typically require three round trips, one for each phase: execute, prepare, and commit. In the execute phase, the coordinator reads the data from the servers while writes are buffered locally. d2PL acquires read locks in this phase while dOCC does not. In the prepare phase, the coordinator sends prepare messages and the buffered writes to the participant servers. d2PL locks all participants while dOCC only locks the written data. dOCC must also validate that values read in the execute phase have not changed. If all requests are successfully prepared, i.e., locks are available and/or validation succeeds, the coordinator notifies the participants to commit the transaction and apply the writes; otherwise, the transaction is aborted and retried.

Transaction reordering typically requires two steps. In the first step, the coordinator sends the requests to the servers, which make requests wait while recording their arrival order relative to those of concurrent transactions. This ordering information usually increases linearly in size with respect to the number of concurrent transactions. In the second step, the coordinator collects the ordering information from participants, sorts the requests to eliminate interleavings, and servers execute the transactions in the sorted order.

These techniques are expensive, e.g., they require multiple rounds of messages, locking, waiting, and aborts. We find that these overheads are wasteful for most of the transactions in many datacenter workloads, and this observation has inspired our protocol design.

## 3 Design Insight & Overview

This section explains natural consistency, which inspires our design, and overviews the key design components.

### 3.1 Exploiting Natural Consistency

For many datacenter transactions, simply executing their requests in the order servers receive them, as if they were non-transactional read/write operations, would naturally satisfy

**Figure 2: An overview of system architecture and transaction execution. NCC follows two-phase commit and has three design pillars: non-blocking execution, decoupled response management, and timestamp-based consistency checking.**

strict serializability. In other words, they arrive at servers in an order that is already strictly serializable. We call these transactions *naturally consistent*. Key to natural consistency is the arrival order of transaction requests.

Many requests in datacenter workloads arrive in an order that is total, i.e., transactions do not circularly affect each other, due to the following reasons. First, many requests in real-world workloads are reads [10, 12], and reads do not affect other reads. For instance, reads that return the same value can be executed in any order, and thus servers can safely execute them in their arrival order. Second, many transactions are short, e.g., they are one-shot [24, 27, 40, 52, 64, 71] or can be made one-shot using stored procedures [20, 34, 51, 60, 67], and thus their requests are less likely to interleave with others’ requests. Third, advances in datacenter networks reduce the variance of message delivery times [49, 50, 54], and thus further reduces the likelihood of request interleaving.

In most cases, the (total) arrival order satisfies the real-time order between transactions because a transaction that happens later in real-time, i.e., it starts after another transaction has been committed, must arrive at servers after the committed transaction has arrived.

Ideally, the system would treat naturally consistent transactions as non-transactional operations and execute them in the order they arrive without any concurrency control, while still guaranteeing strict serializability. This insight suggests room for improvement in existing techniques. For instance, dOCC still requires validation messages which are unnecessary when transactions are naturally consistent. Further, during validation between prepare and commit, dOCC has a *contention window* where it can cause other concurrent transactions to abort. As shown in Figure 1a, such contention windows lead to *false aborts*, where a transaction is aborted despite being consistent. Our design aims to minimize costs for as many

naturally consistent transactions as possible.

### 3.2 Three Pillars of Design

Our design executes naturally consistent transactions in a manner that closely resembles non-transactional operations. This is made possible through three components.

**Non-blocking execution.** Assuming transactions are naturally consistent, servers execute requests in the order they arrive. Requests are executed “urgently” to completion without acquiring locks, and their results are immediately made visible to prevent blocking subsequent requests. As a result, transactions are executed as cheaply as non-transactional operations, without incurring contention windows.

**Decoupled response management.** Because not all transactions are naturally consistent, servers must prevent returning inconsistent results to clients and ensure there are no cascading aborts. This is achieved by decoupling requests’ responses from their execution, with a response sent asynchronously only once it is verified consistent. Inconsistent results are discarded, and their requests are re-executed.

**Timestamp-based consistency checking.** We must check consistency as efficiently as possible, without interfering with server-side execution. We leverage timestamps to capture the arrival order (thus the execution order) of requests and design a client-side checker that verifies if requests were executed in a total order, without incurring overheads such as messages (as in dOCC and TR) or locks (as in dOCC and d2PL).

Figure 2 shows at a high level how these three pillars support our design, and depicts the life cycle of transactions:

- 1 The user submits application requests to a client, which translates the requests into transactions.
- 2 The (client) coordinator sends operations to the par-

ticipant servers, following the transaction’s logic. The servers execute requests in their arrival order. Their responses are inserted into a queue and sent asynchronously. The responses include timestamps that capture requests’ execution order.

- ③ Responses are sent to the client when it is safe, determined by response timing control (RTC).
- ④ The safeguard checks if transactions were executed in a total order by examining the timestamps in responses. The coordinator sends commit/abort messages to the servers and returns the results of committed transactions to the user in parallel, without waiting for servers’ acknowledgments.  $\otimes$  and  $\otimes$  explicitly handle client failures by leveraging a server as a backup coordinator.

**Limitations.** First, our design leverages natural consistency, which is observed in short (e.g., one or few shots) datacenter transactions; while our design supports arbitrary-shot transactions, many-shot long-lasting transactions that are more likely to interleave might not benefit from our design. Second, the timestamps associated with each request, including both reads and writes, must be made persistent (e.g., written to disks) and replicated for correctly handling failures, which could lead to replication overhead, which we detail in Section 5.6.

**An observation.** Key to the correctness of our design is leveraging timestamps to verify a total order that respects the real-time order. Yet, we identify a correctness pitfall in relying on timestamps to ensure strict serializability.

## 4 Timestamp-Inversion Pitfall

We discover that timestamp-based techniques sometimes fail to guard against a total order that violates the real-time order in subtle cases. As a result, executing transactions in such a total order inverts the real-time relationship between transactions, which leads to a violation of strict serializability. We call such violations the *timestamp-inversion* pitfall. Figure 3 shows a minimal construction of timestamp inversion using three transactions.  $tx_1$  and  $tx_2$  are single-machine transactions issued by different clients, and  $tx_2$  starts after  $tx_1$  finishes, so there exists a real-time order  $tx_1 \xrightarrow{rto} tx_2$  that strict serializability must enforce.  $tx_3$  is a multi-shard transaction by a third client that interleaves with  $tx_1$  and  $tx_2$ .  $tx_1$ ,  $tx_2$ , and  $tx_3$  have timestamps 10, 5, and 7, respectively.<sup>1</sup> By following these timestamps, the transactions are executed in a total order denoted as  $tx_2 \xrightarrow{exe} tx_3 \xrightarrow{exe} tx_1$ , which inverts the real-time order  $tx_1 \xrightarrow{rto} tx_2$  and thus violates strict serializability. Specifically, the execution of these transactions violates Invariant 2, subjecting them to consistency anomalies discussed in §2.2.

The timestamp-inversion pitfall is subtle because it happens only if a transaction interleaves with a set of *non-conflicting* transactions that have real-time ordering constraints. We find

<sup>1</sup>A timestamp is generated by either a loosely synchronized physical clock [48] or a causal counter, e.g., a Lamport clock [28].

**Figure 3: A minimal example of timestamp inversion, a real-time diagram shows the ordering of transactions, and how NCC tackles the timestamp-inversion pitfall.**

timestamp inversion to be fundamental as it has affected multiple different systems; we discuss two such systems below. In addition, we find that there are several existing systems that do not explicitly define their consistency model, but give a strong indication of providing strict serializability—e.g., they claim invariants that are equivalent to strict serializability, or are built on or evaluated against strictly serializable protocols. We find that these systems also fall into the pitfall.

**Timestamp inversion affects several prior systems.** The minimal example in Figure 3 can be extended to variants of timestamp inversion that affect different types of transactions in real system designs, suggesting that this pitfall is general and fundamental. For instance, we find two systems from recent SOSPs fall into different variants of the pitfall, and thus are not strictly serializable as claimed. We elaborate below to help future work avoid timestamp inversion, and provide the full counterexamples in a technical report [41].

TAPIR [71, 72] is an integrated protocol that co-designs concurrency control and replication. Its concurrency control is a variant of dOCC which validates writes using timestamps without acquiring locks, while reads are validated in the traditional way. Because reads and writes are executed in timestamp order but validated with separate mechanisms, TAPIR’s read-write transactions may cause an inversion of concurrent writes. For instance, if  $tx_1$ ,  $tx_2$ , and  $tx_3$  in Figure 3 are read-write transactions, then all three transactions would pass TAPIR’s validation, which results in the inversion of  $tx_1 \xrightarrow{rto} tx_2$ . The effect of this inversion is perceivable to the client via future reads. This variant of timestamp inversion requires a detailed analysis of the possible executions, showing that none of them are admissible by strict serializability [41].

DrTM [11, 66] is a specialized design for modern datastores equipped with hardware transactional memory and remote direct memory access. DrTM uses timestamps to validate read leases which are acquired before reading the data, a technique equivalent to executing read requests in the timestamp order.

---

**Algorithm 5.1: Client (transaction coordinator) logic**

---

```
1 Function EXECUTERWTRANSACTION(tx) :
2   results ← {}; t_pairs ← {} // server responses
3   t.clk ← ASYNCHRONYWARETS(tx); t.cid ← clientID
4   for req in tx do
5     // send requests shot by shot,
6     // following tx's logic
7     res, t_pair ← NONBLOCKINGEXECUTE(req, t)
8     results ← results ∪ res
9     t_pairs ← t_pairs ∪ t_pair
10
11    // all shots done, tx's logic complete
12    ok, t' ← SAFEGUARDCHECK(t_pairs)
13    if not ok then
14      ok ← SMARTRETRY(tx, t') // §5.4
15
16    if ok then
17      ASYNCCOMMITORABORT(tx, "committed")
18      return results
19
20    else
21      ASYNCCOMMITORABORT(tx, "aborted")
22      go to 2 // abort, and retry from scratch
23
24
25
26
27
```

---

This makes DrTM's read-only transactions subject to inversion, e.g., when  $tx_1$ ,  $tx_2$ , and  $tx_3$  in Figure 3 are read-write, read-write, and read-only transactions, respectively.

The main contributions of TAPIR and DrTM still stand, just with weaker consistency than claimed. Both teams conjecture that they can fix the systems by using synchronized clocks (e.g., TrueTime [12]) and adapting their designs to use these clocks. Thus, it is likely that their contributions still stand with strict serializability when synchronized clocks are used. However, synchronized clocks require specialized infrastructure and are not generally available (§7). Therefore, NCC is designed to avoid timestamp-inversion without relying on synchronized clocks.

## 5 Natural Concurrency Control

This section presents the basic components of NCC, explains how NCC avoids the timestamp-inversion pitfall, introduces two timestamp optimization techniques and a specialized algorithm for read-only transactions, and concludes with discussions of failure handling and correctness.

### 5.1 Protocol Basics

We build NCC on the three design pillars (§3.2) to minimize the costs for naturally consistent transactions.

**Pre-timestamping transactions.** NCC processes a transaction in two phases: execute and commit. Algorithm 5.1 shows the client (coordinator)'s logic. The coordinator starts a transaction  $tx$  by pre-assigning it a timestamp  $t$  that consists of two fields:  $clk$  which is the client's physical time (Section 5.3 details how it is computed), and  $cid$  which is the client identifier.  $t$  uniquely identifies  $tx$  (line 3). When two timestamps have the same  $clk$ , NCC breaks the tie by comparing their  $cid$ .  $t$  is included in all of  $tx$ 's requests that are sent to servers shot by shot, following  $tx$ 's application logic (lines 4 and 5). These timestamps accompany  $tx$  throughout its life cycle and will be used to verify if the results are consistent.

**Refining timestamps to match execution order.** Algorithm 5.2 details the server-side logic for request execution and commitment. Each key stores a list of versions in the order of the server creating them. A version has three fields: *value*, a pair of timestamps  $(t_w, t_r)$ , and *status*. *value* stores the data;  $t_w$  is the timestamp of the transaction that created the version;  $t_r$  is the highest timestamp of transactions that read the version; and *status* indicates the state of the transaction that created the version: either (initially) *undecided*, or *committed*. An aborted version is removed from the datastore.

The server always executes a request against the most recent version  $curr\_ver$ , which is either undecided or committed (line 35). Specifically, the server executes a write by creating a new undecided version  $new\_ver$ , which is now the most recent version of the key, ordered after  $curr\_ver$  (lines 39 and 40), and executes a read by reading the *value* of  $curr\_ver$  (line 44). NCC's basic protocol can work with a single-versioned data store while multi-versioning is required only for smart retry, a timestamp optimization technique (§5.4). The server refines the most recent version's timestamp pair to match the order in which requests are executed. Specifically, a write request computes  $new\_ver$ 's  $t_w$  as follows: its physical time field is no less than that of the write's timestamp  $t$  and that of  $curr\_ver$ 's  $t_r$ , and its client identifier is the same as  $t$ 's (line 37);  $new\_ver$ 's  $t_r$  is initialized to  $t_w$  (line 38). Similarly, a read request updates  $curr\_ver$ 's  $t_r$  if needed (line 43). Figure 1b shows examples of how timestamps are refined. A version is associated with a  $t_w$  and a  $t_r$ , e.g.,  $A_1$  initially has a timestamp pair (4, 8).  $tx_1$ – $tx_3$  are single-key read transactions with pre-assigned timestamps 10, 2, and 6, respectively. They return the most recent version of  $A$ , i.e.,  $A_1$ , update its  $t_r$  if needed, and return  $A_1$ 's timestamp pair.  $tx_4$  and  $tx_5$  show how writes manage timestamps.

These (refined) timestamps match requests' arrival order and thus also match the execution order: on each key, a read must have a timestamp greater than that of the write it sees, i.e., a read is ordered after the most recent write, and a write must have a timestamp greater than that of the most recent read, i.e., a write is ordered after the most recent read (and thus all previous writes).

**Non-blocking execution and response queues.** The server executes requests in a non-blocking manner and decouples

---

**Algorithm 5.2: Server execution and commitment**

---

```
28 Multi-versioned data store:
29 DS[key][ver] // indexed by key, vers sorted by  $t_w$ 
// ver is either committed or undecided
30 Response queue:
31 resp_qs[key][resp_q] // resp queues for each key
32
33 Function NONBLOCKINGEXECUTE(req, t) :
34   resp ← [] // response message
35   curr_ver ← DS[req.key].most_recent
36   if req is write then
37      $t_w.clk ← \max\{t.clk, curr\_ver.t_r.clk + 1\}; t_w.cid ← t.cid$ 
38      $t_r ← t_w$ 
39     new_ver ← [req.value, ( $t_w, t_r$ ), "undecided"]
40     DS[req.key] ← DS[req.key] + new_ver
41     resp ← ["done", ( $t_w, t_r$ )]
42   else
43      $curr\_ver.t_r ← \max\{t, curr\_ver.t_r\}$ 
44     resp ← [curr_ver.value, ( $curr\_ver.t_w, curr\_ver.t_r$ )]
45   resp_qs[req.key].enqueue(resp, req, t, "undecided")
46   RESPTIMINGCONTROL(resp_qs[req.key]) // §5.2
47
48 Function ASYNCCOMMITORABORT(tx, decision) :
49   foreach ver created by tx do
50     if decision = "committed" then
51       ver.status ← decision
52     else
53       DS.remove(ver)
54   foreach resp_q in resp_qs do
55     foreach resp in resp_q do
56       if resp.request ∈ tx then
57         resp.q_status ← decision
58   RESPTIMINGCONTROL(resp_q) // §5.2
```

---

their execution from responses. Specifically, a write creates a version and immediately makes it visible to subsequent transactions; a read fetches the value of the most recent version whose *status* could be undecided, without waiting for it to commit; the server prepares the response (lines 34, 41, and 44), inserts it into a *response queue* (lines 45 and 46), which asynchronously sends the responses to clients when it is safe. (Section 5.2 details response timing control, which determines when sending a response is safe so timestamp inversion and cascading aborts are prevented.) Unlike d2PL and dOCC, which lock data for at least one round-trip time in the execute and prepare phases (i.e., the contention window), non-blocking execution ensures that a transaction never exclusively owns the data without performing useful work. As a result, the server never stalls, and CPUs are fully utilized to execute requests. Moreover, non-blocking execution eliminates the contention window and thus reduces false aborts.

**Client-side safeguard.** A server response includes the timestamp pair ( $t_w, t_r$ ) of the most recent version, e.g., *new\_ver* for a write and *curr\_ver* for a read. The returned ( $t_w, t_r$ ) represents the time range in which the request is valid. That is, a read must take effect after  $t_w$ , which is the time when the

most recent write on the same key took effect, and no later writes can take effect between  $t_w$  and  $t_r$  on the same key. A write must have  $t_w = t_r$ , meaning that it takes effect exactly at  $t_w$ . When a transaction has completed its logic (i.e., all shots are executed) and the client has received responses to all its requests, the safeguard looks for a consistent snapshot that intersects all ( $t_w, t_r$ ) pairs in server responses by checking if the ( $t_w, t_r$ ) pairs overlap (lines 8, 18–27). This intersecting snapshot identifies the transaction’s synchronization point, i.e., all requests are valid at the intersecting timestamp.

Figure 1c shows an example where NCC executes the same transactions in Figure 1a. The default versions  $A_0$  and  $B_0$  both have a timestamp pair (0, 0).  $tx_1$  and  $tx_2$  are pre-assigned 4 and 8, respectively, and their requests arrive in the same order as they were in Figure 1a. The safeguard enables NCC to commit both transactions, i.e.,  $tx_1$ ’s responses intersect at 4 while  $tx_2$ ’s intersect at 8, without unnecessary overhead such as dOCC’s validation cost and false aborts.

When the client has decided to commit or abort the transaction, the protocol enters the commit phase by sending the commit/abort messages to the servers. If the transaction is committed, the server updates the *status* of the created versions from undecided to committed; otherwise, the versions are deleted (lines 48–53). The client retries the aborted transaction. The client sends the results of the committed transaction to the user in parallel with the commit messages, i.e., asynchronous commit, without waiting for servers’ acknowledgments (lines 11–16).

**Supporting complex transaction logic.** NCC supports transactions accessing a key multiple times, e.g., read-modify-writes and repeated reads/writes, by treating its requests to the same key as a single logical request. For instance, if a read-modify-write has its read and write requests executed consecutively (i.e., they are not intersected by other writes), then only the write response is checked by the safeguard, treating read-modify-write as one logical request; otherwise, it is aborted if there are intersecting writes, e.g., when the most recent version has a  $t_w$  greater than that returned by the read of this read-modify-write. The responses of these requests are grouped together in the response queue, e.g., the write response of a read-modify-write is inserted right after the read response of the same read-modify-write. We explain the details of handling complex logic in the technical report [41].

NCC achieves minimal costs by urgently executing transactions in a non-blocking manner and by ensuring a total order with the light-weight timestamp-based safeguard. Yet, in order to provide strict serializability, NCC must enforce the real-time order between transactions by handling the timestamp-inversion pitfall, as we discuss next.

## 5.2 Response Timing Control

NCC avoids the timestamp-inversion pitfall by disentangling the subtle interleaving between a set of non-conflicting transactions that have real-time order dependencies (e.g., Figure 3),

without relying on synchronized clocks. Specifically, NCC introduces *response timing control* (RTC), which controls the sending time of responses. It is safe to send the response of a request  $req_1$  when the following dependencies are satisfied:

- D<sub>1</sub> If  $req_1$  reads a version created by  $req_0$  of another transaction, then  $req_1$ 's response is not returned until  $req_0$  is committed or it is discarded if  $req_0$  is aborted (then  $req_1$  will be re-executed).
- D<sub>2</sub> If  $req_1$  is a write and there are reads that read the version which immediately precedes the one created by  $req_1$ , then  $req_1$ 's response is not returned until the reads are committed/aborted.
- D<sub>3</sub> If  $req_1$  creates a version immediately after the version created by  $req_0$  of another transaction, then  $req_1$ 's response is not returned until  $req_0$  is committed/aborted.

By enforcing these dependencies, NCC controls the sending of responses so that the transactions which form the subtle interleaving are forced to take effect in their real-time order. For instance, in Figure 3, server A cannot send the response of  $tx_1$  until  $tx_3$  has been committed (assuming at least one of them writes to A). As a result, any transaction  $tx_2$  that begins after  $tx_1$  receives its response, i.e.,  $tx_1 \xrightarrow{rto} tx_2$ , must be executed after  $tx_1$ , and thus after  $tx_3$  as well:  $tx_2$ 's execution on each server is after it begins, which is after  $tx_1$  ends, which is after  $tx_1$ 's response is sent, which is after  $tx_3$  commits, which is after  $tx_3$  executes on each server. This results in a total order  $tx_3 \xrightarrow{exe} tx_1 \xrightarrow{exe} tx_2$ , which respects the real-time order, enforcing Invariant 2, as shown in Part III of Figure 3.

NCC implements RTC by managing response queues, independently from request execution. NCC maintains one queue per key. A queue item consists of four fields: *response* that stores the response message of a request, the *request* itself, *ts* which is the pre-assigned timestamp of the request, and *q\_status* that indicates the state of the request, which is initially *undecided*, and updated to either *committed* or *aborted* when the server receives the commit/abort message for this request (lines 54–57, Algorithm 5.2).

**Managing response queues.** Algorithm 5.3 details how NCC manages the response queue of each key. This logic is invoked every time the server finishes executing a request (line 46) and receives a commit/response message (line 58). NCC iterates over the queue items from the head (i.e., the oldest response) until it finds the first response whose *q\_status* is undecided, which means all earlier requests on the same key have been committed or aborted, i.e., this response has satisfied the three dependencies (lines 60–62 and 71). The server sends this response message to the client if it has not done so (lines 72, 74–77). If this is a read response, then the server sends all consecutive read responses that follow it (lines 73 and 78–81), because all these read responses satisfy the three dependencies. In other words, reads returning the same value do not have dependencies between them. RTC is *effectively* similar to locking the response queues, e.g., the

**Algorithm 5.3:** Response timing control

```

59 Function RESPIMINGCONTROL(resp_q) :
60   head ← resp_q.head() // the oldest response
61   while head.q_status ≠ “undecided” do
62     // find the first response we can send
63     resp_q.dequeue()
64     new_head ← resp_q.head()
65     new_req ← new_head.request; t ← new_head.ts
66     while head.q_status = “aborted”
67       and head.request is write and new_req is read do
68         // handle reads seeing aborted writes
69         resp_q.dequeue() // discard read response
70         // re-execute the read locally
71         NONBLOCKINGEXECUTE(new_req, t)
72         new_head ← resp_q.head()

```

queue is “locked” when a response is sent and other responses must wait, and is “unlocked” when the commit/abort message for the request to which the sent response belongs is received. However, RTC differs from lock-based mechanisms in that it is decoupled from execution and does not introduce contention windows, i.e., data objects are not locked.

**Fixing reads locally.** When the server receives an abort message for a write request, it must invalidate the responses of any reads that have fetched the value of the aborted write. This is necessary to avoid returning invalid results to the client and to prevent cascading aborts. Specifically, the server removes the response of such a read from the response queue and re-executes the read request, e.g., it fetches the current most recent version, prepares a new response, and inserts the new response to the tail of the queue (lines 65–68).

**Avoiding indefinite waits.** To avoid responses from circularly waiting on dependencies across different keys, NCC early aborts a request (thereby aborting the transaction to which it belongs) if its pre-assigned timestamp is not the highest the server has seen *and* if its response cannot be sent immediately, i.e., it is not the head of the queue. Specifically, a write (read) is aborted if there is an undecided request (write request) with a higher timestamp. Then, the server sends a special response to the client without executing the request. The special response includes a field *early\_abort* which allows

the client to bypass the safeguard and abort the transaction. We omit the details from the pseudocode for clarity.

RTC is a general solution to timestamp inversion, without the need for synchronized clocks. It does not incur more aborts even when responses are not sent immediately, because response management is decoupled from request execution. That is, whether a transaction is committed or aborted is solely based on timestamps, and RTC does not affect either pre-assignment or refinement of timestamps. Yet, NCC’s performance also depends on how well timestamps capture the arrival order of (naturally consistent) transactions. That is, timestamps that do not match transactions’ arrival order could cause transactions to falsely abort even if they are naturally consistent. Next, we will discuss optimization techniques that enable timestamps to better match the arrival order.

### 5.3 Asynchrony-Aware Timestamps

NCC proposes two optimizations: a proactive approach that controls how timestamps are generated before transactions start, and a reactive approach that updates timestamps to match the naturally consistent arrival order after requests are executed. This subsection discusses the proactive approach.

The client pre-assigns the same timestamp to all requests of a transaction; however, these requests may arrive at their participant servers at different physical times, which could result in a mismatch between timestamp and arrival order, as shown in Figure 4a. Transactions  $tx_1$  and  $tx_2$  start around the same time and thus are assigned close timestamps, e.g.,  $t_1 = 1004$  and  $t_2 = 1005$ , respectively (client IDs are omitted). Because the latency between  $B$  and  $CL_1$  is greater than that between  $B$  and  $CL_2$ ,  $tx_1$  may arrive at  $B$  later than  $tx_2$ , but  $tx_1$  has a smaller timestamp. As a result, the safeguard may falsely reject  $tx_1$ , e.g., server  $B$  responds with a refined timestamp pair (1006, 1006) which does not overlap with (1004, 1004), the timestamp pair returned by server  $A$ . However, aborting  $tx_1$  is unnecessary because  $tx_1$  and  $tx_2$  are naturally consistent.

To tackle this challenge, NCC generates timestamps while accounting for the time difference,  $t_\Delta$ , between when a request is sent by the client and when the server starts executing the request. Specifically, the client records the physical time  $t_c$  before sending the request to the server; the server records the physical time  $t_s$  before executing the request and piggy-backs  $t_s$  onto the response sent back to the client; and the client calculates  $t_\Delta$  by finding the difference between  $t_c$  and  $t_s$ , i.e.,  $t_\Delta = t_s - t_c$ . By measuring the end-to-end time difference,  $t_\Delta$  effectively masks the impact of queuing delays and clock skew. The client maintains a  $t_\Delta$  for each server it has contacted. An asynchrony-aware timestamp is generated by adding the client’s current physical time and the greatest  $t_\Delta$  among the servers this transaction will access. For instance, given the values of  $t_\Delta$  shown in Figure 4a,  $CL_1$  assigns  $tx_1$  timestamp 1014 (i.e.,  $1004 + 10$ ) and  $CL_2$  assigns  $tx_2$  1010 (i.e.,  $1005 + 5$ ), and both transactions may successfully pass their safeguard check, capturing natural consistency.

---

#### Algorithm 5.4: Smart retry

---

```

83 Function SMARTRETRY( $tx, t'$ ):
84   foreach  $ver$  accessed by  $tx$  do
85     // next version of the same key
86      $next\_ver \leftarrow ver.next()$ 
87     if  $next\_ver.t_w \leq t'$  then
88       return false
89     if  $ver$  created by  $tx$  and  $ver.t_w \neq ver.t_r$  then
90       return false
91     if  $ver$  created by  $tx$  then
92        $ver.t_w \leftarrow t'; ver.t_r \leftarrow t'$ 
93     else
94        $ver.t_r \leftarrow \max\{ver.t_r, t'\}$ 
95   return true

```

---

### 5.4 Smart Retry

NCC proposes a reactive approach to minimizing the performance impact of the safeguard’s false rejects, which happen when timestamps fail to identify the naturally consistent arrival order, as shown in Figure 4b. Initially, version  $A_0$  has a timestamp pair (0, 0), and  $B_0$  has (0, 5). The same transactions  $tx_1$  and  $tx_2$  as those in Figure 1c access both keys. Following NCC’s protocol,  $tx_1$ ’s responses contain the timestamp pairs (0, 4) and (6, 6) from  $A$  and  $B$ , respectively, which will be rejected by the safeguard because they do not overlap. However, aborting  $tx_1$  is unnecessary because  $tx_1$  and  $tx_2$  are naturally consistent.

Instead, NCC tries to “reposition” a rejected transaction with respect to the transactions before and after it to construct a total order, instead of aborting and re-executing the rejected transaction from scratch, which would waste all the work the server has done for executing it. Specifically, NCC chooses a timestamp that is nearest “in the future” and hopes the rejected transaction can be re-committed at that time. This is possible if the chosen time has not been taken by other transactions.

Algorithm 5.4 shows the pseudocode for smart retry. When the transaction fails the safeguard check, NCC suggests a new timestamp  $t'$ , which is the maximum  $t_w$  in the server responses. The client then sends smart retry messages that include  $t'$  to the participant servers, which then attempt to reposition the transaction’s requests at  $t'$ . The server can reposition a request if there has not been a newer version that was created before  $t'$  (lines 85–87) and, if the request is a write, the version it created has not been read by any transactions (lines 88 and 89). The server updates the timestamps of relevant versions if smart retry succeeds, e.g., the created version has a new timestamp pair ( $t', t'$ ), and  $t_r$  of the read version is updated to  $t'$  if  $t'$  is greater (lines 90–93). (Our implementation does not smart-retry the request that returned the maximum  $t_w$ , i.e.,  $t_w = t'$ , because its smart retry always succeeds.) The client commits the safeguard-rejected transaction if all its smart retry requests succeed, and aborts and retries it from scratch otherwise (lines 9 and 10, Algorithm 5.1).

$$\begin{aligned}
t_{\Delta}(CL_1 \rightarrow A) &= 1 \\
t_{\Delta}(CL_2 \rightarrow C) &= 1 \\
t_{\Delta}(CL_2 \rightarrow B) &= 5 \\
t_{\Delta}(CL_1 \rightarrow B) &= 10
\end{aligned}$$

(a) Asynchrony-aware timestamps (b) Safeguard false rejects (c) Smart retry reduces false rejects

**Figure 4: Optimizations that match the timestamps with transactions' arrival order. Asynchrony-aware timestamps proactively controls the pre-assigned timestamps before execution. Smart retry reactively fixes the safeguard's false rejects after execution thus avoids aborting and re-executing transactions.**

Not only does smart retry avoid false aborts, it also unleashes a higher degree of concurrency, as shown in Figure 4c. The servers have executed a newer transaction  $tx_2$  when  $tx_1$ 's smart retry (SR) messages arrive, and both transactions can be committed even if the messages interleave, e.g.,  $tx_1$ 's smart retry succeeds and  $tx_2$  passes its safeguard check, because  $tx_2$ 's pre-assigned timestamps have left enough room for repositioning  $tx_1$ 's requests. In contrast, validation-based techniques would unnecessarily abort  $tx_1$  (considering SR as dOCC's validation messages) due to the presence of the conflicting transaction  $tx_2$ .

**Garbage collection.** Old versions are temporarily stored and garbage collected as soon as they are no longer needed by undecided transactions for smart retry. Only the most recent versions are used to serve new transactions.

## 5.5 Read-Only Transactions

NCC designs a specialized read-only transaction protocol for read-dominated workloads [10, 12, 26, 40, 44]. Similar to existing works, NCC optimizes read-only transactions by eliminating their commit phase because they do not modify the system state and have nothing to commit. By eliminating commit messages, read-only transactions achieve *optimal performance* in the best case, i.e., one round of non-blocking messages with constant metadata [40, 42, 43].

Eliminating commit messages brings a new challenge to response timing control: write responses can no longer track their dependencies on preceding read-only transactions, as they do not know if and when those reads are committed/aborted. To tackle this challenge, NCC aborts a read-only transaction if it could possibly cause the subtle interleaving that leads to timestamp inversion. In other words, NCC commits a read-only transaction if its requests arrive in a naturally consistent order and no intervening writes have been executed since the last time the client accessed these servers.

Specifically, each client tracks  $t_{ro}$  which is the  $t_w$  of the version created by the most recent write on a server, and the client maintains a map of  $t_{ro}$  for each server this client has contacted. A read-only transaction is identified by a Boolean field

*IS\_READ\_ONLY*. The client sends each of its requests to the participant server together with the pre-assigned timestamp (as in the basic protocol) and the  $t_{ro}$  of the server. To execute a read request, the server checks the version at  $t_{ro}$ . If the version is still the most recent, the server continues to execute the read following the basic protocol, e.g., it fetches the most recent version, refines its  $t_r$  if needed, and returns its timestamp pair; otherwise, the server sends a special response that contains a field *ro\_abort* immediately without executing the request. If any of the responses contain *ro\_abort*, the client aborts this read-only transaction; otherwise, the client continues with the safeguard check and, if needed, smart retry, after which the client does not send any commit/abort messages.

This protocol pays more aborts in the worst case in exchange for reduced message overhead in the normal case, a trade-off that is worthwhile for read-dominated workloads where writes are few so aborts are rare, and read-only transactions are many so the savings in message cost are significant. This protocol also expedites the sending of responses for read-write transactions because read-only transactions do not insert responses into the response queue, i.e., a write response depends only on the reads of preceding read-write transactions in Dependency  $D_2$ , not those of read-only transactions.

## 5.6 Failure Handling

**Tolerating server failures.** NCC assumes servers never fail as their state is typically made persistent on disks and replicated via state machine replication such as Paxos [29]. All state changes incurred by a transaction in the execute phase (e.g.,  $t_w$  and  $t_r$  of each request) must be written to the disk and replicated for correctness. For instance, after a request is executed, the server inserts its response into the response queue and, in parallel, writes the state changes to the disk and replicates the request to other replicas. Its response is sent back to the client when it is allowed by response timing control and when its replication is finished. Commit/abort and smart retry messages are also made persistent and replicated. This simple scheme ensures correctness but incurs high overhead. We plan to investigate possible optimizations in future work, e.g., NCC could defer disk writes and replication to the

last shot of a transaction where all state changes are made persistent and replicated once and for all, without having to replicate each request separately. Server replication inevitably increases latency but does not introduce more aborts, because whether a transaction is committed or aborted is solely based on its timestamps, which are decided during request execution and before replication starts.

**Tolerating client failures.** NCC must handle client failures explicitly because clients are not replicated in most systems and NCC co-locates coordinators with clients. NCC adopts an approach similar to that in Sinfonia [4] and RIFL [31]. We briefly explain it as follows. For a transaction  $tx$ , one of the storage servers  $tx$  accesses is selected as the backup coordinator, and the other servers are cohorts. In the last shot of the transaction logic, which is identified by a field `IS_LAST_SHOT` in the requests, the client notifies the backup coordinator of the identities of the complete set of cohorts. Cohorts always know which server is the backup coordinator. When the client crashes, e.g., is unresponsive for a certain amount of time, the backup coordinator reconstructs the final state of  $tx$  by querying the cohorts for how they executed  $tx$ , and commits/aborts  $tx$  following the same safeguard and smart retry logic. Because computation is deterministic, the backup coordinator always makes the same commit/abort decision as the client would if the client did not fail. To tolerate one client failure, NCC needs one backup coordinator which is a storage server replicated in a usual way.

## 5.7 Correctness

This section provides proof intuition for why NCC is safe and live. At a high level, NCC guarantees a total order, the real-time order, and liveness, with the mechanisms (M<sub>1</sub>) the safeguard, (M<sub>2</sub>) non-blocking execution with response timing control, and (M<sub>3</sub>) early aborts, respectively. We provide a formal proof of correctness in a technical report [41].

**NCC is safe.** We prove that NCC guarantees strict serializability by demonstrating that both Invariants 1 and 2 are upheld. These two invariants correspond to the total order and real-time order requirements, respectively.

Intuitively, NCC commits all requests of a transaction at the same synchronization point, which is the intersection of all  $(t_w, t_r)$  pairs in responses, and the synchronization points of all committed transactions construct a total order. Specifically, we prove that the safeguard enforces Invariant 1, by contradiction. Assume both  $tx_1$  and  $tx_n$  are committed, and  $tx_1 \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$ . Without loss of generality, there must exist a chain of transactions such that  $tx_1 \xrightarrow{\text{exe}} tx_2 \xrightarrow{\text{exe}} \dots \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$ . Then, each transaction may have two requests,  $req$  and  $req'$ , such that  $req'_1 \xrightarrow{\text{exe}} req_2$ ,  $req'_2 \xrightarrow{\text{exe}} req_3$ ,  $\dots$ ,  $req'_{n-1} \xrightarrow{\text{exe}} req_n$ ,  $req'_n \xrightarrow{\text{exe}} req_1$ . Consider their returned timestamps, we can derive the following:

- ①  $t'_{r1} \leq t_{w2}, t'_{r2} \leq t_{w3}, \dots, t'_{rn} \leq t_{w1}$ , by NCC's protocol.
- ②  $t_{w1} \leq t'_{r1}, t_{w2} \leq t'_{r2}, \dots, t_{wn} \leq t'_{rn}$ , because all transactions

are committed and by the safeguard logic.

- ③  $t_{w1} \leq t'_{r1} \leq t_{w2} \leq t'_{r2} \leq \dots \leq t_{wn} \leq t'_{rn} \leq t_{w1}$ , by ① and ②.
- ④  $t'_{r1} = t_{w2} = t'_{r2} = t_{w3} = \dots = t_{wn} = t'_{rn} = t_{w1}$ , by ③.
- ⑤  $req'_i$  is a write and  $req_i$  is a read,  $i \in [1, n]$ , by ④, NCC's protocol, and  $tx_1 \xrightarrow{\text{exe}} tx_2 \xrightarrow{\text{exe}} \dots \xrightarrow{\text{exe}} tx_n \xrightarrow{\text{exe}} tx_1$ .
- ⑥  $t_{w2} = t'_{w1}$  and  $t_{w1} = t'_{wn}$ , by ⑤ and NCC's protocol.
- ⑦  $t'_{w1} = t'_{wn}$ , by ④ and ⑥, which contradicts that writes from different transactions must have distinct  $t_w$  because timestamps are unique. Therefore, Invariant 1 holds.

We prove that NCC enforces Invariant 2 by considering two cases while assuming  $tx_1 \xrightarrow{\text{ro}} tx_2$ . In case 1,  $tx_1$  and  $tx_2$  access some common data items. Then, we must have  $tx_1 \xrightarrow{\text{exe}} tx_2$ , because NCC executes requests in their arrival order. Then, it must be true that  $\neg(tx_2 \xrightarrow{\text{exe}} tx_1)$ , by Invariant 1. In case 2,  $tx_1$  and  $tx_2$  access disjoint data sets, and we prove the claim by contradiction. Assume  $tx_2 \xrightarrow{\text{exe}} tx_1$ , then there must exist  $req_2$  and  $req_1$  in  $tx_2$  and  $tx_1$ , respectively, such that  $req_2 \xrightarrow{\text{exe}} req_1$ .  $req_1$ 's response is not returned until  $req_2$  is committed or aborted, by applying response timing control transitively (§5.2). Then,  $req_2$  is issued before  $req_1$ 's client receives  $req_1$ 's response because a request, e.g.,  $req_2$ , can be committed or aborted only after it is issued and executed. Thus, we can derive  $\neg(tx_1 \xrightarrow{\text{ro}} tx_2)$  because  $tx_2$  has at least one request, e.g.,  $req_2$ , which starts before  $tx_1$  receives all its responses. This means  $tx_2$  starts before  $tx_1$  is committed, which contradicts our assumption  $tx_1 \xrightarrow{\text{ro}} tx_2$ . Therefore, Invariant 2 must hold.

**NCC is live.** NCC's non-blocking execution guarantees that requests always run to completion, i.e., execution never stalls (§5.1). Blocking can happen only to the sending of responses due to response timing control, and NCC avoids circular waiting with early aborts (§5.2). Thus, NCC guarantees that transactions finish eventually.

NCC's specialized read-only transaction protocol and optimization techniques such as asynchrony-aware timestamps and smart retry do not affect correctness, because transactions are protected by the three mechanisms (i.e., M<sub>1</sub>, M<sub>2</sub>, and M<sub>3</sub> summarized at the beginning of this subsection) regardless of whether optimizations or the specialized protocol are used.

## 6 Evaluation

This section answers the following questions:

1. How well does NCC perform, compared to common strictly serializable techniques dOCC, d2PL, and TR?
2. How well does NCC perform, compared to state-of-the-art serializable (weaker consistency) techniques?
3. How well does NCC recover from client failures?

**Implementation.** We developed NCC on Janus's framework [52]. We improved the framework by making it support multi-shot transactions, optimizing its baselines, and adding more benchmarks. NCC's core protocols have  $\sim 3$  K lines of C++ code. We also show the results of NCC-RW, a version

**Figure 6: Facebook-TAO and Google-F1 have low contention. TPC-C and Google-WF (varying write fractions) are write-intensive. TPC-C Payment and Order-Status are multi-shot.**

without the read-only transaction protocol, i.e., all transactions are executed as read-write transactions.

**Baselines.** The evaluation includes three strict serializable baselines (dOCC, d2PL, and Janus) and two serializable baselines (MVTO and TAPIR). We chose d2PL and dOCC because they are the most common strictly serializable techniques. We chose Janus because it is the only open-source TR-based strictly serializable system we could find. We chose MVTO because it has the highest best-case performance among all (weaker) serializable techniques, presenting a performance upper bound. We chose TAPIR because it utilizes timestamp-based concurrency control.

Our evaluation focuses on concurrency control and assumes servers never fail. Janus and TAPIR are unified designs of the concurrency control and replication layers, so we disabled their replication and only compare with their concurrency control protocols, shown as Janus-CC and TAPIR-CC, to make the comparisons fair. We compare with two variants of d2PL. d2PL-no-wait aborts a transaction if the lock is not available. d2PL-wound-wait makes the transaction wait if it has a larger timestamp and aborts the lock-holding transaction otherwise. All baselines are fully optimized: we co-locate coordinators with clients (even if baselines cannot handle client failures), combine the execute and prepare phases for d2PL-no-wait and TAPIR-CC, and enable asynchronous commitment, i.e., the client replies to the user without waiting for the acknowledgments of commit messages.

## 6.1 Workloads and Experimental Setup

We evaluate NCC under three workloads that cover both read-dominated “simpler” transactions and many-write more “complex” transactions. Google-F1 and Facebook-TAO synthesize real-world applications and capture the former: they are one-shot and read-heavy. TPC-C has multi-shot transactions and

is write-intensive, capturing the latter. We also vary write fractions in Google-F1 to further explore the latter. Table 5 shows the workload parameters.

Google-F1 parameters were published in F1 [59] and Spanner [12]. Facebook-TAO parameters were published in TAO [10]. TPC-C’s New-Order, Payment, and Delivery are read-write transactions. Its Order-Status and Stock-Level are read-only. Janus’s original implementation of TPC-C is one-shot, so we modified it to make Payment and Order-Status multi-shot, to demonstrate NCC is compatible with multi-shot transactions and evaluate its performance beyond one-shot transactions (though they are still relatively short).

**Experimental setting.** We use Microsoft Azure [47]. Each machine has 4 CPUs (8 cores), 16GB memory, and a 1Gbps network interface. We use 8 machines as servers and 16–32 machines as clients that generate open-loop requests to saturate the servers. (The open-loop clients back off when the system is overloaded to mitigate queuing delays.) Google-F1 and Facebook-TAO have 1M keys, with the popular keys randomly distributed to balance load. We run 3 trials for each test and 60 seconds for each trial. Experiments are CPU-bound (i.e., handling network interrupts).

## 6.2 Result Overview

NCC outperforms strictly serializable protocols dOCC, d2PL, and TR (Janus-CC) by 80%–20× higher throughput and 2–10× lower latency under various workloads (Figure 7) and write fractions (Figure 8a). NCC outperforms and closely matches serializable systems, TAPIR-CC and MVTO, respectively (Figure 8b). NCC recovers from client failures with minimal performance impact (Figure 8c). Please note that Figure 7 and Figure 8b have log-scale axes. Figure 6 summarizes the takeaway of performance improvements.

**Figure 7: NCC achieves much lower latency under read-dominated workloads with its specialized read-only transaction algorithm, 50% lower latency under write-intensive workload, and at least 80% higher throughput across workloads.**

### 6.3 Latency vs. Throughput Experiments

Figure 7 shows NCC’s overall performance is strictly better than the baselines, i.e., higher throughput with the same latency and lower latency with the same throughput.

**Google-F1 and Facebook-TAO.** Figure 7a shows the results under Google-F1. X-axis is the system throughput, and y-axis shows the median read latency in log scale. A horizontal line (O.P.) marks the operating point with reasonably low latency (< 10ms). At the operating point, NCC has a 2–4× higher throughput than dOCC and d2PL. We omit the results for Janus-CC to make the graph clearer as we found that Janus-CC’s performance is incomparable (consistently worse) with other baselines, because Janus-CC is designed for highly contended workloads by relying on heavy dependency tracking, which is more costly under low contention.

NCC has better performance because Google-F1 and Facebook-TAO have many naturally consistent transactions due to the prevalence of reads. NCC enables low overhead by leveraging natural consistency. In particular, its read-only transaction protocol executes the dominating reads with the minimum costs (Figure 6). For instance, at the operating point, NCC has about 99% of the transactions that passed their safeguard check and finished in one round trip. 99.1% of the transactions did not delay their responses, i.e., the real-time order dependencies were already satisfied when they arrived. That is, 99% of the transactions were finished by NCC within a single RTT without any delays. For the 1% of the transactions that did not pass the safeguard check initially, 70% of them passed the smart retry. Only 0.2% of the transactions were aborted and retried from scratch. All of them were committed eventually.

As a result, NCC can finish most transactions with one round of messages (for the read-only ones) and a latency of one RTT (for both read-only and read-write) while dOCC and d2PL-wound-wait require three rounds of messages and a latency of two RTTs (asynchronous commitment saves one RTT). NCC has much higher throughput than d2PL-no-wait due to its novel read-only protocol which requires one round of messages, while d2PL-no-wait requires two. The fewer messages of NCC translate to lower latency under medium

and high load due to lower queuing delay. d2PL-no-wait performs similar to NCC-RW because NCC-RW executes read-only transactions by following its read-write protocol. However, NCC-RW outperforms d2PL-no-wait under higher load because conflicts cause d2PL-no-wait to abort more frequently, while NCC-RW has fewer false aborts by leveraging the natural arrival order. This is more obvious in the Facebook-TAO results shown in Figure 7b, because Facebook-TAO has larger read transactions that are more likely to conflict with writes. The results of Facebook-TAO show similar takeaways.

**TPC-C.** Each experiment ran all five types of TPC-C transactions, and Figure 7c shows the latency and throughput (both in log scale) of New-Order while the throughput of the other four types is proportional. NCC and NCC-RW have ~20× higher peak throughput with ~10× lower latency compared to dOCC. dOCC and d2PL-no-wait have many false aborts when load increases due to conflicting writes. NCC and NCC-RW can execute most naturally consistent transactions with low costs, even if they conflict. For instance, NCC-RW has more than 80% of the transactions passing the safeguard check and fewer than 10% of the transactions being aborted and retried from scratch. NCC-RW has a 50% higher peak throughput than d2PL-wound-wait because NCC-RW requires only two rounds of messages, while d2PL-wound-wait requires three. NCC-RW has higher peak throughput than NCC because TPC-C has very few read-only transactions, which are also more likely to abort in NCC due to conflicting writes. Janus-CC’s performance benefits mostly come from unifying the transaction and replication layers and are less significant in a single-datacenter setting, especially after we made some TPC-C transactions multi-shot.

### 6.4 Additional Experiments

We show more experiments with Google-F1. We chose Google-F1 because it has both read-write and read-only transactions, while Facebook-TAO only has read-only transactions and non-transactional writes.

**Varying write fractions.** Figure 8a shows the throughput while increasing the write fraction. Each system is run at ~75% load according to Figure 7a. The y-axis is the through-

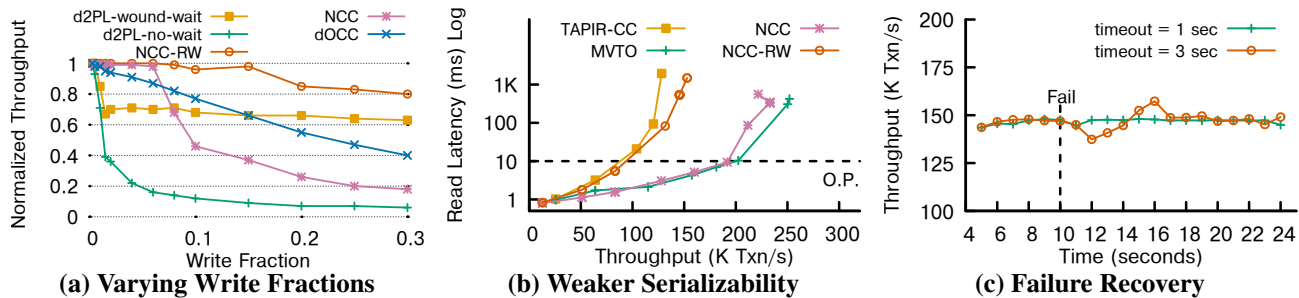

Figure 8: NCC’s performance with different write fractions (Google-WF), compared to serializable protocols (TAPIR-CC and MVTO), and under failures for the Google-F1 workload.

put normalized to the maximum throughput of each system during the experiment. The higher the write fraction, the more conflicts in the system. The results show that NCC-RW is most resilient to conflicts because NCC-RW can exploit more concurrency in those conflicting but naturally consistent transactions, i.e., NCC has fewer aborts. In contrast, other protocols may falsely abort transactions due to failed validation (dOCC) or lock unavailability (d2PL variants). NCC’s read-only transactions are more likely to abort when writes increase because frequent writes cause the client to have stale knowledge of the most recently executed writes on each server; as a result, NCC must abort the reads to avoid timestamp inversion.

**Comparing with serializable systems.** Figure 8b compares NCC with MVTO and TAPIR-CC, which provide serializability, under Google-F1. NCC outperforms TAPIR-CC because NCC has fewer messages with its read-only transaction protocol. MVTO and NCC have similar performance under low and medium load because they have the same number of messages and RTTs. Under high load, MVTO outperforms NCC when many read-only transactions in NCC are aborted: MVTO never aborts reads because it is allowed to read stale versions, whereas NCC must read the most recent version and handle timestamp inversion. In this sense, MVTO presents a performance upper bound for strictly serializable systems, and NCC closely matches the upper bound.

**Failure recovery.** Figure 8c shows how well NCC-RW handles client failures under Google-F1. We inject failures 10 seconds into the experiment by forcing *all* clients to stop sending the commit messages of ongoing transactions while they continue issuing new transactions. Undelivered commit messages cause servers to delay the responses of later transactions due to response timing control, until the recovery mechanism is triggered after a timeout. We show two timeout values, 1 and 3 seconds. NCC-RW recovers quickly after failures are detected, thus client failures have a limited impact on throughput. In realistic settings, failures on one or a few clients would have a negligible impact because uncommitted reads do not block other reads. Similarly, NCC is minimally impacted by client failures because its read-only transactions do not send commit messages and thus never delay later writes.

## 7 Related Work

NCC proposes a new strictly serializable distributed protocol. This section places it in the context of existing strictly serializable techniques, single-machine concurrency control, and techniques that provide weaker consistency. At a high-level, NCC provides better performance, addresses a different problem setting, and provides stronger guarantees, compared to these categories of work, respectively.

**General strictly serializable protocols.** As discussed in Section 2.3, existing general strictly serializable protocols are d2PL, dOCC, TR, or their variants, suffering extra costs when transactions are naturally consistent. For instance, Spanner’s read-write transactions [12], Sinfonia [4], and Carousel [68] are variants of d2PL that must acquire locks. FaRM [15], FaRMv2 [58], RIFL [31] are variants of dOCC that suffer extra validation costs, even if they use timestamp-based techniques to reduce validation aborts. AOCC [2] is a variant of dOCC and operates in a data-shipping environment, e.g., data can move from servers to client caches, which is different from NCC which works in a function-shipping environment, i.e., data resides only on servers. Rococo [51] and its descendant Janus [52] reorder transactions to minimize aborts. Granola [13] requires an all-to-all exchange of timestamps between servers, incurring extra messages and RTTs. Our evaluation shows that NCC outperforms these techniques for real-world workloads where natural consistency is prevalent. When transactions are not naturally consistent, however, these techniques could outperform NCC. Figure 9 summarizes performance and consistency properties of NCC and some representative distributed systems.

**Special strictly serializable techniques.** In addition to the general techniques discussed above, there are several interesting research directions that use specialized techniques to provide strict serializability. Some work utilizes a centralized sequencer to enforce strict serializability [6, 19, 33, 36, 45, 56, 62, 73]. Because all transactions must contact the sequencer before execution (e.g., Eris [33]), in addition to the extra latency, the sequencer can be a single point of failure and scalability bottleneck. Scaling out sequencers incurs extra costs, e.g., Calvin [62] requires all-to-all messages among

| System         | Consistency | Technique        | Latency (RTT) | Lock-free       | Non-blocking | False aborts      |

**Figure 9: The consistency and best-case performance of representative distributed protocols for naturally consistent workloads, processing one-shot transactions with possible optimizations considered. NC means natural consistency, and TS means timestamp-based technique. NCC has the lowest performance costs while providing strict serializability.**

sequencers for each transaction (epoch). Some ensure strict serializability by moving all data a transaction accesses to the same machine, e.g., LEAP [35]. Some rely on program analysis and are application-dependent, e.g., the homeostasis protocol [57]. Some rely on extensive gossip messages for liveness, which lower throughput and increase latency, e.g., Ocean Vista [18] whose latency of a transaction cannot be lower than the gossiping delay of the slowest server even if this server is not accessed by the transaction. General techniques such as NCC do not have the above limitations.

**Strictly serializable read-only transaction protocols.** To the best of our knowledge, the only existing strictly serializable read-only transaction protocol that has optimal *best-case* performance is Spanner [12]. Spanner ensures strict serializability by using d2PL for read-write transactions and by using synchronized clocks (TrueTime) for read-only transactions. TrueTime must be accurately bounded for correctness and those bounds need to be small to achieve good performance, which are achieved by Google’s infrastructure using special hardware, e.g., GPS and atomic clocks [9] that are not generally available. For instance, CockroachDB [61], which began as an external Spanner clone, chose not to support strict serializability because it does not have access to such infrastructure [25]. In contrast, NCC’s read-only transactions achieve optimal best-case performance and provide strict serializability, without requiring synchronized clocks.

**Single-machine concurrency control.** Concurrency control for single-machine databases is different from the distributed setting on which this paper focuses. First, some techniques are not feasible in a distributed setting. For instance, Silo [64] relies on atomic instructions, and MVTL [3] relies on shared lock state, which are challenging across machines. Second, most techniques, e.g., Silo [64] and TicToc [69], follow a multi-phase design and would be expensive if made distributed, e.g., they need distributed lock management and one round of inter-machine messages for each phase, which would

be unnecessary costs for naturally consistent transactions. Their designs, however, are feasible and highly performant for the single-machine setting they target.

**Protocols for weaker consistency.** Many systems trade strong consistency for better performance. For instance, some settle for restricted transaction APIs, e.g., read-only and/or write-only transactions [16, 37, 38]. Some choose to support weaker consistency models, e.g., causal consistency and serializability [17, 32, 38, 39, 46, 61, 65, 70]. In contrast, NCC provides stronger consistency and supports general transactions, greatly simplifying application development.

## 8 Conclusion

Strictly serializable datastores are advocated by recent work because they greatly simplify application development. This paper presents NCC, a new design that provides strict serializability with minimal overhead by leveraging natural consistency in datacenter workloads. NCC identifies and overcomes timestamp inversion, a fundamental correctness pitfall in timestamp-based concurrency control techniques. NCC significantly outperforms existing strictly serializable techniques and closely matches the performance of serializable systems.

**Acknowledgments.** We gratefully thank our shepherd, Atul Adya, for his invaluable feedback that significantly improved this work. We thank the anonymous reviewers for their careful reading of our paper and their many insightful comments and suggestions. This work was supported by the National Science Foundation under grant CNS 1824130, 2130590, 2238768 as well as a gift from Microsoft Research. ## Abstract

We present *Conveyor*, Meta’s software deployment tool, along with the valuable data obtained from managing over 30,000 deployment pipelines that deploy all kinds of services at Meta across millions of machines. We describe a wide range of deployment scenarios that Conveyor supports to achieve universal coverage. At Meta, out of all the deployment pipelines for services deployed via containers, 97% of them employ fully automated deployments without manual intervention: 55% utilize continuous deployment, instantly deploying every code change to production after passing automated tests, and the remaining 42% are automatically deployed on a fixed schedule (mostly daily or weekly) without manual validation. We highlight several distinguishing features of Conveyor, including safe in-place updates to reduce hardware costs, analysis of code dependencies to prevent faulty releases, and the capability to deploy complex ML models at scale.

## 1 Introduction

“*Release early, release often*” [1, 32] is central to Meta’s engineering culture. For example, Meta’s largest service, *Front-FaaS*, which is a serverless function-as-a-service platform, runs on more than half a million machines and has tens of thousands of developers making changes to its code base, with thousands of code commits every workday. Despite this extremely dynamic environment, it continuously releases a new version into production every three hours [33].

Although the concept of frequent software releases is well-established, previous studies have primarily relied on limited surveys or analyses [7, 20, 23, 25, 38–41, 48]. In contrast, we leverage our nine years of direct experience in developing Meta’s deployment tool called *Conveyor* and the wealth of data obtained from managing over 30,000 deployment pipelines to answer the following questions: 1) What is the adoption rate of deployment automation, and what is important in driving the adoption? 2) What is special about deployment safety at hyperscale? 3) What distinguishes the deployment of ML models from traditional service executables? We summarize our answers to these questions below.

## 1.1 Adoption of Deployment Automation

**Universal adoption.** We strongly argue for universal adoption of a *single* deployment tool within an organization to support all kinds of services, both small and large. At Meta, 0.1% and 1% of the largest services consume 40% and 80% of the total fleet capacity, respectively. Similarly, Google reported that “*the top 1% of jobs consume over 99% of all resources* [47].” These largest services often require the most complex deployment features, and neglecting them would lead to fragmentation and difficulties in managing the site. For example, due to FrontFaaS’s demanding requirements, it used to have its own complex deployment tool written in over 30,000 lines of code. This kind of fragmentation complicates the operation of our site. In the event of a site outage, very few people know how to safely revert a specific service’s problematic release.

Furthermore, the impact of a deployment tool on site reliability necessitates many advanced features to ensure the safety of deployments, as outlined in §1.2. While it may be tempting to develop a new custom tool to address specific needs that are currently unsupported by the standard tool, Meta’s experience has consistently shown that these custom tools, owned by individual product teams, have seldom reached the level of maturity required to provide the essential, advanced deployment-safety features. Consequently, without any exceptions, these custom tools have always been assimilated back into the standard tool as it evolves and matures.

Over the past nine years, Conveyor has achieved universal adoption at Meta, and the key to its success lies in its ability to support a wide range of deployment scenarios while ensuring the safety of deployments (§3).

**Fully automated deployments.** After addressing numerous challenges along the way, the adoption rate of *continuous deployment* [39] at Meta has greatly exceeded our initial expectations. With continuous deployment, every time a code change is committed to the code repository, it automatically goes through a series of tests. If it passes those tests, it is deployed to production immediately, without manual intervention. Currently, out of all Meta’s deployment pipelines for services deployed via containers, 97% employ fully auto-

mated deployments: 55% utilize continuous deployment and the remaining 42% automatically deploy on a fixed schedule (mostly daily or weekly) without manual validation.

In contrast, in early 2018, 47% of services at Meta were deployed manually without using any automation tool, 41% utilized an automation tool but still required manual validation, and only 12% were deployed through full automation. The significant increase in fully automated deployments, from 12% to 97%, has greatly reduced developer toil and improved productivity. Moreover, in early 2017, 20% of our fleet's RPC traffic [37] were generated by executables that had not been updated within 30 days. Currently, this number has dropped to around 1%. Up-to-date code brings many benefits, such as faster iteration speed and the timely implementation of bug fixes and security fixes.

To automate deployments, bugs and deployment failures must be embraced as a norm. Instead of introducing manual validations to prevent failures, automated guardrails such as testing and health checks should be implemented to detect release failures early and contain their adverse effects. Specifically, although 5.4% of our deployments fail, deployments are still highly reliable as the majority of those failed deployments are caught during early deployment phases with little to no production impact. The high reliability of automated deployments is evidenced by the fact that only 0.92% of finished deployments are manually reverted or patched by developers.

## 1.2 Deployment Safety at Hyperscale

**Making in-place updates safe.** Due to its strong safety guarantees, the approach of *mirroring update*, which keeps the existing deployment intact and uses a separate set of containers to deploy a new version of the software, is widely used in the industry [2, 11], as it can easily redirect traffic back to the old deployment if the new deployment encounters issues. However, the cost of keeping spare hardware for a second deployment is prohibitive for our hyperscale services. At Meta, we exclusively utilize *in-place updates* for all services, which directly update containers in the existing deployment, eliminating the need for a separate deployment.

Updating a service in place requires precise controls over container updates and health checks to ensure safety. To enable such controls, we have enhanced our cluster manager [45] to allow updating a specific subset of a job's containers to a new version while keeping the remaining containers on the old version, as opposed to the traditional approach that requires updating a job's all containers as a whole [22].

Furthermore, for complex services like sharded databases, it is essential for the service itself, rather than the cluster manager, to determine when to update each container, because the service knows best about its own requirements such as shard replica safety. Our cluster manager's TaskControl interface enables this, whereas existing cluster managers disallow it.

Finally, we have enhanced our monitoring system to conduct health checks on "*moving targets*," i.e., a dynamically

changing subset of a job's tasks. This subset evolves as the deployment progresses, in contrast to traditional health checks that always target a fixed set of tasks, i.e., all tasks in the job. Overall, these precise-control features enable Conveyor to perform in-place updates safely while eliminating the extra hardware costs associated with the mirroring approach.

**Handling complex code dependencies.** Pioneered by hyperscalers such as Google, monorepo [9], which stores the code for an organization's many projects in a single repository, has become increasingly popular due to benefits such as improved code reuse. However, increased code reuse leads to more complex code dependencies, such as a service *X* transitively depending on shared code at a depth of over 10 layers. In such cases, when a bug is introduced to some dependent code, the owner of service *X* might not even know that service *X* is affected. Our data show that about 14% of the to-be-deployed executables are affected by known bugs in dependent code and should not be deployed into production. Conveyor's Bad Package Detector automatically enforces this (§3.2), but existing deployment tools do not support it.

## 1.3 ML Model Deployment

Traditional deployment tools [3, 18, 42, 46] exclusively focus on the deployment of service executables. Even if they evolve to achieve universal coverage for service executables, in the era of rapid proliferation of ML applications, they still leave a significant gap by not addressing the deployment of ML models. Conveyor has been specifically enhanced to address this need and currently about 44% of its pipelines are for model deployments. To support ML models, Conveyor coordinates deployment pipelines for models that share the same inference executable, synchronizes the deployment of different shards of a partitioned large model, and implements phased in-place updates of models through the configuration management system [44], in contrast to the traditional approach of updating executables via the cluster manager. Dedicated ML platforms such as AWS SageMaker can deploy models using the mirroring approach [35, 36], but they do not support the advanced model-deployment features mentioned above.

**Contributions.** We make several contributions in this paper.

- We believe this paper is the most comprehensive report to date on deployment scenarios, operational experience, and production data related to software deployment.
- We demonstrate the feasibility of achieving aggressive goals for software deployment, such as frequent and automated deployment without manual validation, and using a single deployment tool to provide universal coverage for datacenter services, ML models, application configurations, host-level daemons, and mobile apps.
- We present novel techniques that ensure the safety of in-place updates, prevent faulty releases through analysis of code dependencies, and safely deploy ML models.

## 2 Overview of Software Deployment at Meta

To provide context for the discussions in later sections, this section gives an overview of Meta’s software deployment culture and deployment ecosystem.

### 2.1 Deployment Culture

At Meta, we mandate frequent software deployments for multiple reasons. First, frequent releases enhance developer productivity. Engineers at Meta heavily rely on A/B test results of new product features to guide their development. This necessitates frequently deploying and testing new code with real users. Second, frequent releases reduce the complexity of troubleshooting in production because each release contains fewer code changes. Finally, frequent releases ensure timely deployment of bug fixes and security fixes. Consider a widely publicized site outage in 2014 [29]. Two months before the outage, the issue that later caused the outage was identified and the bug fix was already committed to the code repository. Unfortunately, no new deployment took place for two months. In general, preventing human mistakes in software deployments at the scale of thousands of engineers is unachievable without utilizing automation tools like Conveyor.

Meta’s Push4Push program enforces regular deployments through tickets. Service owners get a ticket if their services are not updated within certain days (42 days for low-traffic services and 30 days for high-traffic services), and it escalates to managers at 63 days. In practice, Push4Push results in 96% of services deploying weekly or more frequently.

### 2.2 Deployment Ecosystem

Meta’s private cloud comprises multiple datacenter regions. Each region has its own instance of cluster manager called Twine [45], which manages machines and containers. During a deployment, Conveyor instructs Twine to update containers. Meta’s datacenter software is structured as many microservices [21]. A service comprises one or multiple *jobs*. A job comprises one or more *tasks*, and a task is mapped to a Linux container. Typically, a service is deployed to multiple regions for resilience, running one job for each region where it is deployed, and each of those jobs is managed by a different Twine instance.

Figure 1 presents an overview of the software deployment ecosystem at Meta. Developers define the update procedure for their services by specifying a deployment *pipeline*, which is a directed acyclic graph (DAG) comprising a set of input *artifacts* and a set of *actions*. A simple pipeline is shown at the top of Figure 1, while a more complex example is provided in Figure 3. An *action* represents an operation to be executed and takes a set of *artifacts* as input and potentially generates a new set of artifacts. Examples of artifacts include source code and compiled executables. Once all the input artifacts of a pipeline are ready, the pipeline will be executed, creating a *release*. A release is one execution of a pipeline.

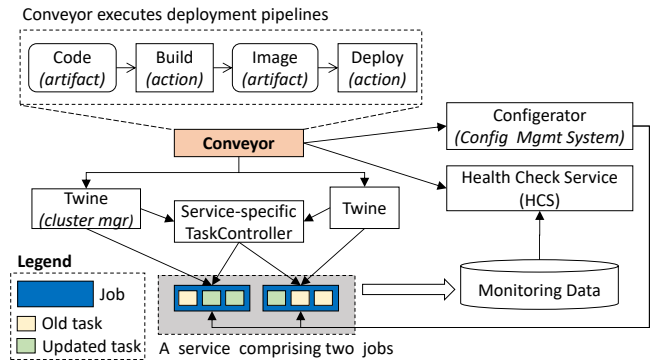

Figure 1: Software deployment ecosystem at Meta. The two Twine instances manage jobs in different datacenter regions.

The `deploy` action drives Twine to update containers and is typically the most complex part of a pipeline. To prevent a bug from instantly impacting all tasks within a job, the `deploy` action updates tasks in *phases*. Each phase updates a subset of tasks, checks their health, and proceeds to the next phase only if no issues are detected. To check service health, Twine and the service itself can log various health signals, such as CPU utilization and user engagement metrics. The Health Check Service (HCS) is responsible for checking these health signals for anomalies based on user-defined rules. For example, it can detect if user engagement drops below a certain threshold. Collecting health signals often requires a waiting period to gather monitoring data, known as the *bake time*. Therefore, a `deploy` action typically includes several phases, each with an update period and a bake period, and such information is defined in a *deployment plan*.

In addition to driving Twine to deploy service executables, Conveyor can also drive Configurator [44], our configuration management system, to implement phased deployments of ML models and configuration files (§3.3). Moreover, a service with special requirements can optionally provide its own TaskController to advise Twine on which tasks are safe to update together, as explained in the example below.

### 2.3 Component Interaction by Example

We illustrate the interaction between various components in Figure 1 through the example of deploying a new software version for a sharded key-value store (KVStore). The KVStore is deployed across two regions, denoted as  $X$  and  $Y$ , with each region running a separate job consisting of six tasks. These jobs and tasks are labeled as  $JobX = [X1, \dots, X6]$  and  $JobY = [Y1, \dots, Y6]$ . These 12 tasks collectively host 500 data shards, each of which has three replicas that are potentially distributed across regions.

According to the KVStore’s quorum protocol, if a shard loses two out of its three replicas, it becomes unavailable. Thus, concurrently updating any two specific tasks carries the risk of rendering certain shards unavailable. Since Conveyor and Twine are unaware of the application-level shard

Figure 2: Phase 1 of updating the KVStore.

placement [24], they cannot determine whether it is safe to update any two specific tasks together. To ensure shard availability, the KVStore provides its own custom TaskController to advise Twine on which tasks are safe to update together.

The `deploy` action of the KVStore consists of two phases: 1) updating three tasks of *JobX*, and 2) updating the remaining three tasks of *JobX* and all six tasks of *JobY* (see §6.5.2 for alternative setups). In phase 1, Conveyor instructs *TwineX*, the Twine instance in region *X*, to update three tasks of *JobX*, as depicted in Figure 2. *TwineX* chooses to update tasks *X1*, *X2*, and *X3* and communicates this intent to the TaskController by sending `request = [X1, X2, X3]`. The TaskController responds with a subset of tasks that can be safely updated together. For example, the TaskController may find that the shard replicas hosted by *X1* and *X3* do not overlap but further including *X2* would result in some shard losing more than one replica. Therefore, it responds with `approved = [X1, X3]`. Consequently, *TwineX* executes the updates for *X1* and *X3* and then notifies the TaskController. The TaskController subsequently responds with the next batch of tasks that are now safe to be updated, in this example, `approved = [X2]`.

Once all tasks in phase 1 of the `deploy` action are updated, Twine notifies Conveyor. Next, during the configured `bake` time, Conveyor periodically invokes the Health Check Service to access the health of *X1*, *X2*, and *X3* (instead of all tasks in *JobX*), by comparing the error rate, latency, and user engagement metric of those tasks before and after the update.

If the health checks pass, Conveyor proceeds to phase 2 of the `deploy` action by instructing *TwineX* to update the remaining 3 tasks of *JobX* and instructing *TwineY* to update all 6 tasks of *JobY*. The process is similar to that in phase 1.

This example highlights a key principle in our design: separation of concerns. Conveyor orchestrates the execution of the deployment plan supplied by the service owner without worrying about how tasks are updated. A custom TaskController usually has a simple implementation since it only needs to determine which tasks can be safely updated together based on the application constraints. The complexity of actually updating tasks and managing their lifecycle is handled by Twine without the involvement of Conveyor or TaskController.

## 3 Deployment Scenarios and Solutions

To achieve universal coverage, Conveyor supports a wide range of deployment scenarios. This section presents these scenarios and the corresponding solutions in Conveyor.

### 3.1 Enabling In-place Updates

The software deployment approach affects hardware costs. The in-place update approach restarts an existing task on the same machine to run the new executable. In contrast, the mirroring approach, which is also called Red-Black [43] or Blue-Green [2] deployment, first starts a new job with the new executable, often on other machines, gradually redirects the traffic from the old job to the new job, and finally shuts down the old job. Although this approach is safer as the traffic can be quickly redirected back to the old job if the update fails, it needs extra hardware to run both the old and new jobs in parallel. Consider the example of deploying Front-FaaS to 500K machines every three hours. A naive mirroring approach would require 500K extra machines, which is unacceptable. One optimization is to divide it into many small jobs and utilize mirroring to update one small job at a time. However, this approach would result in the loss of quick rollback capability and complicate job autoscaling [16, 34]. Although further optimizations might be possible, the resulting solution would not necessarily be cheaper, simpler, or more generic than in-place updates.

Despite the benefits of hardware savings, the in-place update approach lacks widespread support from existing deployment tools due to the difficulty of ensuring deployment safety. Below, we present how we have made in-place updates safe and practical by co-designing our deployment tool (Conveyor) and our cluster manager (Twine [45]).

**Collaborative control between Conveyor and Twine.** As discussed in §2.2, during each phase of the `deploy` action, Conveyor instructs Twine to update a specific number or percentage of tasks, denoted as  $N_{big}$  and then waits for a period of time to collect comprehensive health signals before moving on to the next phase. Twine, however, does not update  $N_{big}$  tasks all at once. Instead, it updates only  $N_{small}$  tasks in one batch, where  $N_{small}$  is much smaller than  $N_{big}$ , to avoid losing too many tasks simultaneously. Twine then checks the liveness of each task before proceeding to update the next  $N_{small}$  tasks. Similar to other cluster managers [22], Twine’s liveness check is rudimentary and only verifies that an individual task is running properly. However, it is unable to detect subtle issues such as the new code’s memory regression compared to the old code, which is handled by Conveyor’s comprehensive health checks (§3.2).

The collaborative control between Conveyor and Twine enables fast and safe deployments by assigning the most suitable functions to the right layers. Let’s consider some alternative designs. If Conveyor instructs Twine to update  $N_{small}$  tasks instead of  $N_{big}$  tasks, and then waits for a period of time to collect comprehensive health signals, the deployment speed

would be too slow. On the other hand, if Twine updates  $N_{big}$  tasks instead of  $N_{small}$  tasks in one batch, the service might lose too much capacity and become overloaded. Finally, eliminating Twine’s rudimentary task liveness check would mean a destructive bug could affect  $N_{big}$  tasks instead of just  $N_{small}$  tasks before being detected.

Unlike the close collaboration between Conveyor and Twine, in the widely used open-source setup of Spinnaker [42] (deployment tool) instructing Kubernetes [22] (cluster manager) to update containers, Spinnaker cannot control the size of each phase,  $N_{big}$ , which defaults to the size of the entire job. This is because Kubernetes disallows partial-job updates. This simplistic approach is not suitable for in-place updates, because, when the comprehensive health checks detect a bug, it is likely that all tasks of the job have already been updated.

**Pluggable TaskControl.** In the task-update protocol described above, most services can use a per-service constant  $N_{small}$  and have no constraints on the specific tasks to be updated. However, the sharded key-value store described in §2.3 provides an example of services that require more precise control of  $N_{small}$  and the specific tasks to be updated. Figure 2 further illustrates how such a service can implement a custom TaskController to ensure safe in-place updates. TaskControl, in general, enables services to have precise control over task updates for various reasons, not limited to data shard availability. For example, FrontFaaS utilizes TaskControl to maximize its deployment speed (§4). Further details on TaskControl can be found in our previous work [24, 45].

**Hardware failure and planned maintenance.** When multiple tasks undergo in-place updates simultaneously, there is a risk of reducing the available capacity of a service to an unhealthy level. Merely controlling the update speed through the deployment pipeline is insufficient since certain tasks may be in an unhealthy state due to machine failures or planned maintenance, which Conveyor is unaware of. To tackle this issue, the service owner can inform Twine of a budget that indicates the maximum number or percentage of tasks that can be offline for any reason, such as task update, hardware failure, or planned maintenance. If the budget is projected to be exceeded, Twine pauses task updates.

**Zero downtime hotswap.** Our routing service in edge datacenters forwards user-facing traffic to our datacenters and holds live HTTPS connections to user devices. Naively restarting a task for an update would cause user-facing errors. Twine provides a same-host hotswap feature to solve this problem. It first starts a new task on the same machine, which binds to the same TCP ports as the old task. Then the new task and the old task cooperate with each other to hand over the live connections from the old task to the new task with the help of eBPF [14]. One limitation of hotswap is that it requires the container to be configured with sufficient memory to start two tasks, which is the reason why it is not used universally.

**Summary.** All of the aforementioned deployment scenarios with in-place updates cannot be properly implemented

without support from the cluster manager. We believe this is a key reason why existing deployment tools primarily use the mirroring approach, since the cluster managers they rely on do not provide the necessary functions for in-place updates.

## 3.2 Deployment Safety

To enable continuous deployment, we accept bugs and deployment failures as a norm and rely on automated guardrails such as testing and health checks to detect release failures early and mitigate their adverse effects. In this section, we describe techniques that help Conveyor deploy safely.

**Moving-target health checks.** After each deployment phase, Conveyor invokes the Health Check Service (HCS) to evaluate the health of the service. Multiple health checks can be associated with a job, and each health check specifies a data source such as a time series database for monitoring data [31], a metric, data transformations (e.g., calculating specific percentiles), and a decision threshold. The metrics encompass system metrics (CPU, memory, crashes), RPC metrics (connections, errors), and application-level business metrics. The thresholds can be absolute (e.g., fail if CPU utilization exceeds 90%), A/B comparative (e.g., fail if the new task’s CPU utilization exceeds that of the task that still has not been updated by 10%), or time-based (e.g., fail if the CPU utilization increases by 10% since the deployment started). By default, a failed health check triggers Conveyor to revert the release.

In contrast to traditional monitoring systems that track the health of an entire job, in-place updates require the HCS to track “*moving targets*”, i.e., a dynamic subset of tasks that change throughout different deployment phases. Achieving this level of precision and adaptability necessitates a seamless integration between Conveyor, Twine, and HCS. Specifically, Twine assigns unique identifiers to tasks, enabling differentiation between the old and new tasks. The monitoring data for tasks is tagged with these identifiers. Depending on the current deployment phase, Conveyor dynamically instructs HCS to perform health checks on tasks with specific identifiers.

**Code dependency analysis to prevent faulty releases.** A monorepo [9] stores the code for an organization’s many projects in a single repository, promoting code reuse but also leading to increased code dependencies. For instance, the ServiceRouter [37] library is compiled into nearly every service in Meta, and it may rely on a high-performance data structure library, which in turn may rely on a profiling library, and so on. In a monorepo setup, whenever a new version of a library is committed, any services that depend on the library will be automatically compiled with the new version. Consequently, the owner of a service may not even be aware that their service is affected by a bug in a shared library. To tackle this issue, Conveyor offers the Bad Package Detector (BPD). If library developers discover a bug in the library, they can report it to Conveyor. The BPD then utilizes a code dependency graph, which is provided by our build system [10], to identify and

cancel the releases of all service executables that were built with the problematic version of the library.

Accurate code dependency analysis poses a challenge for the BPD as it requires finding the right balance between false negatives and false positives. Achieving perfect coverage would entail considering all possible direct and indirect dependencies of a service, which is often impractical. To strike a balance, the BPD currently tracks 14 levels of dependency. Our production data reveals that about 14% of to-be-deployed executables are invalidated by the BPD. This highlights the importance of handling bugs in dependent code.

**Comprehensive testing.** Conveyor supports various types of tests in deployment pipelines. The `PerfTest` tool records and replays production traffic to perform A/B testing between old and new code, while the `IntegrTest` [28] tool sets up interdependent services and tests their interactions. Additionally, `IntegrTest` can perform randomized fuzzing tests. `Canary` updates a small number of production tasks with new code and collects health signals, enabling direct testing in production. Multiple `canaries` can be executed in parallel to test different code variations. Even if a release’s `deploy` action is not chosen for final execution (e.g., a release’s `deploy` action, while waiting to start on Monday at 9 AM, gets superseded by a newer release), it is still valuable to execute the test actions to detect bugs as early as possible.

**Summary.** While other deployment tools also support testing and health checks, they lack some key capabilities. In contrast to HCS’ ability to track “*moving targets*,” traditional health checks rely on alarms defined for an entire job, which is insufficient to support in-place updates. Moreover, bug dependency analysis is not supported by existing deployment tools. Finally, we are not aware of any other large-scale adoption of record and replay as a generic platform for performance tests.

### 3.3 ML Model Deployment

Deployments of ML models for inference have emerged as an important issue, given the rapidly increasing number of ML applications. While existing deployment tools generally do not handle model deployments, Conveyor has been specifically enhanced to address this need and currently about 44% of its pipelines are for model deployments. Below, we describe Conveyor’s support for model deployments.

**Deployment via configuration change.** In Conveyor’s first implementation for model deployments, model update and executable update share the same pipeline, requiring Twine to restart the container. However, as model updates may occur more frequently than updates to inference executables, frequent container restart results in a frequent loss of expensive GPU capacity for request serving. Moreover, since a model often contains gigabytes (GBs) of data, the time required to load GBs of data during the restart can be lengthy.

To solve this problem, some inference services utilize two orthogonal pipelines. One pipeline deploys the inference executable through Twine, while the other deploys the model

data through Configurator [44], Meta’s configuration management system. To track model updates, all tasks serving a model subscribe to a configuration that specifies the current version of the model to be served. When a new version of the model becomes available, instead of exposing it to all tasks simultaneously, Conveyor instructs Configurator to incrementally expose the new version to tasks in phases, following the deployment pipeline. Configurator utilizes a data-distribution tree to notify the tasks in a scalable manner. Once the tasks receive the notification of a new model version, they utilize Owl [15], a peer-to-peer data-distribution system, to fetch the new model. While still serving live requests, a task merges the new model into the old model piece by piece without consuming additional memory as it never keeps full copies of both models in memory simultaneously. Overall, Conveyor ensures safe deployments of models through phased releases, which are meticulously managed via configuration changes.

Conveyor’s ability to perform phased deployments of generic configuration changes extends beyond its use in ML model updates. Conveyor pipelines are widely utilized to ensure safe deployments of various configuration changes.

**Lockstep deployment of interdependent services.** Some of our ML models are too large to fit in one machine’s memory, so they are partitioned into interdependent shards, each including multiple replicas for fault tolerance and throughput. Each shard is mapped to a different job, and typically the first shard serves as the aggregator to combine results from other shards. However, updating different shards independently may cause compatibility issues, because combining outputs from different versions of the shards will produce incorrect results. To ensure compatibility, replicas of the first shard are configured to only receive outputs from replicas of other shards of the same version. This design requires Conveyor to perform a lockstep deployment of different shards to avoid capacity loss during deployment. For instance, 5% of each shard’s replicas are updated at the same time and 5% of the client traffic is directed to the new version, before proceeding to update 10% of each shard’s replicas, and so forth.

**Parent-child pipelines.** Meta’s ML inference system serves tens of thousands of ML models using about 10 different inference executables. Each model, along with its inference executable, is deployed via a separate pipeline. Since many models share the same inference executable, updating one executable may cause thousands of pipelines to initiate a new release at the same time. This not only causes a load spike on Conveyor and Twine, but also increases the risk of an undetected bug in the inference executable impacting many models simultaneously.

While existing deployment tools manage each pipeline in isolation, Conveyor coordinates releases across pipelines that share common artifacts by setting up a parent-child relationship between them. Specifically, each inference executable is managed by a parent pipeline, which includes sophisticated testing but no `deploy` action, while the pipelines for models

served by the executable act as its child pipelines and include the `deploy` action. When updating an ML model without modifying the executable, only the corresponding child pipeline is executed, without involving the parent pipeline. However, when updating the executable, the parent pipeline is executed first. If successful, all the corresponding child pipelines are then executed with randomized delays to avoid starting them at the same time and overloading the system. Moreover, it can be configured in such a way that a subset of child pipelines for less important models is executed first to help detect issues with the executable.

### 3.4 Advanced Features for Universal Adoption

To achieve universal adoption, Conveyor must support advanced use cases. We describe them in this section.

**DAG pipelines.** Conveyor initially modeled deployment pipelines as a sequence of sequential stages, such as `build`→`test`→`deploy`. However, this pattern has not generalized to complex services like FrontFaaS, which may build, test, and deploy two different versions in parallel (§4). The sequential pipeline is overly restrictive in that it requires testing for both versions to finish before the deployment for any version can start. Therefore, we have improved Conveyor by modeling its pipelines as directed acyclic graphs (DAGs). These DAGs support conditions, branching, and mutual exclusion groups. Since multiple releases of a pipeline may be executed in parallel, Conveyor allows users to define actions as a mutual exclusion group, meaning that concurrent releases should not execute these actions in parallel. For example, if a pipeline includes a `load-test` action and a `deploy` action, they may be put in an exclusion group so that a `deploy` action in one release will not accidentally fail its health check due to a `load-test` from another concurrent release.

**Mutable artifacts.** Conveyor initially mandated one `build` action at the beginning of a pipeline, resulting in an immutable artifact, the executable, to be used throughout the pipeline. However, this simple model does not fit well with complex deployment scenarios. One example is feedback-directed optimization (FDO) [12], which involves profiling executables in production and using the profiling data to guide recompilation of the code, resulting in an updated artifact, the new executable. Therefore, Conveyor has been extended to support mutable artifacts and allow multiple `builds` within one pipeline. To perform FDO, for example, the pipeline can first build the baseline executable, deploy it to a small number of tasks that receive production traffic, and collect profiles. It then builds the executable again using FDO and finally deploys the optimized executable to all tasks.

**CLI and daemon deployment.** Every machine in our fleet runs a set of CLI tools and daemons that provide utility functions. As these host-level executables are not managed by Twine, Conveyor provides a `deploy` action type called *Slowroll* to manage them. Due to the massive scale of deploying these executables to every machine, Slowroll adopts a

pull model instead of Twine’s push model. In the pull model, each machine periodically downloads the new version of the software being deployed. These deployments can take a long time to finish. For example, due to the massive scale of deploying a specific daemon to every machine, its pipeline has 43 phases and a deployment can take more than a week. Moreover, some CLI tools are infrequently used, requiring a significantly longer “bake time” (e.g., 8 hours) to collect health signals.

### 3.5 Software Backward Compatibility

Despite backward compatibility being a generic requirement for software deployment, it is largely left for services to handle because it often involves application-specific logic.

**API backward compatibility.** During a deployment, the new and old versions of a service will coexist for a while. When the API of a service needs to be changed, a common practice at Meta is to support both the old and new APIs and gradually switch clients to invoke the new API. Once all clients are migrated to the new API, the code for the old API can be deleted. This is called *N-1* compatibility, meaning that in addition to the current version *N* of the API, it also supports version *N-1* but not version *N-2* or older.

**Database backward compatibility.** When a service update involves data migration from one database to another or an upgrade of the database schema, extra care is needed. For example, when switching from an old database to a new database, a common strategy is to perform double writes: the service writes new data to both databases but always reads data from the old database, while a background process migrates old data from the old database to the new database. This strategy simplifies the rollback process as it only requires deleting the new database and redeploying the old code.

### 3.6 Summary of Distinguishing Features

While Conveyor and Twine provide many features to achieve universal adoption, we consider that the following features distinguish Conveyor and Twine from existing tools most.

1. In-place updates allow us to minimize hardware costs, which is important while operating at hyperscale.
2. TaskControl provides flexibility for services to precisely control the speed and sequence of their task updates.
3. The ability to update a subset of tasks and perform health checks on moving targets enables Conveyor to exert fine-grained control over tasks, enabling in-place updates.
4. In a monorepo [9] setup, it is important to perform code dependency analysis to prevent faulty releases.
5. Features to support ML model deployments have grown to become a first-class citizen in Conveyor.
6. Conveyor provides a one-tool-fits-all solution for safe deployments of various artifacts, such as service executables, ML models, and application configurations.

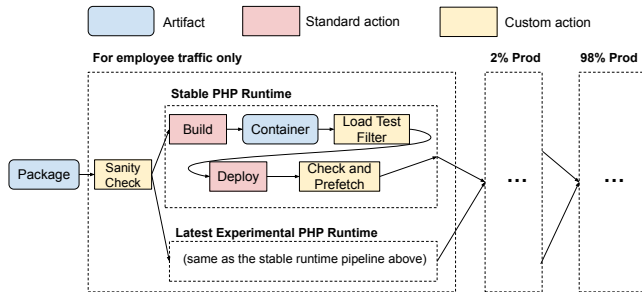

Figure 3: Simplified deployment pipeline for FrontFaaS.

Existing deployment tools lack these features. Without them, Conveyor would not have achieved universal adoption.

Conveyor is designed to be a generic and extensible deployment tool, and does not burden itself with every feature needed by every service. Its extensible architecture allows services to easily implement their own TaskControllers, actions, and new types of artifacts. Moreover, sometimes it is preferable to consider a service redesign to leverage Conveyor’s standard functions. For instance, Meta’s ML inference platform initially hosted multiple ML models as separate processes within a single container, and requested Conveyor to provide the feature of using independent pipelines to update different processes within the same container. Since this feature is complex and not needed by other services, we did not support it in Conveyor and the ML inference platform was ultimately redesigned to adopt the one-model-per-container approach.

## 4 Case Study of FrontFaaS

To illustrate the end-to-end usage of Conveyor, we present a case study of FrontFaaS, a serverless Function-as-a-Service (FaaS) platform for PHP functions. It differs from other serverless platforms such as AWS Lambda [5] in several ways: 1) it only hosts synchronous functions that clients directly invoke, while event-driven asynchronous functions are hosted by another platform; and 2) for efficiency, a single PHP runtime process can execute multiple functions concurrently. Since FrontFaaS is serverless, developers simply commit function code without worrying about code deployment or server provisioning. Each year, tens of thousands of developers commit serverless function code to FrontFaaS, with thousands of code commits each workday. Currently, FrontFaaS runs on over half a million machines and makes a new release every three hours to deploy the code of all functions together [33]. Through FrontFaaS, Meta developers create PHP functions that are servicing traffic from end users when they visit Meta web pages. Note that many Meta employees are end users of Meta products as well, and their traffic is often used for testing purposes as discussed next.

Figure 3 shows a simplified deployment pipeline for FrontFaaS. To enable phased deployments, the machines hosting FrontFaaS are partitioned into three pools: one for servicing employee traffic, one for servicing 2% of production traffic,

and one for servicing the remaining production traffic. Accordingly, the deployment pipeline is divided into three major phases, one for each machine pool. A release proceeds to the next machine pool only if the deployment to the prior pool succeeds. Each pool is split into two sub-pools: one processing a small amount of traffic with an experimental version of the PHP runtime [30] and one processing the remaining traffic with a stable version. If the experimental version outperforms the stable version, it will become the new stable version.

The first step in the deployment pipeline is a custom `sanity-check` action that performs a FrontFaaS specific logic to ensure that there are no deployment-blocking alerts. Then, a standard `build` action is used to build the container image. Independent of specific releases, load tests always continuously run on certain machines to gather performance data and build capacity models. The custom `load-test-filter` action excludes machines that are scheduled to be load-tested from being monitored by health checks, to avoid load-test induced false alarms during health checks. The pipeline then uses a standard `deploy` action to update tasks and run health checks. Finally, a custom `check-and-prefetch` action runs the sanity check again while asking Twine [45] to prefetch FrontFaaS’ container image on machines that will be updated soon. This prefetch reduces the overall duration of each release by 5-30%.

Since FrontFaaS continuously deploys every three hours across more than half a million machines, fast deployment is an important requirement. Within a `deploy` action, FrontFaaS relies on two techniques to accelerate a deployment. First, it implements a custom TaskController that controls the rate at which tasks are updated based on the CPU utilization of FrontFaaS jobs. It tries to concurrently update as many tasks as possible, as long as the temporary loss of those tasks does not cause other FrontFaaS tasks to handle too much traffic and become overloaded. During off-peak hours, updates can be applied to many tasks in large batches, while during peak hours when traffic is high, the Task Controller applies updates in smaller batches to prevent overload. Thanks to this optimization, deployments during off-peak hours are approximately three times faster than those during peak hours.

The second technique to accelerate a deployment is to update tasks and perform health checks in parallel, but the short health-check time requires FrontFaaS to have highly accurate health checks. FrontFaaS primarily relies on three health-check metrics: 1) the number of fatal errors, 2) the number of unavailable tasks, and 3) the write rate of error logs. Every minute during a `deploy` action, these metrics are averaged over the previous three minutes and compared to the average during a three-minute period before the deployment began. If any datacenter region experiences an increase in these metrics above a certain threshold, Conveyor pauses all updates in that region. If too many jobs are paused, Conveyor considers the deployment a failure and initiates a rollback.

Figure 4: Conveyor Architecture.

Overall, FrontFaaS achieves fast and safe deployment at hyperscale by utilizing TaskControl and multiple custom actions made possible by Conveyor’s extensible architecture.

## 5 Design and Implementation of Conveyor

In this section, we briefly summarize Conveyor’s design and implementation.

### 5.1 Conveyor Design

Figure 4 depicts the architecture of Conveyor. Conveyor comprises several stateless services that share a database. The database stores user-defined pipelines, metadata, as well as the last step executed for each release and action. To accommodate the high throughput due to tens of thousands of pipelines, the database is partitioned into many shards.

For robustness and scalability, all components of Conveyor adhere to the worker-pool paradigm. They store the IDs of pipelines, releases, and action runs in a queue. Multiple workers then periodically scan the queue, identify the required operations, and execute them. The number of workers can be scaled up or down based on the load. The execution of a pipeline involves the following steps.

**Create release (Steps 1-3 in Figure 4).** Each pipeline accepts a set of input artifacts. The Release Creator periodically scans for new input artifacts (Step 1) by invoking Artifact Finders (Step 2). When new artifacts are discovered, Conveyor creates a “release object” in the database, thereby triggering the execution of the pipeline (Step 3). We provide seven standard Artifact Finders, and allow users to implement custom Artifact Finders. All Artifact Finders implement a single method, `getArtifacts()`, which returns a set of discovered artifacts. For example, one Artifact Finder identifies latest commits that successfully passed unit tests, while another identifies executables that have been already built and marked with a specific tag.

**Schedule (Step 4 in Figure 4).** The Run Scheduler schedules the execution of releases and actions by periodically scanning through all releases and stepping through each action in each release’s corresponding pipeline. When the input artifacts for an action exist and all preceding actions have success-

fully completed, the Run Scheduler schedules the action for execution.

Because Conveyor allows for multiple active releases derived from one deployment pipeline, the Run Scheduler must coordinate actions across these releases. Some actions, like `canary`, permit concurrent execution on multiple releases, while others, like the `deploy` action, only allow execution on a single release at a time. Therefore, the Run Scheduler must determine which active release executes the `deploy` action. Consider a case where a pipeline deploys to production on every Monday at 10 AM. If multiple code changes have occurred since the last deployment, two releases might be ready to run the `deploy` action on Monday at 10 AM. In this case, the Run Scheduler will cancel the older release.

**Run actions (Steps 5-7 in Figure 4).** The Run Scheduler determines when an action should be executed and notifies the Run Manager accordingly (Step 5). The Run Manager then initiates the execution of the action by invoking a service that implements the action’s logic (Step 6). When executing an action, the Run Manager first invokes the action’s `startRun()` method and then periodically calls its `getRunProgress()` method to track the progress. The outcome of the action is recorded back to the database (Step 7).

Conveyor offers several standard actions, including the `build` action for compiling source code and running corresponding unit tests, various testing actions, the `pkg` action for tagging executables for easy naming and access, the `deploy` action for deploying the new version to production, the `CustomScript` action for running any user-defined script (e.g., to shift traffic before a `deploy` action starts), and the `ManualPick` action for pausing a pipeline and awaiting the service owner’s decision. Conveyor’s extensible architecture allows users to create custom actions by implementing the `startRun()` and `getRunProgress()` methods.

### 5.2 Implementation of the Deploy Action

Since the `deploy` action is the most complex part of Conveyor, we describe it in more detail below. Like a sub-pipeline within the greater Conveyor pipeline, the `deploy` action’s deployment plan specifies the number of phases, which jobs and tasks to update in each phase, the baking time after each phase, and the success criteria. Conveyor supports both percentage and task-count based configuration when specifying the success criteria and the tasks to be updated.

A few widely used deployment plans are commonly employed. For small services or services that prioritize deployment speed, a common plan is to request Twine to update all of their tasks in a single phase. Therefore, the number of tasks to update in a phase,  $N_{big}$ , as described in §3.1, equals the total number of tasks in the job. However, please recall from §3.1 that Twine is still configured to update only  $N_{small}$  tasks at a time to avoid losing too many tasks simultaneously. For services that prioritize safety, their jobs are often updated region by region, as our services are always designed to toler-

ate the loss of a whole region. To balance safety and speed, a common strategy is to update an exponentially increasing number of tasks in each phase (e.g., 1% of tasks in the first phase, 10% in the second, and 100% in the last), assuming that a bug is likely to be revealed in the early phases.

For services requiring high deployment speed, Conveyor can update tasks and perform health checks in parallel. As described in §3.1, during a deployment phase, Conveyor by default requests Twine to update a group of  $N_{big}$  tasks, waits for the updates to finish, and then periodically performs health checks during the bake time. The whole process can take a long period of time. With the parallel approach, Conveyor submits the request for Twine to update  $N_{big}$  tasks and then immediately performs health checks while the update is still in progress. This approach saves the wait time but necessitates the service to have highly accurate health checks due to the short health-check time.

Finally, users have the option to deploy to environments that are not managed by Twine by implementing custom *deployment types*. For instance, we maintain a pull-based deployment type for CLI tools and Linux daemons running on bare-metal machines (§3.4). Furthermore, users have created over 20 custom deployment types for various non-standard deployment targets, such as VMs in public clouds, application configurations, and serverless stream-processing functions.

To implement a custom deployment type, a user needs to build a service that implements a few methods. When initiating a new `deploy` action, the `fetchDeployUnits()` method is invoked, returning a list of *deploy units*. Each deploy unit represents a group of tasks to be updated. Then the `executeUpdates()` method is called to update a set of deploy units with a specific set of artifacts for deployment. Finally, the `deploy` action periodically calls the `trackUpdates()` and `runHealthChecks()` methods until all updates are completed. If any health checks fail, the `deploy` action fails early.

### 5.3 Availability, Reliability, and Recoverability

Currently, Conveyor is implemented in 360K lines of Rust code, including test code and utility tools, and its components run on several hundred machines. Conveyor is not the performance bottleneck in software deployment, as other tools that Conveyor relies on, such as Twine, often perform more extensive work than Conveyor itself.

For high availability, both the database used by Conveyor and each Conveyor component are replicated across multiple datacenter regions. However, it is not necessary to replicate every Conveyor component in every region. Conceptually, one global setup of Conveyor manages the deployments of all services across all regions. A Conveyor component in region  $X$  can communicate with the Twine instance in region  $Y$  to remotely drive the deployment of services in region  $Y$ .

Presently, Conveyor's service level objective (SLO) is to ensure that less than 0.5% of deployments fail due to issues in Conveyor or any of its dependencies, such as Twine, Health

Check Service, build service, and Configurator. Conveyor consistently meets or exceeds this SLO.

The circular dependency between Conveyor and Twine poses challenges to their recoverability. Conveyor consists of a set of services that are deployed via Conveyor itself and hosted inside containers managed by Twine. Similarly, Twine is also implemented as a set of services that are deployed via Conveyor and hosted inside containers managed by Twine itself. When Conveyor or Twine fails, the entire ecosystem cannot update itself. To address this issue, we have designed them to be self-recoverable whenever possible and have introduced manual recovery tools for worst-case scenarios. In the event that Conveyor fails and cannot deploy bug fixes for itself, direct commands can be issued to Twine to start new jobs for Conveyor with the proper bug fixes.

To set up Twine to manage itself, we have implemented a two-layer deployment approach. The top layer consists of two independent instances of Twine, and under normal conditions, one instance can manage and update the other. These top-layer instances are responsible for managing and updating the numerous Twine instances in the bottom layer, which in turn manage and update user jobs. As long as at least one of the top-layer's Twine instances is functioning properly, all Twine instances can be updated normally. In the event that both top-layer Twine instances experience malfunctions, we have a dedicated tool that can be used to directly bootstrap a top-layer Twine instance and initiate the recovery process.

### 5.4 Lessons from Conveyor's Evolution

Over the course of nine years, Conveyor has undergone significant evolution, progressing from v1 to v2, and eventually to v3. Each subsequent version represents a complete system rewrite that incorporates the valuable lessons we have learned.

As a CLI tool, Conveyor v1 enables service owners to manually initiate phased in-place updates of services. Service owners could define the rollout phases and health checks. The Health Check Service (HCS) was developed along with Conveyor from the very beginning. Despite Conveyor v1 being relatively simple, about 12% of services adopted it, demonstrating a strong need for a standard deployment tool.

The biggest change from Conveyor v1 to v2 was to make it a long-running service so that it could automatically start deployments on a pre-configured schedule without manual intervention. We also introduced a more complete pipeline model, where a pipeline consisted of a sequence of phases, each comprising a set of actions. Several enhancements were implemented, including support for the Bad Package Detector (BPD), parent-child pipelines, and pull-based deployments. To boost adoption, Conveyor and Twine were made extensible by providing various interfaces for custom integrations, such as TaskControl, custom actions, and custom artifact finders. As a result of these features and the company-wide Push4Push program, about 94% of services adopted Conveyor.

The remaining 6% of services that did not adopt Conveyor were the largest and most complex ones, requiring more advanced features. Furthermore, the rapid adoption of Conveyor exposed its limitations in terms of performance and reliability. As a result, Conveyor v3 was introduced as another complete rewrite, this time switching from Python to Rust. The data model evolved from a sequential pipeline to a DAG. Additional features were implemented, including lockstep deployment, mutable artifacts to support feedback-directed optimization (FDO), deployment of mobile apps and application configurations, and better support for ML models and FrontFaaS. These enhancements helped Conveyor achieve universal adoption.

One ongoing evolution of Conveyor v3 is to enhance its real-time responsiveness. In Conveyor’s current architecture, the latest state of each release is stored in a database, and a group of Conveyor workers periodically poll the database to identify actions that are ready for execution. We chose this periodic polling design for its robustness. However, the deployment of ML models and application configurations now requires faster execution of pipelines that cannot be supported by the polling method. Therefore, in Conveyor’s new design, the completion of one action will immediately trigger the execution of the next action without any delay. However, we will still maintain the polling mechanism as a reliable fallback to safeguard against any transient failures.

## 6 Evaluation in Production

In this section, we use production data to help answer the following questions:

1. Has Conveyor achieved universal coverage?
2. Do developers trust fully automated deployments?
3. Are Conveyor’s deployment-safety mechanisms effective?
4. How often do deployments fail and why do they fail?
5. What are the observed patterns in pipeline setup, and what are the best-practice recommendations for pipeline setup?

Using three weeks of data from April to May 2023, we studied all deployment pipelines, which amounted to more than 30,000 pipelines. We divide them into four categories:

- *Regular services*: 24.4% of the pipelines deploy traditional non-ML services through containers managed by Twine [45]. This category serves as the primary point of comparison with other deployment tools, as those tools may not support the other categories listed below.
- *Large services*: 0.45% of the pipelines deploy the largest services that consume 80% of our fleet’s total capacity, with each of them using at least 7,700 servers. These large services are a subset of regular services.
- *ML models*: 44.4% of the pipelines deploy ML models, predominantly through Twine, with some utilizing Configurator [44] to control when a task consumes a new model.
- *Other pipelines*: The remaining 31.1% of pipelines are used for various purposes, such as running tests without per-

forming an actual deployment. The data we report for this category will only include those with at least one `deploy` action, which amounts to 6.7% of all pipelines. These pipelines deploy artifacts that are not managed by Twine, such as CLIs, daemons, configurations, and mobile apps.

### 6.1 Universal Coverage

It is challenging to precisely calculate the percentage of services that should utilize Conveyor but do not use it, primarily due to the presence of experimental services that will never be deployed in production. Interviewing the owners of tens of thousands of services to determine this percentage would be impractical. Instead, we focus on calculating the coverage for all 195 largest services. These services tend to be complex, making the adoption of Conveyor more challenging compared to other services.

Conveyor achieves 100% coverage for these large services, with the following caveats: 1) One of them is an ML training job, where software updates during its training run are intentionally avoided. 2) Five of them are short-lived experimental services that do not need automated deployments as they will not be deployed into production. Overall, the advanced features described in §3 enable Conveyor to achieve universal coverage, even for the most complex services.

### 6.2 Trust in Fully Automated Deployments

To understand whether developers trust fully automated deployments, we classify pipelines into five categories based on their release schedules: 1) *Continuous deployment*, which is executed immediately whenever the input artifacts are ready; 2) *Daily*, which is executed at least once every working day at a fixed time, such as 9AM; 3) *Weekly*, which is executed at least once each week; 4) *Biweekly/monthly*, which is executed biweekly or monthly; 5) *ManualPick*, which may automatically execute early actions such as small-scale deployments, but requires human confirmation before executing the final stage of large-scale `deploy` actions.

Table 1 shows that among regular services, 54.6% adopt continuous deployments, and in total 96.5% adopt fully automated deployments without manual validation. These results indicate that with the guardrails provided by testing, health checks, and automated revert of faulty releases, developers release often and trust fully automated deployments.

Although only 71.8% of large services adopt fully automated deployments, it already demonstrates a high degree of trust in deployment automation, considering that they are complex and hyperscale services serving billions of users.

|         | Continuous | Daily | Weekly | Biweekly/Monthly | ManualPick |
|---------|------------|-------|--------|------------------|------------|
| Regular | 54.6%      | 24.8% | 16.8%  | 0.4%             | 3.5%       |
| Large   | 16.0%      | 16.8% | 37.4%  | 1.5%             | 28.2%      |
| ML      | 99.9%      | 0.0%  | 0.0%   | 0.0%             | 0.0%       |
| Other   | 48.5%      | 26.3% | 19.0%  | 0.3%             | 5.9%       |

Table 1: Classification of pipelines based on their schedules.

Figure 5: TaskControl slows down the deployment speed for FrontFaaS during peak hours.

One main reason for the remaining ones using manual validations is that they have highly complex health checks, making it difficult to achieve both a low false positive rate and a low false negative rate simultaneously, regardless of how the decision threshold for health checks is set.

Although the deployments of some services are already fully automated, they still prefer deployments on a fixed schedule (daily or weekly) over continuous deployment for several reasons. First, a failed deployment of a complex service may cause a partial outage in production, which can take hours to mitigate. Therefore, it is preferred to start the deployment at a fixed time in the morning to ensure that incident mitigation does not extend into the night. Second, although almost all services are fault-tolerant against task updates, they may experience degraded SLOs during a task update. For example, updating a ZooKeeper ensemble will trigger a leader re-election and result in delays in responding to client requests. These services prefer to avoid degraded SLOs caused by frequent deployments of every single code change.

### 6.3 Deployment Safety at Hyperscale

To ensure the safety of in-place updates, Twine’s TaskControl API allows services with special needs to exert precise control over their task updates. For example, FrontFaaS’ custom TaskController dynamically adjusts the deployment speed in order to safely and continuously deploy every three hours across more than half a million machines. Figure 5 illustrates what happens in a region that runs over 10,000 FrontFaaS tasks. The top figure shows the normalized request rate for FrontFaaS, along with the percentage of updates to FrontFaaS tasks in that region. The bottom figure shows the average CPU utilization of those FrontFaaS tasks. During the site’s peak hours, which occur between hours 8 and 15, FrontFaaS’ TaskController instructs Twine to reduce the number of task updates in order to prevent the temporary loss of too many

Figure 6: CDF of the number of executables canceled by the Bad Packet Detector (BPD) per reported bug.

|            | Regular services | Large services | ML models | Other pipelines |
|------------|------------------|----------------|-----------|-----------------|
| Successful | 27.5%            | 15.4%          | 33.7%     | 38.0%           |
| Failed     | 13.8%            | 20.9%          | 5.2%      | 4.2%            |
| Canceled   | 58.7%            | 63.7%          | 61.1%     | 57.8%           |

Table 2: Breakdown of the end states of releases.

tasks and avoid overloading the system. Consequently, it takes longer to complete a release during these peak hours. Despite the fluctuating load on the site and the load spikes caused by task updates (see the bottom figure), the overall CPU utilization remains below 75%. Without TaskControl, this level of application-specific adaptation and precise control is hard to achieve with other deployment tools.

To ensure the safe deployment of services that share a monorepo [9], which often entails complex code dependencies, developers can report bugs to Conveyor. The Bad Package Detector (BPD) automatically identifies the affected executables scheduled for deployment and cancels their releases. While only approximately one such bug is reported to Conveyor per day, their impact tends to be widespread. Figure 6 illustrates the number of executables affected by these bugs. Around 15% of these bugs impact over 10,000 executables. Certain bugs, such as those found in Meta’s RPC library [37], have the potential to impact every service. Due to the broad impact of these bugs, the BPD cancels approximately 14% of all executables scheduled for deployment. This extensive impact highlights the need for automated code dependency tracking in a monorepo to ensure deployment safety.

### 6.4 Deployment Failures

To understand how often deployments fail and why they fail, we analyze the failure data of releases and `deploy` actions.

#### 6.4.1 Release Failures

Over the three weeks of our evaluation, Conveyor generated millions of releases. Table 2 summarizes the end states of these releases. Release cancellations commonly occur when a new release supersedes an old release that was not yet deployed. While most releases are canceled, they are still highly valuable as they facilitate the execution of builds and tests, aiding in the early detection of bugs.

Figure 7: Breakdown of release failures by action types.

Although the release failure rate seems high, it actually indicates the effectiveness of deployment automation. Let’s consider a simple pipeline consisting of `build`→`test`→`deploy`. If a release fails during the `build` or `test` action, it means that the problem is detected early, preventing a faulty release from reaching production. This is precisely why, despite the high failure rate, developers maintain a high level of trust in deployment automation (§6.2).

We show the breakdown of release failures by action types in Figure 7. As an example, the value of “40%” for the “*regular*” bar in the `build` category does not mean that 40% of builds fail for regular services. Instead, it means that out of all failed releases for regular services, 40% of them failed while executing the `build` action. The value of the “*ML*” bar in the `deploy` category is 93.6%, but we cap it at 50% to make other bars more visible.

Figure 7 shows that, except ML models, the majority of release failures are detected by standard builds and tests (`canary`, `IntegrTest`, and `PerfTest`). Note that builds involve running unit tests and will fail if any tests do not pass. For ML models, the setup of parent-child pipelines between inference executables and models (§3.3) helps reduce failed releases. During the three weeks, nine failures occurred in the parent pipelines. Among them, eight were detected by unit tests, and one was detected by `PerfTest`. These failed parent pipelines did not trigger the execution of the corresponding child pipelines. Otherwise, the number of failed child pipeline releases would have increased by about 50%.

#### 6.4.2 Failures in Deploy Actions

Failures in `deploy` actions occur at the important stage of updating tasks and could lead to user-visible errors. The failure rates of `deploy` actions vary across pipeline types: regular services (5.4%), large services (6.2%), ML models (14.3%), and other pipelines (1.1%). In all cases, health check failure is the top reason for `deploy` failures, followed by update timeout, which is typically caused by too many unhealthy tasks during a deployment.

Figure 8 presents the breakdown of health check failures. While system-level metrics, such as CPU, memory, crashes, and RPC errors, can help identify many problems, “*AppSpecific*” metrics still play a significant role. Frequently used such metrics include the increase in the number of specific errors

Figure 8: Breakdown of health check failures.

|                | Regular services | Large services | ML models | Other pipelines |
|----------------|------------------|----------------|-----------|-----------------|
| False negative | 0.92%            | 3.14%          | 0.012%    | 0.12%           |
| False positive | 11.5%            | 41.3%          | 0.0025%   | 17.4%           |

Table 3: False positives and false negatives of health checks.

returned to users, increase in the number of retries, decrease in correctness metrics, or changes in user engagement.

Developers often need to make a tradeoff between false positives and false negatives when using health checks to detect bugs because health anomalies can also be caused by other factors such as hardware failures or changes in workload. To approximate the rate of false negatives (i.e., bugs not being detected), we calculate the percentage of releases that finished successfully but were later reverted or patched by developers. However, since developers sometimes patch or revert a release for purposes other than fixing bugs (e.g., to do a quick test), these numbers should be viewed as an upper bound for false negatives. To approximate the rate of false positives (i.e., health anomalies in the absence of a bug), we calculate the percentage of `deploy` actions that reported health anomalies but were allowed to proceed by a human.

As shown in Table 3, except for ML models, the occurrence of false positives is significantly higher than that of false negatives. Notably, the rate of false positives for large services reaches as high as 41.3%. This is because health checks for large services are typically more intricate, and developers tend to use stringent health check thresholds to ensure release safety. When faced with health anomalies, they prefer to rely on manual investigations to determine whether to proceed with a release or not.

Figure 9 further presents the point at which a `deploy` action fails. The *progress* metric is calculated as the number of tasks that are supposed to be updated till the end of the failed phase divided by the total number of tasks to be updated in all phases. We exclude single-phase `deploy` actions from this figure, since their progress is either 0 or 1. Figure 9 reveals a bimodal pattern, where failures occur either very early or very late. While many bugs can be detected when only a small subset of tasks is updated, some bugs, such as subtle performance regression, can only be detected after they are deployed at scale. These kinds of bugs pose the most challenging problem for software deployment.

Figure 9: The progress of failed deploy actions.

Figure 10: Number of actions per pipeline.

## 6.5 Pipeline Patterns & Recommendations

In this section, we analyze various aspects of pipeline statistics to gain a better understanding of how pipelines are used in production. Based on our findings, we provide best practices for pipeline design in §6.5.4.

### 6.5.1 Pipeline Configuration

Figure 10 shows that the average number of actions per pipeline varies: regular services (3.5), large services (12.2), ML models (2.0), and other pipelines (4.0). As expected, large services have much deeper pipelines. For ML models, all child pipelines (§3.3) use a uniform setup with two actions: build and deploy. The parent pipelines for inference executables have more actions such as PerfTest, but since the number of child pipelines is about 1,000 times larger than that of parent pipelines, the statistics here mainly represent those of child pipelines.

We further examine the popularity of different types of actions, represented as the percentage of pipelines that include at least one corresponding action type. As shown in Figure 11, build and deploy are the two most popular actions, as expected. We observe two distinguishing characteristics of large services. First, they are more likely to include tests (canary, IntegrTest, and PerfTest). Second, they rely more on human decisions (i.e., ManualPick) to determine whether to proceed.

### 6.5.2 Deploy Action Configuration & Runtime Statistics

To balance safety and speed, a deploy action often consists of multiple phases, each updating a subset of tasks. We observe a few popular patterns in the setup of deploy actions: 1) the “*super linear*” pattern, which updates a small percentage of

Figure 11: Percentage of pipelines that use a specific action.

Figure 12: Breakdown of different deploy patterns.

tasks in the first phase and updates a higher percentage in later phases; 2) the “*single*” pattern, which updates all tasks in one phase; 3) the “*single parallel*” pattern, which uses one phase but updates multiple jobs in parallel; 4) the “*region-by-region*” pattern, which updates one region’s jobs per phase; and 5) the “*linear*” pattern, which updates the same percentage of tasks in each phase. By definition, these patterns are not exclusive. For example, a *region-by-region* pattern could be *linear* as well. To separate them, we use the following rule: *single parallel* > *single* > *region-by-region* > *linear* > *super linear*. It means that, if a *deploy* action meets more than one definition, we categorize it as the first one in the chain.

As shown in Figure 12, the setups are very diverse. Among regular services, simple ones prefer the *single* pattern and complex ones prefer the *super linear* pattern to balance safety and speed. Large services employ various *misc* patterns, with a concrete example shown in §6.5.3. ML models mostly use the *super linear* pattern. Among other pipelines, simple ones prefer the *single* pattern and complex ones prefer the *region-by-region* pattern for safety.

The execution time of deploy actions has a long-tail effect: for regular services, its P50 is 2.3K seconds and P99 is 86K seconds; for large services, its P50 is 2.0K seconds and P99 is 186K seconds (52 hours); for ML models, its P50 is 2.9K seconds and P99 is 9.8K seconds; for other pipelines, its P50 is 0.33K seconds and P99 is 15K seconds. We will elaborate on the long deploy time in §6.5.3.

Table 4 further decomposes deploy action’s execution time into four components: *task update*, *bake*, *preprocessing*, and *postprocessing*. Recall that the bake time is the time after all updates in a phase have been completed, during which Con-

|                | Regular services | Large services | ML models | Other pipelines |
|----------------|------------------|----------------|-----------|-----------------|
| Task update    | 21.2%            | 45.1%          | 39.2%     | 31.4%           |
| Bake           | 31.7%            | 25.1%          | 58.1%     | 29.6%           |
| Preprocessing  | 18.7%            | 2.9%           | 1.9%      | 5.4%            |
| Postprocessing | 28.4%            | 27.0%          | 0.9%      | 33.6%           |

Table 4: Time spent in different stages of `deploy` actions.

veyor periodically checks the health of the updated portion of a service. *Preprocessing* and *postprocessing* refer to custom operations performed before and after updating a subset of tasks, respectively. Examples include redirecting traffic and conducting end-to-end tests. Overall, Table 4 shows that operations other than task updates consume the majority of the time, emphasizing the importance of holistic optimization of the pipeline setup when deployment speed is a concern.

### 6.5.3 Real-world Example of Long Deploy Time

Large services that prioritize deployment safety may require multiple days to complete their `deploy` actions. To illustrate this, we present a real-world example of a foundational storage service at Meta that operates in every datacenter region. Its `deploy` action is configured to make progress on workdays from 9AM to 6PM without manual intervention. If the execution of the `deploy` action does not finish by 6PM, it will pause and continue on the next workday at 9AM.

Its deployment follows the *super linear* pattern for a few regions and then switches to the *region-by-region* pattern for the remaining regions. With over 20 phases in total, each of the early phases has a bake time of one hour, while the remaining phases have a bake time of 10 minutes. On average, task updates per phase take about 25 minutes. Taking into account the bake time, the early phases run for about 85 minutes each, while the remaining phases run for about 35 minutes each. Considering the total number of phases and their duration, the `deploy` action typically completes the early phases within one day and then resumes the next workday at 9AM. If everything goes smoothly, the deployment finishes on the second day. However, transient issues may cause it to retry and delay the completion time until the third day.

### 6.5.4 Recommendations for Pipeline Design

We recommend the following best practices for pipeline design. In general, we recommend using the *super linear* pattern as a starting point, as it provides a good balance between speed and safety. Moreover, we recommend including a phase in the middle of the pipeline to update all tasks within a region as opposed to never updating any whole region until the last phase. This is important because many services have regional dependencies, and certain issues, such as performance regressions, may only become noticeable when the code runs at the scale of a full region. Finally, we recommend scheduling deployments for the mornings of Monday to Thursday, so that developers have a full work day to troubleshoot any deployment issues. They may adopt continuous deployment after health checks and tests have matured.

## 7 Related work

There is a rich set of deployment tools, such as Spinnaker [42], AWS CodeDeploy [3], AWS CodePipeline [4], Azure Deployment Manager [46], Azure Pipeline [6], Google Cloud Build [17], Google Cloud Deploy [18], and CircleCI [13]. Cluster manager is also a well-studied topic. Examples include Kubernetes [22] and YARN [49] from open source, Borg [47, 50] from Google, and Protean [19] from Azure. Section 3 discussed advanced features that distinguish Conveyor and Twine from existing systems.

A number of prior works have studied and surveyed possible problems in software deployment [20, 23, 38, 41, 51], mostly based on open-source projects or individual case studies. As described in §3, the scale and diversity of the services at Meta have introduced many new challenges, such as in-place updates, handling complex code dependencies, fast deployment of large services like FrontFaaS, and deployment of complex ML models. Dedicated ML platforms such as AWS SageMaker can deploy models using the mirroring approach [35, 36], but they do not support in-place updates or the advanced model-deployment features described in §3.3.

Multiple works have focused on individual problems during deployment. For example, Gandalf tries to locate the problematic deployment after failures are detected [26]. ZebraConf tries to detect configuration updates that may cause compatibility issues [27]. Boyer et. al. [8] propose a declarative approach to update services, instead of the imperative approach used by most deployment tools, including Conveyor.

## 8 Conclusion

We presented the deployment scenarios, operational experience, and production data related to software deployment at Meta, along with the design and implementation of Conveyor. We demonstrated the feasibility of frequent and fully automated deployments supported by a single deployment tool for all services. Additionally, we presented novel techniques for in-place updates, analysis of code dependencies to prevent faulty releases, and the safe deployment of ML models.

## Acknowledgments

This paper presents nine years of work by past and current members of several teams at Meta, including Conveyor, Twine, Health Check Service, Configuration Management, Release Engineering, and Inference Platform. In particular, we would like to call out the current members of the Conveyor team who are not on the author list: Alex Rock, Arvind Gautam, Brian Fitzpatrick, Eddy Li, Haydn Kennedy, Jared Bosco, Jimmy Zeng, Marcos Pertierra Arrojo, Marija Trifkovic, Matthew Boardman, Rudy Pikulik, Mike Belov, Matthew Almond, Nippun Goel, Shawn Cui, and Martin Reichhoff. We thank Hui Lei, all reviewers, and especially our shepherds, Ding Yuan and Malte Schwarzkopf, for their insightful comments.

## Abstract

Distributed on-disk database systems could either use an expensive commit protocol like two-phase commit (2PC) to guarantee atomicity, and suffer from *slow* distributed transactions, or forgo 2PC, which lead to weaker semantics, limitations to the programming model, or constrained scalability, making the system less *general*. We argue this compromise is no longer necessary within modern datacenters. Low latency 2PC ( $\sim 150$   $\mu$ s on Azure for 2PC over Paxos) can be achieved using low-latency storage for the relatively small transaction logs, fast RPCs, and careful protocol design. With fast 2PC, the data contention bottleneck for many transactions shifts from 2PC to reading the data itself from the relatively slow storage while holding transaction locks.

We present Chardonnay, a scalable, on-disk, multi-versioned transactional key-value store optimized for single datacenter deployments with fast 2PC. Chardonnay has a *general* interface supporting point reads, scans, and writes within multi-step strictly serializable ACID transactions. The key mechanism underlying Chardonnay's design is strongly consistent snapshot reads on commodity hardware, using a novel lock-free read protocol. Chardonnay uses this protocol to cheaply determine the read-write sets of queries, enabling Chardonnay to transparently prefetch data needed for a transaction prior to the execution of the transaction and the acquisition of locks. This enables Chardonnay to achieve *fast* transactions by minimizing contention, and avoids aborts due to deadlocks by ordering lock requests.

## 1 Introduction

The holy grail of distributed databases is to provide an abstraction of a single-server database that can run SQL ACID transactions at high performance while maintaining high availability. Recent work [27, 33, 47, 52, 57, 69, 81, 82, 84] shows that ACID distributed transactions

with strong isolation and consistency semantics can be made efficient and scalable within in-memory database systems. However, keeping all data in memory can be prohibitively expensive, especially for large applications, as DRAM's cost per GB is over 10–50 $\times$  more expensive than regular (e.g., TLC or QLC) NAND SSD [34].

Therefore, due to their significantly lower cost, many applications use distributed databases [11, 12, 29, 74], which store their data on disk-based storage engines such as RocksDB [8, 32, 58] or LevelDB [7]. The classic architecture for such systems [65], popularized by System R\* [59], is to shard the data horizontally across a collection of shared-nothing machines, and use a distributed commit protocol such as two-phase commit (2PC) [48] to ensure atomicity of distributed ACID transactions. Unfortunately, distributed transactions in these systems have significant performance limitations [17, 30, 42, 52, 57, 76, 81].

Due to these challenges, many scale-out on-disk systems avoid providing any multi-key ACID transaction support at all [26, 31], or limit it to local transactions accessing keys within a single machine or partition [23, 61]. Other systems offer support for distributed transactions, but forgo 2PC and sacrifice *generality* in one or more ways, e.g., by offering weaker semantics [16, 54, 78, 79], restricting the programming model [76], or employing an architecture that limits system scalability [13, 49, 87]. Nevertheless, due to strong developer demand [14], many popular SQL DBMSes now support general distributed ACID transactions [11, 29, 74], despite being a lot slower than local transactions. Table 1 shows the trade-offs made by various popular on-disk systems.

We argue that this compromise between performance and generality is no longer necessary within the modern datacenter. The high performance penalty of 2PC historically has been due to the high latency of RPCs and flushing log entries to disk. Fortunately, neither is the case any more. Modern datacenter networks are fast [22], and systems such as eRPC [46] have demonstrated that

| System                     | Serializable | Linearizable | General API | Distributed TX | High Contention         |

| Chardonnay                 | ✓            | ✓            | ✓           | Fast           | ✓                       |

Table 1: Comparison of representative on-disk distributed database systems.

RPCs can run at single-digit  $\mu$ s latency within the data-center even without using RDMA. Additionally, storage devices based on low-latency SLC NAND [10] or 3DX-point [1] also provide single-digit  $\mu$ s latencies [6, 9, 10], making them ideal for persisting database logs.<sup>1</sup> Furthermore, many recent frameworks [45, 66, 83, 85, 86] fully or partially bypass the Linux I/O software stack, further boosting I/O performance.

This leads us to revisit the assumption that 2PC is the primary bottleneck inherent in scale-out on-disk database system designs. However, using a fast 2PC protocol reveals new bottlenecks. As we show in §4, even *eliminating the entire latency of the commit protocol is not sufficient* to achieve good performance for high-contention workloads, because transactions frequently hold locks while fetching cold items from storage. Therefore, the data contention bottleneck shifts to reading the data from disk, since reading data from a typical SSD can be orders of magnitude slower than the network.

We present Chardonnay, a distributed multi-version transactional key-value store that is deliberately tailored for this new era of fast 2PC. Chardonnay is designed for single-datacenter deployments, since cross-datacenter 2PC latency would be high. It supports point and range reads, as well as writes, within classical multi-step strictly serializable ACID transactions, making it suitable as the storage engine for a SQL database (e.g., similar to CockroachDB [74]). Chardonnay uses the classic shared-nothing architecture<sup>2</sup> and uses strict two-phase locking (2PL) [37] to guarantee strict serializability [43] for read-write transactions, as well as 2PC to ensure atomicity for distributed transactions.

The core insight of Chardonnay is that fast RPCs enable strictly serializable lock-free snapshot queries within the datacenter in a *general* fashion, i.e., without using specialized clocks, limiting scalability, or weakening the performance and semantics of read-write transactions. Low-latency, high-throughput RPCs are key to allow all committing transactions in Chardonnay to

cheaply read a counter, called the *epoch*, that serves as a global serialization point. The system increments the epoch periodically, independent of transactions, so unlike designs with a centralized sequencer [18, 87], maintaining the epoch can be distributed and highly scalable. The main challenge is that unlike systems with a single global log or coordinator, Chardonnay uses one log per partition, so it cannot enforce global epoch ordering of commits. Instead, we co-design the snapshot read and commit protocols to guarantee their equivalence to epoch ordering (§6). The idea is rather simple: Snapshot queries may block waiting for write locks to be released (once) for correctness, but they do not acquire any locks, so they do not contend with the read-write transactions.

Beyond the direct benefit of efficient, lock-free read-only queries, this enables two important benefits, as Chardonnay leverages this snapshot read protocol to optimize the execution of read-write transactions. First, Chardonnay runs the user’s transaction in a *dry run* mode using the snapshot protocol to (approximately) compute and prefetch the transaction’s read set, which in the vast majority of cases allows Chardonnay to shift the work of reading cold data from storage outside of the contention period of the transaction. Second, since read and write sets can be efficiently computed using the snapshot protocol, Chardonnay also uses them to plan the locking scheduling in a manner that avoids deadlock aborts.

At the systems and design level, our main contribution is Chardonnay, the first (to our knowledge) on-disk system that achieves high performance for both low and high-contention workloads, without sacrificing strong semantics, restricting the programming model, or limiting scalability. The novel mechanisms introduced in Chardonnay are:

- Novel lock-free snapshot read protocol:** Chardonnay uses fast RPCs to guarantee strict serializability without relying on specialized hardware, synchronized clocks, making assumptions about clock skew, or limiting scalability.
- Automatic prefetching:** Chardonnay leverages the snapshot protocol to do a “dry run” of the query, which loads and pins all the keys accessed by the

<sup>1</sup>It is of course possible to store the entire database on such devices, but they cost significantly more than commodity SSDs.

<sup>2</sup>Which, we posit, has aged like fine wine.

transaction to main memory. This allows Chardonmay to avoid waiting for data read from slow storage while holding locks. Unlike similar schemes introduced by prior work [3, 75, 76], Chardonmay's prefetching mechanism works for scans, and neither requires changes to the user code, nor incurs significant additional latency or contention.

3. **Lightweight deadlock avoidance:** By computing read and write sets in advance, Chardonmay avoids deadlocks by determining the lock acquisition order.

Collectively, these techniques enable Chardonmay to have excellent performance under high contention. Indeed, as we show in §9, Chardonmay's throughput under extremely high contention is only 15% lower than under extremely low contention. In contrast, the throughput of a baseline System R\*-style system (even utilizing fast 2PC) drops by over 85%. The dry run phase adds overhead which is largely wasteful for low contention workloads, but we consider this a worthwhile trade-off, and we allow disabling dry runs on a per transaction basis.

A general takeaway is that within on-disk systems, the availability of fast datacenter RPCs makes distributed and multi-core system designs look increasingly similar. Some of our ideas (epoch-based versioning) are inspired by multi-core database systems [77]. This unlocks the potential for adopting additional insights from multi-core single-node systems in a distributed setting. The flow of ideas can also go in the other direction: while distributed transactions were our primary motivation when designing Chardonmay, the challenge of high contention is not unique to distributed transactions, and in fact many single-node database systems run with low isolation precisely to mitigate this issue [15]. Our results show that Chardonmay's techniques can be useful for them too.

## 2 Background

This section discusses transaction semantics and commit protocol performance in distributed database systems.

### 2.1 Strict Serializability

Strict Serializability [43] (also known as External Consistency [29]) is considered the gold standard of distributed transaction semantics. It is the combination of the following two properties [69]:

- **Serializability:** every execution is equivalent to some serial ordering of committed transactions.
- **Linearizability:** if transaction A commits before transaction B starts, then A should precede B in the equivalent serial ordering.

### 2.2 2PC Recap

Two-phase commit (2PC) is a classic commit protocol with many variants [48]. The basic flow works as follows: after a transaction finishes execution on multiple *participant* servers or shards, a *coordinator* starts the first phase by issuing *Prepare* RPCs to all participant. Each participant can vote yes or no in response to the RPC, where a yes vote is a promise by the participant that it will not unilaterally abort the transaction and will be able to (eventually) commit the transaction when asked. Before voting yes to a Prepare RPC, the participant typically persists all of the transactions writes to a durable log so it can recover from any failures. If any participant votes no (or never responds due to failures or timeouts), the coordinator aborts the transaction. Otherwise, it logs the decision to commit to durable storage and then runs the second phase of the protocol by issuing *Commit* RPCs to the participants so they can apply the transaction and release locks. A well known problem of 2PC is that it is *blocking* [20, 70], wherein the failure of the coordinator at inopportune moments prevents the participants from making progress. This can be addressed by replicating the coordinator state for availability [17, 29, 40].

### 2.3 The Penalty of 2PC

2PC traditionally incurs a significant performance overhead for two main reasons. First, it requires at least two network round trips and two synchronous log writes to persistent storage per transaction [41, 57], which incurs network and storage I/O overhead, as well as CPU usage by the TCP/IP stack [81]. For example, typical 2PC commit latency within a single datacenter in systems like Spanner is in the double digit milliseconds [29], which puts a hard upper bound of less than 100 TPS on transactions that update a write-hot record. Second, the coordination necessary to guarantee isolation can significantly decrease concurrency, leading to performance degradation, as well as high abort rates [15]. This increased contention due to 2PC is particularly harmful for short transactions common in OLTP workloads, due to the high latency of the commit protocol relative to the time it takes to execute the transaction logic [76]. The impact of contention is evident in locking-based concurrency control schemes such as 2PL, but optimistic concurrency control (OCC) schemes are also not immune, and can in fact perform worse under high contention [41, 51, 82].

## 3 Requirements

We now define Chardonmay's stated objective, *fast and general* transactions for on-disk databases, in more detail. Fast encompasses the following requirements: First,

latency for short OLTP transactions should be low (hundreds of  $\mu\text{s}$ ) regardless of whether it is single partition or cross-partition; hence the performance penalty of distributed transactions should be relatively small. Second, the system needs to support long-running read-only queries efficiently, without impacting OLTP read-write transactions. Finally, the system should be able to maintain high throughput for both low and high contention workloads. General means providing a general, unrestricted programming model and API (e.g. capable of supporting a full SQL layer) and the highest level of semantics (i.e. strict serializability) without imposing overall scalability limits or using specialized hardware.

#### 4 Measuring Contention Footprint

Data contention is a major issue for traditional on-disk shared-nothing distributed database designs. Most real-world workloads have low contention most of the time, but occasionally a small number of extremely hot data items appear, significantly degrading overall throughput [39, 76]. Other workloads are characterised by high skew such that a small portion of the database receives a majority of the load. For example, half of the NYSE trades happen on 1% of the symbols, and breaking news can cause a sharp spike in trades on a small group of symbols [68]. Indeed, data contention is a bottleneck that hinders truly scalable transaction processing, even in RDMA-enabled in-memory distributed database systems [82], and on multi-core single-node systems [62].

Following the terminology of Calvin [76], we define a transaction’s *contention footprint* as the total duration from the instant the transaction acquires its first lock until it releases its last lock. In this section we use YCSB [28] to study the contention footprint of simple, single operation transactions in System R\*-style systems. To this end, we built two simple baseline systems based on the System R\* architecture on top of RocksDB, using its transaction and 2PC support in our experiments:

- **Baseline-Slow.** The client invokes database functions using (slow) gRPC [5]. Both the write-ahead log (WAL) and the database are placed on a directly attached SSD.
- **Baseline-Fast.** Uses (fast) eRPC (with FlatBuffers [4] for serialization format) instead of gRPC, and the WAL is put on an emulated fast NVMe device.

Our baseline implementations ignore crucial practical considerations (such as replicating coordinator state for high availability to deal with the well-known 2PC blocking problem), and transactions more complicated than a single read or write. Therefore, our results underestimate the contention footprint. Nevertheless, they are instructive. All our experiments run on Microsoft Azure VMs. The entire key universe is assigned to a single shard. We

Figure 1: Contention footprint of YCSB read (left bar) and write (right bar) transactions. % represent the proportion of the data in DRAM. Chardonnay achieves a similar contention footprint to fully in-memory (“Baseline-Fast 100%”) with only 10% of its data in DRAM.

run YCSB-A with 50% point reads and 50% point writes with uniform random distribution. All experiments use one client with 5 threads, which runs on a dedicated VM in the same Azure region as the server. To control the amount of DRAM used by the system, we disable the OS page cache and vary the size of the block cache, which is RocksDB’s read cache. We run a full 2PC at the end of each transaction, including in the case of reads, to measure transaction overhead, even though technically 2PC is not needed since there is only one shard. Read transactions release locks during the Prepare phase, so the Commit phase does not contribute to their contention footprint. For durability, Calls to Prepare and Commit always wait for the write to be flushed to storage.

We show how the average latency of read and write operations each contribute to the contention footprint in Figure 1. On Baseline-Slow, the bulk of the contention footprint comes from running 2PC. On Baseline-Fast, the latency of 2PC is significantly lower due to the fast RPC library and fast log storage. The yellow bars show that the contention footprint of read transactions is much higher when only 10% of the dataset is in main-memory, since the majority of reads have to fetch data from SSD storage. Write transactions (red bars) are not much affected by the available DRAM, since writes are buffered in-memory (at the server) until the Prepare phase where they get written to the WAL.

We deduce two takeaways from this simple experiment. First, with a modern RPC library, fast intradatacenter network, and small amount of fast NVMe storage, distributed databases can significantly reduce 2PC latency. Second, once the latency of 2PC is reduced, the data contention bottleneck becomes reading the data needed by the transaction from the relatively slow SSD.

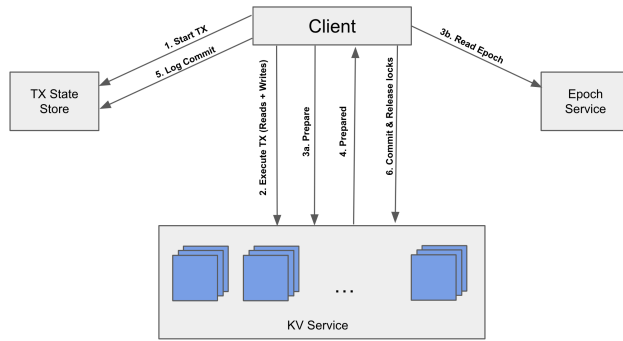

Figure 2: Transaction Lifetime in Chardonnay.

## 5 Architecture

Chardonnay has four main components:

1. **Epoch Service.** Responsible for maintaining and updating a single, monotonically increasing counter called the **epoch**. The epoch service exposes only one RPC to its clients, which returns the latest epoch. Reading the epoch serves as a global serialization point for all committing transactions. The epoch is used to assign transaction timestamps at commit time and is essential for our lock-free strongly consistent snapshot reads (§6). The epoch is only read, not incremented, by each transaction.
2. **KV Service.** The core service that stores the user key-value data. It uses a replicated shared-nothing range-sharded architecture similar to other modern System R\*-style systems [11, 29, 74].
3. **Transaction State Store.** Responsible for authoritatively storing the transaction coordinator state in a replicated, highly-available manner so that client failures do not cause transaction blocking. We chose to store the transaction state separately from the user’s key-value data to enable 2PC latency optimizations, which we describe in appendix A.1.
4. **Client Library.** Applications link this library to access Chardonnay. It is the 2PC coordinator, and provides APIs (Figure 3) for executing transactions.

Figure 2 illustrates how the components interact during the lifetime of a transaction. The basic flow of a read-write transaction is almost the same as in a classic shared-nothing System R\*-style system, except we add step 3b to read the epoch in parallel to the Prepare phase.

### 5.1 Epoch Service

The epoch service is a Multi-Paxos replicated state machine maintaining a single counter, the *epoch*. One replica is designated leader. It increments the epoch at a fixed configurable time interval (e.g., 10 ms) by appending an entry to the Paxos log so it is durably replicated.

It exposes one RPC, *read-epoch*, which returns the value of the epoch. The system maintains the invariant:

**Monotonic Epoch Invariant:** If a *read-epoch* call returns a value  $e$ , then all subsequent *read-epoch* calls must return a value greater than or equal to  $e$ .

We cannot rely on simply reading the value from the leader replica, since a leader might lose its status without realizing it for a while. It is possible to run the client RPCs through the Paxos state machine. However, since each committing transaction reads the epoch, this would be too costly. Instead, we consider the epoch updated when it is applied to the state of a majority of replicas, not just when it is appended to the log. The client sends read RPCs to all replicas and considers the current epoch value to be the one returned by a majority of the replicas. If no value has a majority, the client retries the read.

There is a trade-off in choosing the epoch advancing interval. It needs to be long enough compared to typical transaction duration that the value is usually read from the CPU caches of replicas, and without requiring retries due to no value having a majority. On the other hand, if it is too long, it adds to linearizable snapshot read-only transaction latency, as we explain in §6. We find that advancing the epoch once every 10 milliseconds works well in our experiments.

A single core can support tens of thousands of clients and serve up to millions of eRPC calls per second [46]. Furthermore, the client library batches multiple *read-epoch* calls from multiple concurrent transactions into a single RPC. Since each RPC does very little work (reads a word from main memory that is usually cached), we expect this design to be sufficient for all practical purposes. Nonetheless, in the interest of generality we show how to scale-out the epoch service in appendix A.3.

### 5.2 KV Service

The key universe is partitioned into disjoint contiguous subsets called **ranges**. Each range is assigned to a number of range servers (e.g., three) and is comprised of a database and a WAL that is implemented via Paxos. The WAL is placed on a fast NVMe device for low latency, while the database is stored on commodity SSD storage. One of the range replicas is designated as a *leader*, which holds a leader lease. It maintains a lock table to implement two-phase locking, using existing range locking techniques [50, 55]. All reads and writes go through the leader.

To simplify the description in this paper we will assume the ranges and replica-to-server assignments are static, although in practice ranges need to be moved, split and merged to balance load effectively. This can be accomplished using well-known techniques [23, 26, 29, 74], which we leave for future work.

### 5.2.1 Leader Selection and Disjointedness

Each range should have a designated leader replica that holds the leader lease. The leader selection is piggy-backed on the Paxos log implementation, i.e., a replica attempting to acquire the leader lease does so by appending a lease acquisition entry to the Paxos log. This log entry includes, among other information, the identity of the replica that is the lease holder, an *epoch interval* entitling the replica to leadership status as long as the epoch (maintained by the epoch service) falls within this interval, and *leader sequence number*, which is incremented whenever a new replica becomes the leader (but not when an existing leader renews its lease). The leader returns the sequence number to the client on every request, so the client can detect leadership changes and abort the transaction if the transaction observes two different leaders for the same range. When a leader is renewing its lease or a new leader is taking over, they read the epoch from the epoch service and set the upper interval ahead of the current value (by 100 in our prototype); it is important that the upper end is not too far ahead of the epoch, because this would effectively prevent other replicas from taking over if the leader goes down, until the true epoch catches up.

To prevent two replicas from acquiring leases with overlapping epoch intervals, a lease acquisition entry by a replica includes a copy of the lease believed to be the most recent. Other replicas will reject a replica's attempt to get the lease if they are aware of a more recent lease having been granted. This guarantees that at any point in time there is at most one leader for any range, and that only one range leader can successfully prepare transactions for an epoch. We call this the *Leader Disjointedness* invariant. In §5.4 we explain how we use it to validate transaction locks, and later in §6 we describe its role in the correctness of our lock-free snapshot reads.

## 5.3 Transaction State Store

The transaction state store is responsible for storing the state of active transactions in the system in a fault-tolerant, replicated manner, to mitigate 2PC blocking.

Each transaction can be in one of the following states: *Started*, *Committed*, *Aborted*, and *Done*. Note that being *Prepared* is not of concern here. We use the well-known presumed abort optimization [59], meaning that the service replies *Aborted* to a participant's inquiry about the state of a transaction unknown to the service. Being in *Done* state means that all transaction participant *ranges* have learned about the commit outcome of the transaction so that the service can safely forget about it.

The service is hash-partitioned by transaction id. Each partition is assigned to (typically) three servers. We do

```
class IChardonnay {
public:
    Transaction* start();
    std::string get(Transaction *tx, const std::string &key);
    std::vector<std::string> scan(Transaction *tx,
                                const std::string &lowerBoundInc,
                                const std::string &upperBoundExcl);
    std::string put(Transaction *tx,
                    const std::string &key,
                    const std::string &val);
    void del(Transaction *tx, const std::string &key);
    void abort(Transaction *tx);
    bool commit(Transaction *tx);
};
```

Figure 3: Simplified Chardonnay Client API

not need a per partition log to order transactions, since transactions are already ordered by 2PL. Instead, within a partition, each transaction state is represented as its own Multi-Paxos replicated log, which can have at most 3 entries. Position 0 always contains the Started entry, position 1 can either contain Committed or Aborted, and position 2 is to record Done state. This unusual design is key to a 2PC latency optimization that we describe in appendix A.1.

Recall that the client in Chardonnay acts as the 2PC coordinator. If the client crashes after starting the *Prepare* phase and before completing the transaction, the participant ranges need to determine whether to commit or abort. A KV Service range leader will attempt to put an Abort entry in the transaction state log (in position 1). If it succeeds, it can safely abort the transaction. The transaction state store is the source of truth regarding a transaction outcome. If the KV range leader successfully installs an abort decision for the transaction with the TX state store, a slow client cannot then succeed in committing it at a later point. Alternatively, after running the Paxos state machine, the KV range could learn that the client already put a Commit entry in that log position, in which case it can safely apply the transaction.

## 5.4 Client

The client provides an interface for users to access the database, and also acts as the 2PC coordinator in Chardonnay. After the transaction finishes execution, the client reads the epoch from the epoch service in parallel to issuing Prepare RPCs to participant range leaders. Each leader that accepts the Prepare request responds with a *Prepared* message that includes the epoch interval on its lease. The client then checks that the epoch it read falls within the lease's epoch interval of every participant, and if not, aborts the transaction. This is necessary to maintain the leader disjointedness invariant. If all the participants prepare successfully and the lease validations pass, the client then calls the transaction state store

to record the transaction's commit durably. The Commit record includes the participant ranges and the value of the epoch. Finally, the client calls the participant range leaders to notify them of the commit so they can record it locally and release all the locks. Transactions in Chardonnay must wait until the transaction Commit is recorded before releasing any locks, for the correctness of snapshot reads (§6). This implies that even read locks for successfully prepared transactions have to survive leader changes and thus must be logged in the WAL during the Prepare phase.

Many, if not most transactions only touch keys within a single range, so they do not need 2PC. First, the client reads the epoch. Then, it sends a Commit message to the leader, which checks that the epoch falls within the lease's epoch interval. If so, the leader appends to the WAL and if successful, returns success. If not, it aborts.

## 6 Snapshots

This section describes Chardonnay's multi-versioning and snapshot read protocols. Snapshot reads are essential to efficiently support read-only queries. They also underpin the techniques described in subsequent sections. Queries have to be declared as read-only from the start; a transaction that starts normally without this declaration but only performs reads is treated as a read-write transaction by the system, and does not utilize the lock-free snapshot read algorithm.

### 6.1 Versioning

Each user record has a key  $k$  and one or more versions stored in the database. The key for each version is the pair  $\langle k, \text{VID} \rangle$ , where VID (version ID) is determined as follows. Its prefix is the value of the epoch that the client reads in parallel to running the Prepare phase of 2PC. A counter (starting from 1) is appended to the epoch to distinguish writes by different transactions in the same epoch. A transaction chooses a single suffix that makes its VID greater than that of the existing VIDs in its write set. Deletes need to have versions as well, so they appear as tombstones. For convenience, the system also stores an unversioned record with just the key  $k$  which holds the latest value and is updated in place.

### 6.2 Read Algorithm

**Epoch Ordering Property:** There exists an equivalent ordering to the transaction ordering enforced by Chardonnay's strict 2PL such that for all pairs of committed transactions,  $T_1$  with an epoch  $e_1$ , and  $T_2$  with an epoch  $e_2$ , if  $e_1 < e_2$ , then  $T_1$  precedes  $T_2$ .

We present a proof sketch of this property in appendix A.2. The epoch ordering property ensures that epoch boundaries are consistent points in the serial order and appropriate for serializable snapshot reads, i.e., a transaction can get a consistent snapshot as of the beginning of the current epoch  $e_c$  by ensuring it observes the effects of all committed transactions that have a lower epoch. Suppose all the transactions with an epoch  $e < e_c$  have committed. Reading a user key  $k$  as of the start of epoch  $e_c$  translates to reading the value of key  $\langle k, \text{VID} \rangle$  such that VID is the largest value  $< \langle e_c, 0 \rangle$  in the database. Hence, the snapshot read algorithm would simply work by reading the epoch  $e_c$ , then reading the appropriate key versions.

The main challenge is ensuring that the snapshot is complete, i.e., no more transactions will be committing with an epoch below  $e_c$ . Any transaction that has not started to prepare is guaranteed to have an epoch of at least  $e_c$ , by the monotonic epoch invariant.

The problem is prepared (or preparing) transactions that are not yet known to have committed. Fortunately, any such transaction that could possibly commit writes must *already* be holding write locks at the current range leader. More formally, the transaction must be holding write locks on any replica whose leader lease's epoch interval upper end is above  $e_c$ . To see why this holds, suppose a transaction  $T$  with an epoch  $e_T < e_c$  has completed the Prepare phase but not the Commit phase. Recall from §5.4 that the client acting as  $T$ 's coordinator receives the epoch range of the lease from the range leader it used to perform the Prepare, and checks whether  $e_T$  falls within that epoch range. If it did not, then the client aborts the transaction so it cannot possibly commit. Otherwise, recall that transactions do not release any locks until the commit phase, including across leader changes. Therefore, it must be that the locks are held on the leader whose lease's epoch range contains  $e_c$  (and by the leader disjointness invariant, there can be at most one such replica), and any subsequent leader replica. A similar argument shows why the same holds for transactions that started but have not finished the Prepare phase. Hence, the read algorithm first reads the current epoch  $e_c$  (once per transaction), ensures it is below the upper end of the leader's epoch interval, and *waits* for the current holders of write locks (if any) on its read set to release these locks before executing the reads. The read is not attempting to *acquire* locks, so it does not contend with read-write transactions.

The algorithm as described so far does not guarantee linearizability, because a transaction  $T$  would not observe the effects of transactions in epoch  $e_c$  that committed before  $T$  started. If desired, ensuring linearizability is easy at the cost of some latency; after  $T$  starts, it waits for the epoch to advance once and then use the new epoch.

## 6.3 Garbage Collection

Chardonnay must periodically remove old record versions to avoid running out of space. Chardonnay uses the lower end of its range leader lease's epoch interval to determine which versions are no longer needed and can be garbage collected. There is a background job running on each range replica that removes versioned records (other than the newest version of a record) whose epoch is less than a delta from the lower end of the epoch interval. A snapshot read must validate that its epoch value lies within that delta from the lower end of the interval after executing its reads, to avoid reading an incomplete snapshot due to versions being deleted. In our experiments we configure the delta to be 6000, so that versions are kept at least for roughly one minute before they are GC'd. Additionally, since snapshot reads only happen at epoch boundaries, when a new version of a record is inserted, if it has the same epoch as the previous version then that previous version is immediately deleted. This optimization significantly reduces the number of versions maintained for records that are updated very frequently (i.e. highly-contended records).

## 7 Prefetching

Our experiments in §4 show that with fast 2PC, reading from slow storage becomes a primary cause of a transaction's contention footprint. Hot contended records will typically be cached in the database's memory. However, this does not fully address the issue because a transaction might access hot records along with other cold records that are not good candidates for caching. There are several well-known techniques to work around this problem [20]. For example, the programmer could manually prefetch records before executing the transaction. Another technique is to ensure hot records are the last to be accessed. This is beneficial because it minimizes the execution time during which access to the hot record causes a conflict. Unfortunately, these are not always applicable, and they push a lot of complexity to programmers.

We could require the programmers to label their queries with the read set. Then the system can prefetch the records (i.e., key-value pairs) identified by those keys to memory before executing the transaction and pin them until the transaction finishes, so that no time is spent reading from slow storage while locks are held. However, this scheme restricts the programming model, and is incapable of supporting *dependent queries*, that is, ones whose read set cannot be determined prior to executing the query [76]. This contradicts Chardonnay's goal of a general programming model (e.g., supporting SQL).

Instead, Chardonnay *transparently* uses the client's code to first execute the query in a lock-free, *dry run*

mode to load the read set to memory, then executes normally with 2PL.

It is of course possible for the read set to change by the time the actual transaction executes. One reason is that only the *values* of one or more records change due to a write by another transaction. Chardonnay handle this correctly and with no performance penalty, by reflecting the changes in its prefetching buffer (§7.3). The other possibility, in the case of dependent queries, is that the set of *keys* itself changes, so the transaction has to read some keys that had not been prefetched and pinned. This does not pose a correctness problem but may cause a transaction to read additional data from disk while it is holding the locks, and thereby increasing its contention footprint. Fortunately, prior work has shown this seldom happens in real-world workloads [76]; dependent queries are commonly ones that must read from a secondary index to identify their full read and write sets. Since secondary indices are fairly expensive to modify, they are seldom kept on fields whose values are updated very frequently. One example of such transactions is the "Payment" transaction of the TPC-C benchmark. Since the TPC-C benchmark workload never modifies the index on which Payment transactions' read and write sets may depend [76], the set of keys read by a Payment transaction never changes between the dry run and the execution.

One additional benefit of strongly consistent dry run queries is that if the application logic aborts the transaction on its own, there is no need to perform the actual execution. On the other hand, using dry run queries has two main disadvantages. First, it adds to the query latency, although this additional latency does not contribute to the contention footprint. Second, it requires executing the transaction logic twice before committing. While OLTP read-write transactions tend to be small, this could still be wasteful if the transaction is compute-intensive, particularly in low contention cases. The user can disable dry run queries by using a different API. In the future, we plan to explore automatically deciding when to do prefetching based on the characteristics of the workload.

### 7.1 API

The API shown in Figure 3 is more suited to user-interactive transactions (e.g., a user executing a multi-statement SQL transaction at a console, examining intermediate results before writing more queries). To use prefetching, a slightly different API is used to start the transaction where the caller passes a function that executes the transaction logic, i.e.,

```
<typename T>
T run(std::function< T( Transaction* ) > query)
```

Within the function, the code can freely call the read, scan, or write APIs using the transaction object that gets

passed. There are essentially no restrictions on the code inside the function, even though in practice it would have no side effects beyond the transaction's writes to the database itself. This does not add any unusual restrictions; any transaction might have to abort, and side effects outside of the transaction cannot be rolled back.

## 7.2 Semantics

The dry run query runs under snapshot isolation using our snapshot read mechanism that we described in §6, and can be configured to be strictly serializable if desired. Running under a lower isolation level such as *read committed* [19] could be problematic because it exposes the programmer's code to anomalies that would not happen in the serializable execution. This might cause the client's code to abort the transaction, prematurely ending prefetching, or worse, crash. Therefore, we do not use a lower isolation level because prefetching should be transparent to the user.

## 7.3 Design

Each range leader maintains a *prefetching buffer* to store a transaction's read set's records in main memory. The prefetching buffer tracks which records are in main memory and allows transactions to request pinning keys. Any committed write to a pinned record updates the value in the buffer, so that it becomes a write-through consistent cache for pinned records, and any transaction that needs to read a pinned key can just get its value from the cache and not have to go to the database.

To efficiently support range-queries, the prefetching buffer tracks key ranges not just individual keys; if a key range is pinned to the buffer, and a new transaction inserts (or deletes) a record whose key falls within that range, that new record is pinned too. Hence, a transaction that sees a range is pinned to the buffer can satisfy a range read from the cache without going to the database.

When a transaction is running in dry run mode, it reads the committed, snapshot value from the database without acquiring any locks, requests pinning the key (or key range), and then returns the committed value to the client to continue executing the query. In most cases both the snapshot and latest versions can be read using a single IO, so this does not typically increase the IO overhead. Writes made by the dry run query never make it to the KV Service, and are discarded at the client after the dry run. After the dry run completes, the client library reruns the transaction in normal mode. When that transaction finishes (i.e. commits or aborts), the keys are unpinned and become eligible for eviction.

It is possible that a request to pin a record cannot be satisfied because the range leader has run out of mem-

ory. In this case the dry run query could be delayed until memory frees up, or just be aborted. This serves as effective admission control prior to acquiring any locks. Some care is needed to avoid a potential live-lock situation, but in the worst case transactions can skip prefetching.

## 7.4 Handling Resource Contention

Dry run queries execute most of the transaction logic in Chardonnay, so that when the actual transaction executes it only needs to perform minimal work. However, if we are not careful, the activity from dry run queries and other background tasks such as garbage collection and compaction can compete with transactions for resources on the machines running the KV-service ranges. As a side effect, this could slow down the lock-acquiring transaction and increase data contention. Therefore, we dedicate resources on each machine to transactions to ensure they are insulated from lower-priority activity that does not hold locks.

## 8 Deadlock Avoidance

Since Chardonnay uses 2PL, it has to deal with the problem of deadlocks. An easy solution is transaction timeouts, since they are needed anyway to deal with various possible failures. Unfortunately, a deadlocked transaction would be holding locks for the entire timeout duration before these locks are released. Another popular choice is a deadlock prevention scheme such as Wait-Die or Wound-Wait [64], but they can be too conservative (i.e., aborting transactions that are not deadlocked) which can become problematic under high contention. A more common choice in practice is deadlock detection [63] via detecting cycles in the wait-for graph [38, 72] and breaking the cycle by choosing a transaction to abort. This requires significant overhead for maintaining the global wait-for graph state, and potentially frequent aborts.

By making all transactions acquire their locks in the same order, we can prevent deadlocks. In Chardonnay, the read and write sets of the transaction are (approximately) computed by dry run queries, prior to acquiring any locks. We acquire the locks in ascending key order prior to actually executing the transaction. A naive implementation of this idea would require adding  $|\text{read\_set} \cup \text{write\_set}|$  round-trips to the contention footprint to acquire the locks. Instead, the client uses an approach similar to RPC Chains [71], which cuts the round-trips required roughly in half compared to the naive approach. The client in Chardonnay sends one RPC to the first range from which it needs keys. The range acquires all the local locks, performs all the necessary local reads, and then forwards the request to the next range. The client immediately sends an RPC to the last range in the

(a) 10% Distributed Transactions.

(b) 100% Distributed Transactions.

Figure 4: Contention Microbenchmark Throughput Results

request, which holds the RPC until the request arrives. After finishing its local work, the last range replies to the client’s RPC with all the read results. When this is done, the client runs the transaction logic. If the transaction invokes a read for a key or key range (that the client already has), the client returns it immediately since it has the lock on the data (and will detect and abort the transaction if that lock is lost before commit). If transaction’s read or write set changes between the dry run and actual transaction, the client cannot serve the reads from its local cache and has to send the read requests to the ranges. We fall back to Wound-Wait for these locks.

If most transactions are likely to perform multiple read operations involving multiple network round-trips and reads from slow storage, then a developer might be tempted to parallelize those accesses, if possible, to reduce the contention footprint. Whether this is done with parallel threads or asynchronous APIs, it adds complexity to the programming model. Our scheme gets the same benefit without this complexity. On the other hand, the scheme can actually increase a transaction’s contention footprint, because lock acquisition has to be serialized. There is no overhead for the common case of transactions accessing a single range. We allow the programmer to disable ordered lock acquisition per transaction. In the future, we plan to adaptively apply the technique.

## 9 Evaluation

In this section we study how Chardonnay performs under contention (§9.1), its scalability (9.2), and its snapshot read performance (§9.3). To evaluate contention, we use a benchmark used by Calvin [76], which is inspired by TPC-C’s New-Order transaction. For scalability experiments, we use the standard TPC-C benchmark, and for read latency we use YCSB [28]. In all experiments the KV service range leaders use Standard.L8s.v2 Azure

VMs, which provide 8 vCPU cores and 64GB of memory and support accelerated networking necessary for eRPC. We place the database on directly-attached SSD for high IOPS. For the WAL, we emulate NVMe on DRAM via RAMdisk, since it is not currently offered on Azure. We advance the epoch every 10ms. All results are 10 minute averages unless otherwise stated.

### 9.1 Contention Microbenchmark

We use a benchmark introduced in Calvin [76] to evaluate Chardonnay’s performance under high contention. Each transaction in the benchmark reads 10 records, performs a constraint check on the result, and if the check passes, updates a counter in each record. The records in each KV-service range are divided into two disjoint sets: cold and hot. Each transaction can either be local or distributed. A local transaction accesses 9 records chosen at random from the cold set in the target range, and 1 record chosen at random from the hot set. A distributed transaction is similar, except it accesses 8 cold records and an additional hot record in a different range. The number of cold records in each range is much larger than available memory so cold records will be mostly served from disk. The number of hot records is determined by a parameter called the *contention index*, which is set to be the inverse of the number of hot records and represents the probability that two transactions accessing the same range will conflict. Hence, a contention index of 0.01 means that there are 100 hot records per range, while a contention index of 1 means that there is 1 hot record (which is accessed by *all* transactions touching that range). The contention index controls the degree of parallelism within each range (e.g., a contention index of 1 means that all transactions within a range are serialized).

We wrote each transaction using simple, synchronous APIs. This means that all reads are executed sequentially.

This is not a requirement, but it highlights the additional benefits of Chardonnay’s dry run and deadlock avoidance schemes, which move sequential operations outside of the contention footprint. The ordering of the reads done by each transaction is random, so there is variance in the time hot records spend under lock.

**Setup.** We use 6 ranges, and each range leader is assigned its own VM. We evaluate the following configurations of Chardonnay:

- **Baseline.** All transactions run without dry-run queries, so they do not perform prefetching or ordered lock acquisition. This is essentially a classic shared-nothing system architecture with a fast 2PC implementation, and Wound-Wait for deadlocks.
- **Prefetching-only.** Transactions run with dry-run queries, but only do prefetching and not ordered lock acquisition.
- **Chardonnay.** All transactions perform prefetching and ordered lock acquisition.

Initially, we planned to compare against CockroachDB [74] as a representative for a modern shared-nothing system. However, we realized that retrofitting the system with eRPC would be a very significant engineering effort. Running the (full SQL) system unchanged on the same experimental setup yielded low throughput (TPS per node is 90% less than Chardonnay). Hence, we use our baseline configuration for apples-to-apples comparison, as it is a good representative of the shared-nothing architecture.

We plot the throughput and abort rates under different values of contention index in Figures 4 and 5.

**Analysis.** As expected, under low contention, the dry run queries in Chardonnay are mostly wasteful and consequently the baseline configuration has slightly better throughput. Notably, full Chardonnay performs better than prefetching-only even under low contention. This is because ordered lock acquisition issues Lock & Read requests in a batched, efficient manner, as opposed to sequentially issuing an RPC per read during the transaction execution in the prefetching-only configuration. This further supports our intuition that Chardonnay’s ordered lock acquisition scheme enables writing the transactions in a simple, synchronous manner without a significant performance penalty. As contention increases, the overall throughput becomes constrained by the contention footprint, and in particular, the length of time locks on hot records also increases. The baseline configuration has the sharpest drop in throughput, since it has to issue multiple RPCs and reads from slow storage while holding locks. The full Chardonnay configuration performs best under high contention and has *zero* aborts. Prefetching-only fares much better than baseline,

even though it suffers a significant drop in throughput due to increased deadlock avoidance abort rates under contention, as well as increased contention footprint due to RPCs.

In the 10% distributed transactions case, transactions essentially never deadlock since they can only conflict on one record in the vast majority of cases. Yet, the Wound-Wait deadlock avoidance scheme is too conservative and results in many unnecessary aborts as contention increases; see Figure 5. Note that because the base configuration’s transactions have a much larger contention footprint, even a relatively modest 0.001 contention index is affected by these superfluous aborts. A less conservative scheme such as deadlock detection would not suffer from this, at the cost of taking much longer to resolve the deadlock when an actual one appears. In Chardonnay, we largely avoid deadlock aborts and only use Wound-Wait as a fall-back mechanism, as discussed in §8.

One interesting property of Chardonnay is that distributed transactions are not dramatically more expensive than local transactions. The peak throughput under low contention with 100% distributed transactions is roughly 22% lower than with only 10% distributed transactions. This makes the importance of reducing cross-partition transactions less significant, thus relieving database administrators and developers from the requirement to continually re-partition the application data to minimize cross-partition transactions [30, 35, 36, 60, 73]. The big difference in throughput between 10% and 100% ratio of distributed transactions under higher contention index values is largely because each transaction in the 100% distributed case accesses two items from the hot set, not because the transaction is distributed. This is in part because 2PC is highly optimized in Chardonnay, but also because non-distributed transactions have to go through a phase of reading the epoch before committing. Our results for the 10% distributed case show that the benefits of Chardonnay are not limited to distributed transactions.

## 9.2 Scalability

The scalability of the System R\*-style shared-nothing architecture is well established [80], but Chardonnay introduces the *read-epoch* operation during each transaction’s 2PC. Therefore, we need to ensure that the epoch service can keep up with an increasing scale.

**TPC-C New-Order.** Similar to prior work [76], we limited our TPC-C implementation to the New Order transaction, which is the bulk of the TPC-C workload including almost all distributed transactions that require high isolation. We would expect similar results if we were to run the full TPC-C benchmark. We assign each KV service range leader to a dedicated VM and have it

Figure 5: Abort rates for 10% distributed tx micro-benchmark. Chardonnay’s deadlock aborts are 0%.

host 10 warehouses. We limit the overall throughput to 2500 TPS per node, since we aim to evaluate the scalability of the system rather than the raw per-node peak throughput. The clients run on dedicated VMs, separate from Chardonnay nodes. (Recall that in Chardonnay, the execution of the transaction logic happens on the client.) We plot the results in Figure 6, which show stable 2PC latency as the system scales linearly.

**Comparison with Calvin.** Chardonnay is able to reach similar New-Order throughput scale as reported by Calvin [76], *without Calvin’s significant programming model restrictions* (described in §10). Calvin’s reported single-datacenter latency is much higher than Chardonnay (~100ms), but the comparison is not meaningful since it does not use fast RPC and storage. However, with 10ms epoch duration as in our setup, we expect Calvin adds 5ms to the median latency since it groups transactions into batches at the start of each epoch. Therefore, even with fast RPC and storage, we expect Calvin’s median latency to be higher than Chardonnay’s P99 latency.

**Epoch microbenchmark.** To test the limits of the Epoch service, we wrote a micro-benchmark where each thread simulates a Chardonnay client node running 2PC. We run 30 client nodes with 8 threads each, where each thread is issuing 5000 read-epoch calls per second for a total of 1,200,000 calls per second. The median latency is below 60  $\mu$ s, which is less than the median for the full Prepare phase. Since *read-epoch* runs in parallel to Prepare, this does not increase the overall 2PC latency.

### 9.3 Snapshot Read Latency

We use YCSB with 50% write and 50% read to evaluate snapshot read latency, using a setup similar to §4. Read operations run with snapshot isolation for this pur-

Figure 6: TPC-C New-Order transaction results.

pose. The dataset fits in DRAM since our focus is measuring protocol overhead, not IO latency. When running with a uniform distribution of keys, the median latency of reads is roughly 220  $\mu$ s. On the other hand, when running with Zipfian 0.99 distribution it increases to nearly 355  $\mu$ s. This is because most reads in the Zipfian case are going to write-hot records and hence almost always have to wait for locks to be released before they can execute. We also run the read operations with strict serializability. The median latency of the read operations increases by ~5ms since they need to wait for the epoch to advance.

### 9.4 Range Reads

We devise a simple experiment to demonstrate Chardonnay’s effectiveness for range reads. The experiment involves a single range that contains 100 records. There are two client threads, one is a writer thread that is continuously deleting and then re-inserting a random record in the range, and the other is a reader that is executing a range query to read all records. Even though the reader thread is not doing any writes, its range read query is not declared as read-only so that it runs as a read-write transaction, not as a snapshot read. We compare the number of insert operations per second in Chardonnay and the baseline from §9.1. The results are in Table 2. Without prefetching, the baseline has to execute the range read against the database each time while holding the lock on the entire range, resulting in a longer contention period and thus slowing down the writer.

## 10 Related Work

**Shared-nothing.** Spanner [29], and CockroachDB [74] are prominent modern examples of systems that utilize shared-nothing architecture, both primarily targeting inter-datacenter operations with globally-distributed workloads. Spanner uses specialized hardware to

	Chardonnay	Baseline
Insert TPS	914	197

Table 2: Range Read Results.

achieve clock synchronization guarantees that are necessary for its external consistency support. Many design choices in the system make it hard to support fast transactions within the datacenter. For instance, Spanner guarantees correctness of readers by introducing a delay for writers during the commit protocol until the clock uncertainty interval has passed, which can add many milliseconds to a transaction’s contention footprint. In contrast, Chardonnay guarantees correctness by having readers potentially wait for write locks so that the contention footprint for writers does not have to increase. CockroachDB is a system with similar emphasis on global distribution. It does not guarantee external consistency to avoid requiring specialized clocks, and instead provides the weaker single-key linearizability (which still relies on bounded clock skew). Its concurrency control protocol has optimistic components optimized for low contention.

**Shared Disk.** Shared-disk [13] is another classic DBMS architecture [25, 44] that has become popular in recent years in systems such as Amazon Aurora [78, 79], Socrates [13], and Google’s AlloyDB [2]. These systems are single-master, in which only one node actively writes the database, limiting scalability. Aurora also has a multi-master mode which does not offer serializability, and works well for partitionable workloads with little cross-partition activity. In contrast, Chardonnay can horizontally scale both reads and writes with strict serializability and supports fast cross-partition transactions.

**Shared Log.** Hyder [21] and Tango [18] scale-out compute without partitioning by utilizing a shared log that is accessed by all compute nodes. Appending to and replaying the log can be a bottleneck limiting scalability.

**Deterministic Systems.** Deterministic execution has been explored as an alternative to distributed commit in systems such as Calvin [76] and Aria [56]. A major benefit of using determinism is eliminating transaction aborts due to deadlocks [63], which Chardonnay largely achieves using its lock ordering scheme. Deterministic execution databases typically have to restrict the programming model to one-shot transactions. They also group incoming transactions into batches before executing them, which can add tens of milliseconds to latency.

Another significant limitation of most deterministic database systems is they require knowing a transaction’s read and write set upfront [75, 76]. To support dependent queries, a programmer can precede a transaction with a lower isolation *reconnaissance* query to compute

its read/write sets (e.g., OLLP [75, 76]). However, compared to dry run queries in Chardonnay, reconnaissance queries require changes to the client transaction code and run at low isolation level, exposing the code to anomalies that do not appear in the real execution. Furthermore, if the read or write set of the transaction changes between running the reconnaissance query and actual transaction, the transaction must abort. Fauna [3], a DBMS based on Calvin’s design, eliminates the need for manual reconnaissance queries at the cost of adding a round of Raft consensus to the transaction’s contention footprint, and using OCC, degrading performance under contention. Snapper [53] is a transaction library for single-node systems based on the Actor model, which enables deterministic execution for transactions that can be labeled with their read and write sets, while simultaneously supporting non-deterministic execution for transactions where this is not possible.

The Calvin paper proposes using the read set to prefetch data prior to sequencing the transaction. Prefetching in Calvin requires precisely estimating I/O latency [76]. It also happens after the reconnaissance query, adding to query latency. Notably, Calvin’s designers do not discuss range reads. Presumably even if a transaction’s entire readset is in memory, it still needs to run the range query against the database to ensure no other transaction has inserted or deleted records within that range.

**Distributed epoch-based commit.** Coco [57] is an in-memory system that applies epoch-based group commit in a distributed setting. It uses a centralized coordinator to *synchronously* commit transactions in epoch order. This requires adding many milliseconds of latency to read-write transactions. In contrast, Chardonnay is an on-disk system that guarantees the equivalence to epoch ordering, but transactions commit out of epoch order for low latency.

## 11 Conclusions

This paper presents Chardonnay, a scale-out, general-purpose, multi-versioned, on-disk transactional key-value store optimized for single datacenter deployments with fast 2PC. Chardonnay takes advantage of fast RPCs to support strictly serializable snapshot reads without relying on specialized clocks or assumptions about maximum clock skew. Chardonnay achieves high performance for high contention workloads by automatically and transparently loading and pinning data from slow storage to main memory prior to acquiring any locks, and avoids deadlocks by ordering its lock requests. We believe that the design principles of Chardonnay can also be applied in other settings, such as multi-core single-node systems for high contention workloads.

## A Appendix

### A.1 Optimizing 2PC

**Pipelined WAL.** Since RPCs and log writes are cheap in our system and low latency is paramount, we do not batch multiple operations into a single WAL entry. Instead, each operation (e.g., a transaction’s Prepare) has its own WAL entry (hence runs its own instance of the Paxos state-machine). Furthermore, appends to the WAL are pipelined [67] (i.e., we do not wait for the previous entries to be completely written and applied before starting a new one). Log entries are still applied to the database in log order for correctness, however. Note that a Prepare must go through the range leader, which drives appending it to the log. The long-lived leader design allows the leader to complete a log append using one RPC in the common case. Hence the latency of a Prepare operation is roughly the sum of the latencies of two RPCs and one NVMe write.

**Client-driven Commit.** As mentioned earlier, we use Paxos to replicate the state of each transaction in the transaction state store. However, to minimize the number of required round-trips, we do not designate any of the replicas as a leader. Leaders in Paxos are an optimization used in part to avoid the dueling proposers problem. Since we carefully designed the state of each transaction to be an independent Multi-Paxos log, the client is the only proposer in the vast majority of cases. So requiring it to go through a leader to run the Paxos protocol to commit (or abort) the transaction adds the latency of a su-

perfluous RPC to the Commit operation (which happens under transaction locks). Furthermore, the client utilizes a variant of the well-known technique of chaining Paxos instances together [24]. As illustrated in Figure 7, when performing the RPC to run the second (Accept) phase of Paxos to append log entry 0 (i.e., recording transaction start), the client simultaneously runs the first (Propose) phase of Paxos entry number 1 (i.e., reserving the right to propose the value of proposal number 0). Thus, it incurs the latency of only one RPC to append the decision.

### A.2 Proof Sketch of Epoch Ordering

We show that if  $e_1 < e_2$ , then  $T_1$  cannot have a dependency or anti-dependency on  $T_2$ . Given that, we can show that the transaction dependency DAG has no edges that go from a transaction with a higher to a lower epoch.

We proceed by contradiction by assuming this is false. This implies that there is (transitively) a read-write or write-write conflict between  $T_1$  and  $T_2$ , and  $T_2$  was ordered first. Therefore,  $T_2$  released a lock and sometime later  $T_1$  acquired a lock. However, since  $e_1 < e_2$ , the monotonic epoch invariant implies  $T_1$  finished execution (and acquired all its locks) before  $T_2$  did so, a contradiction as transactions do not release any locks until commit. Hence,  $T_1$  precedes  $T_2$  in the equivalent order.  $\square$

### A.3 Scaling the Epoch Service

Here we discuss briefly how to scale-out the epoch service while maintaining the correctness of our snapshot reads. The basic idea is introduce intermediary *epoch publishers* between the epoch service and its clients. Each publisher maintains a single counter (the epoch) and is Paxos replicated for high availability, much like the epoch service itself. However, the publishers do not advance the counter themselves. Instead, when the epoch is advanced by the epoch service, it issues RPCs to each publisher to advance their epoch value. The epoch service does not advance the epoch again before it updates *all* the publishers (each of which is highly available). Each client is assigned to one of the publishers, and uses the same procedure to read the epoch from that publisher exactly as it would from the epoch service itself.

This design requires slightly weakening the monotonic epoch invariant, since it is possible for a client to read a value of the epoch that is one less than the true epoch. Furthermore, when a client is assigning an epoch to a transaction, it needs to ensure the epoch is at least as high as that of any record in its read and write sets, even if the version it reads from the publisher is lower. Linearizability of snapshot reads can be ensured at the cost of additional latency, by waiting for the epoch to advance twice instead of just once.

## Abstract

ScaleDB is a serializable in-memory transactional database that achieves excellent scalability on multi-core machines by asynchronously updating range indexes. We find that asynchronous range index updates can significantly improve database scalability by applying updates in batches, reducing contention on critical sections. To avoid stale reads, ScaleDB uses small hash *indexlets* to hold delayed updates. We use indexlets to design ACC, an asynchronous concurrency control protocol providing serializability. With ACC, it is possible to delay range index updates without adverse performance effects on transaction execution in the common case. ACC delivers scalable serializable isolation for transactions, with high throughput and low abort rate. Evaluation on a dual-socket server with 36 cores shows that ScaleDB achieves 9.5× better query throughput than Peloton on the YCSB benchmark and 1.8× better transaction throughput than Cicada on the TPC-C benchmark.

## 1 Introduction

In-memory databases [5, 10, 15, 21, 23, 42] are becoming increasingly popular: they perform well under a wide range of workloads and support requirements, such as real-time constraints, that are challenging for their disk-based counterparts [16]. They also, however, face scalability demands that sharding can only partially address: many real-world workloads have skewed access distributions [30, 47, 50, 68, 75], and the frequent hotspots they generate in individual shards require database solutions that can scale on multi-core servers.

Unfortunately, despite years of research, scaling in-memory databases on multi-core architectures remains challenging. Existing work [62, 73, 79] eliminates the bottleneck on a shared timestamp in the concurrency control protocol. Other work [37, 38, 60, 63, 77] has focused on improving the scalability of indexing structures in isolation from the database architecture. Nonetheless, current databases scale poorly on multi-core architectures (§3.1). In particular, shared range-index structures (e.g., B<sup>+</sup> trees) continue to be a main source of contention [77], and the high cost of updates to these indexes, even by unrelated transactions, is a major factor limiting scalability [62]. As fast storage via solid-state drives and persistent memory becomes the norm, contention on these structures is intensifying.

\*Currently at Google. Work done during PhD at UT Austin.

We believe that continuing to scale with these application and hardware trends requires a fresh approach. Our main observation, supported by recent work in file systems [34, 35], is that contention on shared data structures is often not fundamental, but simply an artifact of a particular system architecture. In particular, we find that contention caused by synchronous updates to sorted range-index structures is unnecessary in the common case. Our analysis (§3.2) shows that it is possible to delay many common range-index updates, without compromising on strong consistency guarantees or latency requirements for transactions. Delayed updates may be batched to reduce contention on shared range-index structures.

These observations lead us to propose a decoupled database design, centered around minimizing *unnecessary contention* among unrelated transactions. Our main technique is to decouple committing a transaction from updating the affected range indexes: we update range indexes *asynchronously*, while using scalable hash-based *indexlets* to track writes of recently committed transactions. Based on this asynchronous architecture, we design *asynchronous concurrency control* (ACC), a novel concurrency control protocol that provides serializability for concurrent transactions without compromising scalability, commit latency, or throughput. ACC is an optimistic concurrency control protocol that builds on indexlets to provide *phantomlets* for scalable phantom<sup>1</sup> detection [32]. ACC uses locks in indexlets, rather than in range indexes, to provide scalable atomic transaction commit.

We present ScaleDB, a scalable multi-core in-memory transactional database based on asynchronous concurrency control. By decoupling transaction execution from range index updates, ScaleDB can focus on improving the scalability of the former in isolation from the latter and without undesirable performance tradeoffs. By avoiding unnecessary contention on shared data structures in the common case, ScaleDB delivers scalable serializable isolation for ACID transactions, with high throughput, low commit latency, and low abort rate.

We make the following contributions:

- An analysis of the range index scalability bottleneck and of asynchronous range-index updates as a way to alleviate that bottleneck for unrelated transactions (§3).

<sup>1</sup>*Phantom* anomalies arise when insertions or deletions by other concurrently committing transactions cause two identical range scans in the same transaction to return a different set of rows.

- The design (§4) and implementation (§5) of ScaleDB, a scalable in-memory database that decouples range index management from transaction execution to allow asynchronous update of range indexes in the common case.
- Asynchronous concurrency control (ACC), a novel concurrency control protocol that provides serializability in an asynchronous database (§4.2). ACC uses *phantomlets* to scalably detect phantoms in range scans and provides scalable locks in indexlets to atomically commit transactions.
- A performance evaluation of ScaleDB on a dual-socket server with 36 cores, which shows that ScaleDB scales better than Cicada and Peloton. At scale, ScaleDB achieves 9.5× better query throughput than Peloton on the YCSB benchmark and 1.8× better transaction throughput than Cicada with shared indexes on the TPC-C benchmark.

## 2 Background

Modern relational databases face challenging scalability demands. In addition to serving as backends for large-scale web applications [11, 17, 25, 31], they are offered as a service in public clouds [1, 4, 74], and must support applications that can be simultaneously write and read intensive; require both low transaction commit latency and high transactional throughput; and, increasingly, run analytical queries (on data from sources such as sensors, real-time analytics, and machine learning [19, 27]) that require maintaining a large number of indexes on every write.

In-memory databases are particularly suited to handle these diverse workload requirements, and their adoption is further facilitated by high-capacity non-volatile and disaggregated memories, as they allow for more data to be held in memory, with access latencies comparable to DRAM [53, 72]. Just as new memory technologies are shifting performance bottlenecks away from storage and towards multi-core CPU contention, such diverse workload requirements raise the bar for in-memory database scalability.

### 2.1 Prior Work

Existing efforts to improve the scalability of in-memory databases have focused on three bottlenecks: (i) range index structures; and serializable transaction isolation for both (ii) low-contention workloads and (iii) high-contention workloads (*i.e.*, transactions with dependencies). The work on range index structures has happened in isolation from the rest. This observation is key to the case for ScaleDB (§3).

**Range index structures.** Range indexes are an efficient method for data retrieval. In addition to providing exact-match lookup of database records in logarithmic time, they also allow fast scans of records in sorted order. Despite decades of work [37, 38, 48, 59–61, 63, 65], scalability of range indexes under concurrent accesses remains elusive. This is primarily due to the hierarchical nature of these data structures. For instance, in a B<sup>+</sup>tree index, inserting or deleting a new record can require modifying a chain of internal nodes all the way up

to the root. Performing such modifications atomically while supporting concurrent access from multiple threads requires synchronization [45, 77].

One approach to synchronization uses locks [48, 59, 65]. Recent optimizations [37, 38, 63] remove shared cache line contention between readers trying to acquire a lock per node, by making them optimistic. However, readers must read a version number per node to verify their optimistic assumption, which can cause contention with writers trying to increment it. Similarly, writers still contend on cache lines, trying to acquire spinlocks on individual tree nodes. Frequently accessed nodes such as the root of a B<sup>+</sup>tree or the index node at the end of the range (for append workloads) become hotspots of contention.

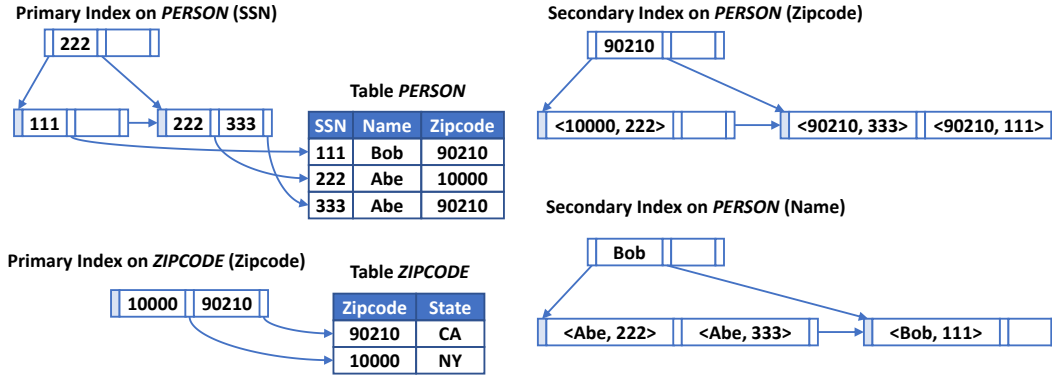

An alternative are lock-free data structures [46, 49, 61]: they use atomic operations and multi-versioning to avoid lock contention on critical sections. Yet, as recent work [45] points out, their theoretical guarantees are “mostly irrelevant to performance and scalability on multi-core hardware”, as they cannot avoid contention on global memory locations.

A recent study [77] evaluated state-of-the-art range indexes [46, 48, 60, 61, 63] on the YCSB [40] benchmark and showed that none of these indexes scale well. Even on a read-heavy workload with only 5% inserts, these indexes only scale up to 12× when increasing cores by 20×. On an insert-only workload with threads appending new inserts to the end of a range, their scalability collapses when going from a single NUMA node (20 cores) to two NUMA nodes (40 cores), with throughput dropping between 50% to 66%. The limited scalability of range indexes has been reported in previous work [62] and we expand on this analysis in §3.1.

**Serializability for low-contention workloads.** The use of a shared timestamp for ordering transactions [33, 57] made timestamp allocation a principal bottleneck to the scalability of concurrency control [78]. Even when updated using atomic hardware primitives, a shared timestamp can force *unrelated transactions* to contend and results in excessive cache coherence communication. Recent work eliminates the timestamp bottleneck, but incurs high transaction commit latency due to either a high abort rate [62, 79] or batching in group commits [73].

An approach proposed by the H-store project [54, 70] avoids coordination by partitioning the database and accessing each partition from a single thread. This approach scales well for applications whose databases can be cleanly partitioned and where most transactions only access a single partition. However, many applications do not fit this profile and can experience worse performance [69].

**Serializability with dependencies.** Much work has focused on scaling serializable ordering on *contended* transactional workloads [42, 44, 51, 55, 56, 58, 62, 66, 67, 76]. Serializability requires respecting data dependencies among transactions reading and writing the same database record.

**Figure 1.** Simple database layout with range indexes. Tables are represented by primary indexes. Records are stored sorted by primary index key. Schema information is stored in a catalog (not shown). Arrows are pointers.

**Figure 2.** Cicada scalability on TPC-C ( $C_{wh=thd}$ ) with partitioned and shared indexes.

Though such dependencies are ultimately a barrier to scalability, various techniques can reduce their impact, including multi-versioning [44, 58, 62], static analysis [66, 76], exploiting commutativity in some workloads [51] and backoff [62]. These techniques are complementary to our work, which is focused on *mechanism contention*, *i.e.*, on contention that arises between unrelated transactions as an artifact of how the database implements certain mechanisms (*e.g.*, range indexes), rather than from fundamental requirements of its isolation guarantees.

### 3 The Case for ScaleDB

ScaleDB’s main contribution lies in recognizing that removing the indexing bottleneck requires looking beyond range index structures; instead, it is necessary to understand and correct the architectural design decisions that make range indexes a hotspot of contention in today’s in-memory databases.

**Range index background.** To understand the significance and structure of range indexes, consider Figure 1, which shows a simple database with two tables. Tables are implemented as collections of indexes and include one primary index and zero or more secondary indexes. For example, table PERSON

has primary index SSN and two secondary indexes, Name and Zipcode. Table records are stored on the heap and pointed to by the table’s primary index.

Range indexes have many uses. A primary range index allows quick retrieval of a table’s records by primary key for both point and range queries. Primary keys within a table must often be unique and an index can enforce this *uniqueness constraint* efficiently. Secondary indexes are also used extensively. They support analytical queries [39] and help maintain the consistency of the database by serving as *foreign keys*, *i.e.*, columns of a table that refer to a primary key of another table. For example, a foreign key constraint on the Zipcode column in the PERSON table implies that deleting the 90210 zipcode from the ZIPCODE table requires deleting all records with the 90210 zipcode from the PERSON table. The secondary index on the Zipcode column makes this operation efficient—in the Figure, the root node of the corresponding secondary tree points directly to the range of all SSNs in the 90210 zipcode; we can use these values as keys to traverse the primary index of the PERSON table.

Range indexes can limit scalability because concurrent updates to the same index, even if caused by unrelated transactions, can lead to contention. For instance, inserting or deleting a single record in a B+-tree (Figure 1) may alter its leaf node structure (a leaf node may split, or may coalesce with another leaf node), requiring the atomic update of potentially many internal nodes, all the way to the root.

### 3.1 Database Scalability Analysis

To explore the limits of database scalability, we evaluate Cicada [62], a state-of-the-art scalable in-memory database. Cicada was shown to be more scalable than several other databases [42, 55, 56, 73, 79]. However, as we show next, it still incurs range index mechanism contention.

We run TPC-C [22], a standard OLTP benchmark simulating purchase transactions on a configurable number of independent warehouses. We use a machine with two CPU sockets, each with an 18-core Intel Xeon Gold 6154 CPU. We increase the number of transaction processing server threads from 1 to 36 and use as many warehouses as threads for each data point. This configuration ( $C_{wh=thd}$ ) has very low contention, since threads (almost always) run queries on their own warehouses, thus avoiding contention on the same records with other threads. Therefore,  $C_{wh=thd}$  allows us to isolate and understand the scalability impact of mechanism contention on range indexes.

Figure 2a shows Cicada’s goodput scalability relative to a single core. Cicada stops scaling beyond 24 cores on the canonical TPC-C workload, with indexes shared between between threads. To show that scalability is limited by range index mechanism contention, we also evaluate a configuration where 8 out of the 9 TPC-C tables, and their associated indexes, are partitioned by warehouse  $id^2$ . This configuration scales well for  $C_{wh=thd}$ , but it does not generalize to more skewed workloads.

Figure 2b shows that Cicada’s poor scalability on the shared index configuration is due to an increasingly high abort rate. To reduce multi-core contention on the same index nodes by multiple threads, Cicada uses multi-version concurrency control (MVCC) for both its records and indexes; if an index node needs to be modified, Cicada creates a new version in thread local memory and installs it into the index on successful transaction commit. However, to enforce serializability, transactions that perform a range scan must, at commit time, validate that no new record matching the range predicate was inserted since the scan (*i.e.*, must avoid *phantoms*). For this purpose, at transaction commit, Cicada validates all index nodes whose key range intersected with the range scan predicate; if this validation fails, the transaction aborts. Thus, range index contention manifests in Cicada as a higher rate of transaction aborts instead of contention on index nodes.

<sup>2</sup>The default configuration of the Cicada prototype

### 3.2 When Can Range Indexes Scale?

The previous analysis demonstrates that scalability in state-of-the-art databases is primarily limited by contention on range indexes. A key contributor to this contention is that the updates to range indexes, that take place once a transaction commits, are performed *synchronously*. Of course, all indexes, whether range or hash, must, on a query, return the most recently committed record corresponding to an index key, but range indexes have an additional obligation: they must ensure that range scans issued immediately after a transaction commits will not miss any record inserted or updated by that transaction. It is to discharge this obligation that records are inserted synchronously into all primary and secondary indexes – which not only requires sorting these records with respect to *all* records already in the table, but also creates contention on the internal nodes of a range index among otherwise non-conflicting transactions.

Our design is then motivated by a simple question: *can this obligation be met without triggering a synchronous cascade of updates over shared data structures?* To move towards an answer, we run an experiment to measure the latency between the last time a record is written (inserted or updated) and when it is read as part of a range scan (*W-to-RS latency*).

We use three transactional application benchmarks (Table 1) from the OLTP-bench [43] suite, designed to evaluate modern cloud database workloads. These benchmarks range from moderately write-heavy (Epinions) to very write-heavy (TPC-C), and the percentage of read queries involving a range scan varies from a single digit to 100%. We ran these benchmarks on a MySQL 8.0 instance running on a 20 core (40 hardware threads) Intel Xeon machine, with as many clients as needed to saturate throughput. We emulate an in-memory database by setting the MySQL in-memory buffer pool to a large-enough size, so that in all three cases the entire database fits in memory and we are never disk-bound.

Figure 3a shows the cumulative distribution of the W-to-RS latency. For Epinions and Seats, we use a single curve each to characterize the behavior of all their range scans: we find that the 5th percentile W-to-RS latency is above 500ms and the median is between 8 and 85 seconds. We instead report the latency of each range scan in TPC-C separately, since they behave quite differently: *DelivSumOrderAmt*, a range scan on a primary index, responsible for 3% of all TPC-C read queries, has a median W-to-RS latency of 1ms; the other two TPC-C range scans are on secondary indexes and their median W-to-RS latencies are orders of magnitude higher. Epinions and SEATS also show lower W-to-RS latency for range scans of primary indexes, though with a much smaller ( $2\times$  to  $5\times$ ) gap. The low W-to-RS latency of *DelivSumOrderAmt* is due to the TPC-C Delivery transaction, which contains an update followed by a read on the same range in the *Orderline* table. We discuss in §4.2.3 how ScaleDB’s design avoids unnecessary aborts in such situations and therefore performs well on TPC-C (§6).

Figure 3. Range scan property distributions of three application benchmarks.

Figure 3b shows the distribution of the number of records read by range scans in each benchmark. For all benchmarks and all range scans, the median number of records read was at most 6, while the 99th percentile was at most 26 records. Epinions had two range scans in read-only transactions that read thousands of records. However these range scans comprised only 0.068% of all read queries in Epinions and had a median W-to-RS latency of at least 66 seconds.

For brevity, we omit a similar analysis for point queries, but their behavior was mixed. For instance, in TPC-C, four point queries had median Write-to-Point-Query (*W-to-PQ*) latencies ranging from  $350\mu\text{s}$  to 21ms. These point queries – from the NewOrder and Payment read-write transactions, which together comprise 90% of the benchmark – read heavily updated records in the District and Warehouse tables. At the other extreme, two point queries in TPC-C had median W-to-PQ latencies of 4 and 15 seconds.

**Conclusion.** The overall picture that emerges from this analysis is the following:

1. While point queries often read recently written records, for range queries that is the exception rather than the rule. This holds especially true for secondary indexes.
2. In the vast majority of cases, the number of records that a range query reads (especially as part of read-write transactions) is small.
3. Large range scans rarely happen and, when they do, they are usually within a read-only transaction.

These findings suggest an opportunity to fundamentally rethink how to maintain range indexes within in-memory databases. If, in the common case, synchronous updates to range indexes are not necessary to produce consistent range scans, it may be possible to design new scalable data structures that can synchronously store record updates and hold them temporarily, until they are *asynchronously* applied to the range indexes. Of course, range scans should be *always* consistent, not just in the common case, and the mechanisms

needed to enforce this guarantee should themselves be scalable. These are the opportunities and challenges that shape the design of ScaleDB.

#### Why are asynchronous range index updates scalable?

Asynchronously updating range indexes offers a host of opportunities that we seek to exploit. Accumulating a number of updates, so they can be applied as a batch to the range index, is more efficient than applying individual updates, as it avoids repeated walks of the index tree (e.g. inserts to the same B+ tree leaf node). Given the cache contention arising from concurrent walks of the range index, batched updates benefit CPU cache locality and improve performance isolation among CPU cores. They also incur less overhead for repeated lock operations, since they allow us to acquire locks only once for several updates. We can facilitate this process by sorting accumulated updates before applying them to the range index, outside of a critical section. Finally, for skewed access distributions that update the same record repeatedly within a short time span, only the last update in the batch needs to be applied to the range index, reducing the overall work required. We will see in §4.1 that asynchronous updates are scalable, while relieving the underlying range index structure of fine-grained locking, multi-versioning, and lock-free techniques. This simplifies serializability, as we will see in §4.2.

#### 4 ScaleDB Design

The foundation of ScaleDB’s design, building on the analysis in §3, is that range indexes are asynchronously updated to provide scalability. But how can this asynchronous architecture provide scalable transaction processing? And how can serializable isolation be guaranteed when range indexes are no longer kept synchronously consistent?

**Scalable transaction processing with indexlets.** To asynchronously update range indexes, we need a temporary store for writes that can be scalably maintained and flushed with

minimal overhead. We tackle this problem with a new data structure: hash-based *indexlets* that temporarily and synchronously record all range index writes. Indexlets leverage the flat structure of hash indexes to avoid contention among updates to unrelated records. A common issue with hash indexes is *rehashing* – resizing the hash index when it is at capacity [14]. Database hash indexes require rehashing, as their size cannot be known a-priori. Instead, indexlets only hold updates temporarily and are periodically merged by ScaleDB into range indexes. Thus, rehashing can be avoided by bounding the maximum number of delayed writes held in an indexlet based on the W-to-RS latency and write rate to the underlying table. We describe indexlets and how to efficiently size and scalably merge them in §4.1.

### Serializability with asynchronous range index updates.

We design *asynchronous concurrency control (ACC)*, a concurrency control protocol that provides serializability in an asynchronous database architecture. ACC integrates optimistic concurrency control (OCC) [57, 73] with asynchronous range index updates. Both are optimistic approaches: just as OCC assumes that most transactions do not contend, asynchronous range index updates assume that most W-to-RS latencies allow us to leave range indexes temporarily stale without negatively affecting goodput.

Since recent writes are held in indexlets, asynchronously enforcing serializability with good performance requires first checking indexlets on any point read, and, for range scans, efficiently detecting the small number of instances when a scan has accessed a stale portion of a range index. This check is necessary to avoid *phantoms* [32], as well as to ensure that transactions read the most recent value of each key returned by a scan.

ACC’s technique for avoiding phantoms relies on *phantom indicators*, which leverage ACC’s asynchronous design to scalably indicate the existence of a phantom to range-scanning transactions. Using the leaf nodes of the range index as partitions of its keyspace, writing transactions can produce a unique phantom indicator for each range covered by a leaf node. Each leaf node evolves through a series of version changes that happen whenever a merge to a range index affects that leaf node. Phantom indicators, uniquely derived from leaf nodes and their current version, are inserted by transactions into phantom detection indexlets (or *phantomlets*). Maintained for each range index, phantomlets allow range scanning transactions to scalably detect phantoms at commit time. We detail ACC and phantomlets in §4.2.

**Durability.** To provide durability, ScaleDB uses write-ahead redo logging. Transactions receive a globally-ordered timestamp from a system-wide clock, a hardware feature that industry trends and experimental evidence (§5.4) indicate will remain in future servers. As a result, threads can scalably log their transactions without coordination at commit time while pushing the overhead of merging logs to recovery.

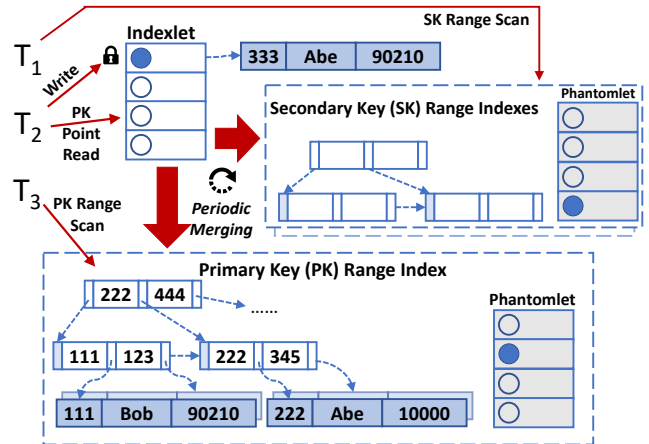

Figure 4. Asynchronous range index update for the *PERSON* table.

**Example.** To see how it all fits together, consider the example in Figure 4. Transaction  $T_1$  does a range scan by zipcode, which is executed on the appropriate secondary range index. Concurrently,  $T_2$  inserts the record with SSN 333 into the *PERSON* table and does a point read for an SSN from the same table.  $T_3$  does a range scan by SSN, which is executed on the primary range index.

Instead of synchronously updating the range indexes and potentially contending with other transactions, ScaleDB inserts  $T_2$ ’s new record, using its primary key (SSN), in the table’s indexlet and marks it as valid (filled circle). It does this atomically by acquiring a write lock on the indexlet entry. This may cause true contention if concurrent transactions access the same key, but it does not cause mechanism contention.  $T_2$  also does a point read for an SSN. To do so, it first checks the indexlet for the latest version of the record, temporarily holding a read lock on the record’s indexlet entry. It is not found there (empty circle), so  $T_2$  next reads from the primary range index. Range indexes have been read-only, and thus scalable, for this execution.

Periodically, the contents of the indexlet are merged into the underlying primary and secondary range indexes. The indexes are concurrent, so conflicting accesses by reading and merging threads are synchronized. We discuss the details of ScaleDB’s concurrent range index in §5.3. Because merging is periodic, it occurs in a coordinated and concentrated fashion when compared with synchronous range index updates.

Range-scanning transactions consult phantomlets to detect phantoms due to newly inserted records. They do this for each range index leaf node traversed as part of the range scan. To aid phantom detection, each writing transaction indicates *once* per version for a leaf node that it has inserted records. Here,  $T_2$  inserts a phantom indicator for the [222,345] leaf node into the phantomlet, indicating a possible later merge of the key with SSN 333 into that range index node. Upon a merge, not all updates might fit in the [222,345] node and the

structure of the range index might be altered during a merge. However, phantom indication is only required for unmerged records. We discard phantom indicators when the indicated records are merged. A reading transaction scanning just the [111, 123] node does not abort, as there are no phantoms indicated for this node.

#### 4.1 Asynchronous Range Index Updates

To update range indexes asynchronously, we record delayed writes in indexlets for the duration of a per-indexlet and per-thread *merge epoch*. At the end of an epoch, a thread merges its writes from the indexlet into the associated range indexes, and starts a new epoch. For a given indexlet and thread, the merge epoch ends as soon as either (i) the thread has filled a maximum *batch size* of entries in the indexlet; or (ii) a maximum epoch duration has been reached. Both batch size and maximum epoch duration are configured separately for every indexlet, and each thread decides independently for each indexlet when it has reached the end of its merge epoch.

**Indexlets.** ScaleDB uses hash-table-based indexlets with open addressing [41] to synchronously and scalably absorb concurrent, committed writes that affect range indexes. Thus, indexlets are associated with tables that have range indexes. For each such table, ScaleDB creates an indexlet, indexed by the table's primary key. If there is no primary key, ScaleDB creates an implicit primary key (a common practice [12]). The per-table indexlet naturally covers writes that affect secondary indexes, as secondary indexes refer to the primary index (as shown in Figure 1).

Recorded writes include insertions, updates, and deletions. Insertions and updates affecting a range index are simply recorded in the corresponding indexlet, and the record is updated on the heap (in per-thread arenas to avoid contention on memory allocation). Special care is required to ensure that deletes are handled consistently. Indexlets mark a record as deleted instead of deleting its key from the indexlet. This approach has two benefits: it ensures that a later read of the same key finds the deleted record in the indexlet rather than finding an older version in a range index; and it allows coalescing a key deletion followed immediately by an insert of the same key, without merging the delete into the range indexes.

**Merge epoch.** Each thread independently decides when its merge epoch ends, after which it merges the keys and record references into the table's range indexes. A thread can occupy a maximum *batch size* of  $b_i$  entries in any given indexlet  $i$  before it has to merge them into the range indexes. Too small a  $b_i$  causes contention similar to synchronous merging into range indexes. Too large a  $b_i$  results in stale range scans, which can lead to transaction aborts. We use  $b_i = \text{Expected write rate}(table_i) \times W\text{-to-RS latency}(table_i)$ .

During quiescent periods for write transactions, threads may not reach their maximum batch size quickly enough, leaving range indexes stale for too long. To avoid this, we cap the

length of the merge epoch of each indexlet separately, based on the W-to-RS latency of that indexlet's table: thus, a thread's merge epoch ends when it either reaches its maximum batch size or its maximum merge epoch length.

To make hash collisions rare, the size of indexlet  $i$  is set to  $s_i = 4 \times \#t \times b_i$ , where  $\#t$  denotes the number of threads. Given that each entry in an indexlet only occupies a single cache line, this results in modest memory consumption even for tables with a high write rate (§6.3).

**Asynchronous merging.** Each thread keeps a list of indexlet entries where it performed a write. At the end of its merge epoch, it sorts this list in primary range index key order (§3.2), and then iterates through the list, atomically merging each individual record. Merging involves updating the range index and removing the record from the indexlet, while holding a per-entry lock, thus ensuring atomicity for each key's merge. Each lock is released as soon as the key is merged into the primary index.

If secondary indexes exist, the merging thread additionally retains private copies of each record reference in thread-local storage. After the primary range index is merged, the thread then merges each secondary index, using these copies.

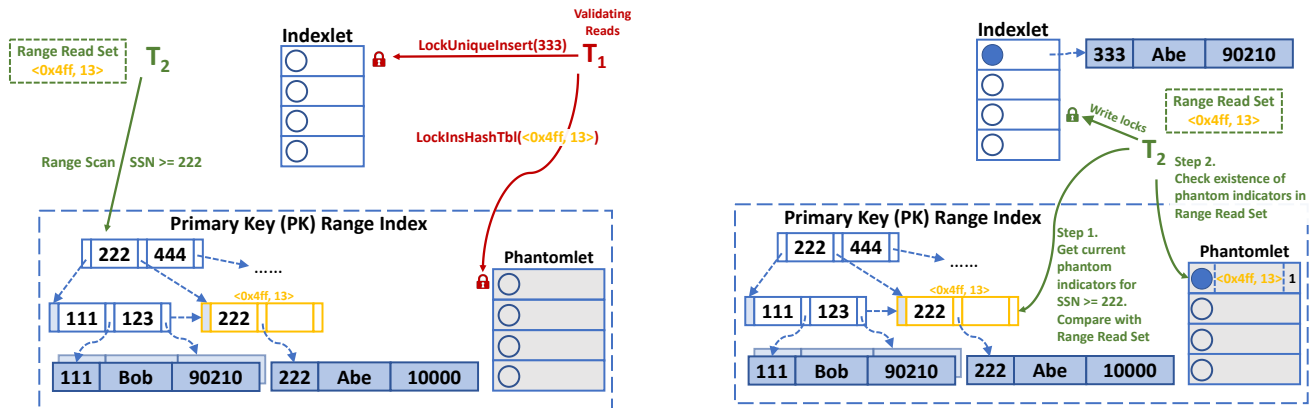

After merging each range index (primary or secondary), the merging thread also decrements any phantom indicators that it had inserted into the corresponding phantomlet during the concluded merge epoch (§4.2.1).

#### 4.2 Asynchronous Concurrency Control

We design asynchronous concurrency control (ACC), a concurrency control protocol that provides serializability within an asynchronous database. ACC is based on optimistic concurrency control (OCC), which it integrates with asynchronous range index updates. To do so, ACC uses two novel constructs: phantom indicators (§4.2.1) and locks in indexlets for atomic commit of transactional writes (§4.2.2).

**OCC** minimizes transaction contention by optimistically executing transactional reads and atomically publishing a transaction's writes at the end of its execution. To do so, OCC transactions execute in three phases—*read*, *validation*, and *commit*. During the *read* phase, reads are done optimistically, without holding locks, and are tracked in a transaction's private *read set*; writes instead are buffered in a private *write set*. The *validation* phase ensures that transactions may commit atomically. To do so, the database acquires locks on all values identified in the write set and then validates that collected values in the read set have not been altered by concurrently executing transactions. If the reads are validated, the *commit* phase commits the transaction's writes and releases its locks. Otherwise, the transaction aborts (releasing locks as well).

**ACC** extends the OCC phases and integrates them with asynchronous range index updates. During the read phase, point reads search the indexlet first, and, if they miss, search the primary range index. The same process is followed for

(a) Before validating successfully,  $T_1$  acquires locks for atomically inserting the record with SSN=333 into leaf index node [222,] and its phantom indicator <0x4ff, 13>. Concurrently,  $T_2$  does a range scan for SSN  $\geq$  222, during its read phase.

(b)  $T_2$  detects phantom indicator <0x4ff, 13> corresponding to [222,] while validating the range scan SSN  $\geq$  222. It will abort:  $T_1$  committed earlier, but  $T_2$ 's range scan missed the record with SSN=333, inserted by  $T_1$  in the indexlet.

Figure 5. Asynchronous phantom detection example.

updates and deletes, during the validation phase, allowing existing records to be brought into the primary indexlet first, before being updated in place. This guarantees that point queries always read the latest value of a record. On the other hand, range scans (from primary or secondary indexes) are executed directly on the range indexes, but need to check for phantoms at commit.

#### 4.2.1 Phantom Detection

Phantom detection is difficult in a database with asynchronously updated range indexes, as phantoms may occur in indexlets, which do not support efficient range lookup. ACC's technique for detecting phantoms leverages the leaf nodes of a range index which undergo coarse-grained version changes due to asynchronous merges by different threads. To track these changes, each leaf node  $l$  maintains a version number  $v_l$  which is incremented only when an insert or delete is merged into that node. If  $l$  splits due to an insert, then half of its keys are moved to a sibling leaf node  $m$  with  $v_m = 0$  while  $v_l$  is incremented.

To detect phantoms, ScaleDB uses a *phantomlet* per range index to perform a scalable variant of *index node validation* [73]. Phantomlets use the indexlet architecture (§4.1), but do not need merging. Inserting transactions atomically insert *phantom indicators* into phantomlets at transaction commit, indicating that they have inserted a phantom into a corresponding range index leaf node. The phantom indicator is composed of the concatenation of a leaf node  $l$ 's memory address  $M_l$  and version  $v_l$ .

At commit time, for each inserted key  $k$ , the inserting transaction asks the range index for the phantom indicator  $\langle M_l, v_l \rangle$  of the leaf node  $l$  that currently covers the range intersecting with  $k$ . If the phantom indicator does not exist in the

phantomlet, it is inserted. If the transaction validates, it atomically increments the value of the phantom indicator (initially 0). This is accomplished by locking phantom indicators as part of locking the transaction's write set (using LockInsHashTbl or LockRUDHashTbl on the phantomlets, see §4.2.2).

Threads keep track of the phantom indicators they have inserted and decrement their values at the end of their merge epoch. The last thread which decrements the value to 0, removes it from the phantomlet.

When validating a range scan, a reading transaction can use the same phantom indicator to check whether a phantom was inserted in a range covered by the leaf node *at the version it read*. To do so, ACC splits OCC's read set into two parts and extends them with additional information. For each point read, the key of a record  $r$  is stored along with a copy  $t_r^{PS}$  of the record's current commit timestamp  $t_r$  (§4.3) in a *point read set*. Storing the commit timestamp allows efficiently verifying whether the record changed, later during validation. For every range scan, ACC stores the keys of the scan results in the point read set, but also stores in a *range read set*, a phantom indicator for each range index leaf node encountered during the scan. Finally, it stores the range scan predicate in the range read set.

Read set validation happens differently for the point read set and the range read set:

- For the point read set, ACC reads from the indexlet and (if not found) searches in the primary range index. If the key of record  $r$  is not found in either index or  $t_r^{PS} \neq t_r$  ( $r$  received a write), the transaction is aborted. An optimization here is to only abort if  $t_r < t_T$ , where  $t_T$  is the timestamp allocated by this committing transaction (§4.3).
- For each range scan, ACC asks the range index for the current list  $c$  of phantom indicators that match the range scan predicate. If  $c$  is different in length than the original list  $o$

stored in the range read set, it aborts. If not, then there is still the chance that phantoms were inserted, but they have not been merged yet or they were merged but did not result in leaf node splits. ACC goes through each corresponding pair of phantom indicators in  $c$  and  $o$ , at the same index in the lists, verifying that the pair is identical, and that performing a `LockFreeRdHashTbl` (§5.2) for this phantom indicator on the phantomlet returns nothing. If any of these checks fail, it aborts.

Figure 5 shows a simple example illustrating asynchronous phantom detection.

#### 4.2.2 Atomic Commit

ACC holds locks on keys between the validation and commit phases, in order to atomically publish a transaction’s writes. Since ScaleDB writes are asynchronous, ACC locks need to cover records referenced by indexlets. Indexlets never rehash, allowing ACC to hold locks directly in indexlet entries as a way to hold locks on records.

To build transactions, ACC uses two types of locks on records: `LockUniqueInsert` is used to atomically insert a record with uniqueness constraints, while `LockUpdDel` is used to atomically update or delete an existing record. These locks are acquired on a transaction’s write set at the start of the validation phase, and released either at transaction abort or at the end of the commit phase.

**Unique insertion.** To lock for the unique atomic insert of a record, ACC performs two steps:

1. ACC searches for a duplicate record in the indexlet and, if not present, acquires a lock on an empty indexlet entry for the record to be inserted. This step is done atomically by calling `LockInsHashTbl`, provided by the indexlet. `LockInsHashTbl` acquires per-entry spinlocks along the hash probe path. If it finds an empty entry, it sets  $e_{ins}$ , the future location of the record being inserted, to that entry’s index. If the entry is not a search terminator (§5.1), it continues the search for a duplicate record, until the probe lands on a search terminator. If a duplicate is found, all spinlocks are released and the transaction is aborted. Otherwise, `LockInsHashTbl` is successful. In that case, it releases any acquired spinlocks on entries after  $e_{ins}$  in the probe path. Spinlocks on  $e_{ins}$  and entries before it in the probe path are held until `LockUniqueInsert` is released: this allows atomically inserting a record and updating search termination metadata (see §5.1) at transaction commit. With a properly sized indexlet, probe lengths are short and there is negligible mechanism contention for unique inserts.
2. ACC searches the primary range index to make sure that the key has not already been inserted there.

If either step fails, the transaction aborts. If both succeed, a lock for unique insert has been acquired. Our open addressing scheme probes indexlet entries in a deterministic order for

Figure 6. LockUniqueInsert Example.

each record. Hence, contending transactions attempting to insert the same record are serialized.

Figure 6 shows an example illustrating `LockUniqueInsert`. Transactions  $T_1$  and  $T_2$ , on different threads, are in their validation phase. They are concurrently trying to acquire `LockUniqueInsert` for a record with primary key (on SSN) 111.  $T_1$  acquires `LockInsHashTbl` in step 1. Its hash probe starts at entry 57 in the indexlet, which is currently occupied by a record with key 333—inserted by a recently committed transaction. Subsequently, another transaction brought the record with key 222 into the indexlet, for an update; it was inserted into entry 58 due to collision with key 333.  $T_1$ ’s hash probe acquires spinlocks along its probe path, until it lands on entry 59, which is both empty and a search terminator: thus, successfully acquiring `LockInsHashTbl` for key 111. Here, overflow counts (OC in the figure, see §5.1) are used to terminate searches (when OC = 0).

In step 2,  $T_1$  searches the primary range index for key 111, to ensure uniqueness; since it finds the record, it will abort. If  $T_1$  had been able to commit, it would have incremented the OC for entries 57 and 58 and inserted the new record (with key 111) into  $e_{ins} = 59$ , before releasing the spinlocks. Meanwhile,  $T_2$  gets serialized behind  $T_1$  (on entry 57’s spinlock), trying to acquire `LockInsHashTbl`. It will eventually abort as well.

**Update and deletion.** To acquire a `LockUpdDel`, ACC performs two steps:

1. It searches the indexlet for the record and, if found, locks the entry. This step is done atomically by calling `LockRUDHashTbl`, provided by the indexlet. `LockRUDHashTbl` is simpler than `LockInsHashTbl`, since it does not need to atomically enforce uniqueness or maintain the metadata for search termination. It acquires per-entry spinlocks along the hash probe path, but releases each spinlock as it moves to lock the next entry in the path. A probe can end when it either finds the record or lands on a search terminator entry.

In addition to its use in the first step of LockUpdDel, LockRUDHashTbl is also used to atomically search the indexlet for point queries, during the read phase of the transaction.

2. If the record was not found in the indexlet, ACC acquires LockInsHashTbl for the record, fetches the record from the range index, inserts a reference to the record in  $e_{ins}$  and then downgrades the lock to LockRUDHashTbl, which involves releasing the spinlocks on the entries before  $e_{ins}$  in the probe path.

For range updates or deletes, we search the range indexes directly and acquire LockUpdDel for every key satisfying the predicate. If there is not enough space in the indexlet, the transaction aborts. In this rare case, the indexlet is merged and temporarily disabled to retry the transaction synchronously, re-enabling the indexlet after the transaction commits.

### 4.2.3 Repairing Stale Range Scans

During the read phase, ACC can repair stale scans before returning them, to reduce the chance of a later transaction abort. This is typically done for scans used in a later update or delete query. For instance, the TPC-C Delivery transaction has a range scan that returns the earliest order within a district in the NEW-ORDER table and then deletes that order in the next query. This transaction can abort, even for a single thread, if the scan is done on the range index, but the earliest order returned by the scan has already been marked deleted in the indexlet in a previous Delivery transaction.

ACC repairs such scans, prior to returning them, by looking up each key in the indexlet to check if it has been updated or deleted. If so, it repairs the scan to return the latest version. To avoid paying this cost for all range scans, the client can explicitly set this option in the query for scans that will be updated or deleted.

ACC also maintains a per-thread per-table index of the keys which were inserted by each thread during its current merge epoch. When returning a range scan, ACC repairs it by merging any records returned by running the same scan on the local index as well. This avoids spurious aborts by the phantom detection algorithm (§4.2.1), due to keys that were inserted by the same thread in a prior transaction and are waiting to be merged into the range indexes.

### 4.3 Durability

ScaleDB achieves durability using write-ahead logging to a redo log. Each worker thread writes to its own separate log, without coordinating with any other worker thread. To ensure that transactions do not read values that have not been made durable, a thread only releases write locks and replies back to the client once it has logged the transaction to its redo log. Each redo log entry contains the new values of the keys written by the transaction  $T$  as well as a commit timestamp  $t_T$  assigned to it during the validation phase, after all the locks have been acquired by ACC. This timestamp, unique for each transaction, is derived from a scalable system-wide clock

(§5.4) and is consistent with  $T$ 's place in the serializable order. During recovery, ScaleDB first merges all the per-thread transaction logs in timestamp order, and then replays them.

To see why ScaleDB is recoverable despite uncoordinated logging, consider the example of three transactions  $T_1 \xrightarrow{ww} T_2 \xrightarrow{rw} T_3$ , each of them running on a separate thread.  $T_1$  writes  $x_1 = 42$  and  $T_2$  read-modify-writes that value to  $x_2 = 52$ , thus creating both a write-after-write (ww) and read-after-write (wr) dependency with  $T_1$ . Next,  $T_2$  reads  $y_1 = 33$ ; later  $T_3$  read-modify-writes it to  $y_2 = 36$ , creating a write-after-read (rw) dependency between  $T_2$  and  $T_3$ .

Because ScaleDB only releases write locks after the log entry has been made durable, if  $T_1$  is not logged, then  $T_2$  will either read  $x_0$  or it will wait for  $T_1$ 's write lock to be released to read  $x_1$ . Thus, after a crash, if  $T_2$  read  $x_1$  and is logged, then  $T_1$  must be logged as well. This argument extends transitively to a chain of such direct dependencies.

The second possibility is that after a crash  $T_2$  is not logged, but both  $T_1$  and  $T_3$  are. In this case, ScaleDB must not have committed  $T_2$  and replied back to the client. Thus, it will recover only  $T_1$  and  $T_3$ , in order, which is fine. Notice that, if, in fact  $T_2$  *does* get successfully logged, ScaleDB's system-wide timestamps allow correctly ordering  $T_2$  and  $T_3$ 's log entries at recovery, despite the fact that there was no direct communication among them.

### 4.4 Correctness

Using ACC, ScaleDB guarantees serializability [28], with the additional guarantee that the equivalent serial order is one where transactions are ordered by their commit timestamps. ACC derives its correctness guarantees in part from the guarantees provided by the locks and data structures it builds upon, as well as its descendance from OCC, which guarantees serializability [73]. The key difference from OCC is that ACC must deal with ScaleDB's asynchronous updates to range indexes. Our proof of correctness [64] shows that ACC's atomic commit and phantom detection protocols provide serializability in this scenario.

## 5 Implementation

We implement ScaleDB by modifying the Peloton [18] in-memory SQL database, written in C++. We replace the storage back-end, while retaining the code for networking, SQL parsing, query planning and query optimization.

### 5.1 Indexlet and Phantomlet Hash Table

Our indexlet and phantomlet implementations build on a simple open-addressing [41] hash table which uses linear probing for resolving collisions. We considered more sophisticated open-addressing schemes like Cuckoo hashing [2, 7] but found that the ability to hold transactional locks would have been complicated by displacement of keys and the fact that the cuckoo hashing probe path is an undirected graph with a possible cycle, which could have caused deadlocks.

Also recall that our hash table does not need to rehash: thus we can avoid mechanism contention on maintaining a count of occupied entries in the entire hash table.

One issue with using an open addressing hash table is how to ensure that searches terminate correctly after merging. When removing a record  $r$  from an indexlet entry, we cannot simply mark the entry as empty, because then any records displaced by  $r$  would not be found on a subsequent lookup (the search would terminate at  $r$ ). Tombstones, which are traditionally used in open addressing tables, have the problem of accumulating and making search probes ever longer. Instead, we used a scheme used by the recent non-concurrent F14 hash table [29, 36]. Each entry maintains an *overflow count*, that is incremented whenever an insert probe finds the entry already occupied. When removing a record reference at the end of a merge epoch, we atomically decrement the overflow counts on its probe path, before marking it as free. Similarly, when inserting a record reference, we atomically increment the overflow counts on its probe path. An entry whose overflow count is zero is a search terminator (§4.2.2).

## 5.2 Lock-Free Reads

To avoid reader contention on the same indexlet or phantomlet entries, ScaleDB provides *LockFreeRdHashTbl* (based on seqlocks [3]). To implement these, we add a version number to the per-entry spinlocks in the indexlet or phantomlet hash tables. Writers (doing inserts, updates or deletes) increment the version number after acquiring the spinlock but before any writes. At spinlock release, the version number is incremented again. Readers do not acquire the spinlocks but instead read the version number, before and after they perform the read. If the version number changed during the read or it is initially odd in value, then there was interference from a concurrent writer and the reader retries.

The limitation of this design is that it cannot be used if the data being read has internal pointers; otherwise, writers could invalidate pointers that a reader had already followed. To solve this, we can use Read-Copy-Update (RCU) [24] for implementing *LockFreeRdHashTbl* [73]. However, RCU can add significant complexity to the design; e.g., it requires garbage collection of previous versions of the data, after ensuring that no readers are actively reading it.

Our current prototype does not implement RCU. Instead, we only use *LockFreeRdHashTbl* for use-cases where the data does not have internal pointers; e.g., during the ACC validation phase, we use it to atomically search phantomlets, thus avoiding mechanism coordination between threads searching for phantom indicators for the same leaf node version of a range index. We also use *LockFreeRdHashTbl* to validate point reads in indexlets with fixed-length keys. If the data has internal pointers, we instead use *LockRUDHashTbl* (§4.2.2).

## 5.3 Concurrent Range Index

Our range index implementation is a B+ tree with optimistic latch coupling (OLC) [60], used in a recent study [77] that compared the scalability of state-of-the-art range indexes. In the OLC tree, reads do not acquire the per-node spinlocks when traversing the tree. Instead, they validate a per-node version number by reading it before and after reading the node's contents. If the two versions are not the same, they restart their traversal. Writers initially traverse like readers, but restart and acquire spinlocks along the path if they detect interference from another writer or if nodes need modification.

## 5.4 System-wide Synchronized Clock

For scalable durability, ScaleDB assigns timestamps to transactions derived from a system-wide synchronized clock. Synchronized hardware clocks are available on modern multi-core processors, such as the timestamp counter (TSC) on recent Intel x86 processors, which runs at a constant rate. Intel has indicated [52] that “*this is the architectural behavior moving forward*” and that “*the OS may use invariant TSC for wall clock timer service*”. As a result Linux uses the TSC as the clock source on x86 across multiple CPU sockets, after running boot-time tests to ensure synchronization [8, 9]. Recent work [34, 35] on multi-core filesystems has used it for scalable ordering across cores. Finally, virtual machines also provide synchronized virtual TSCs by either using the underlying hardware (fast) or emulating it if not synchronized (slow) and even across migrations [20, 26].

On architectures where a system-wide TSC is not available, it is possible to use a dedicated timing thread [71] for handing out timestamps. This approach requires a core dedicated to the timing thread, which continuously increments a local variable and then stores the value to a global time variable. A thread requiring a global timestamp simply reads the time variable. On the Intel Skylake architecture, such a timing thread increments the local variable every 0.87 cycles which is actually 15% faster than the TSC [71], but requires a core.

## 6 Evaluation

Our evaluation aims to understand how ScaleDB performs in terms of throughput scalability of committed transactions on various workloads, including YCSB and TPC-C, and how the various ideas in the design of ScaleDB contribute to performance. Our comparison baselines are Peloton, upon which ScaleDB is built, and Cicada.

Our evaluation answers the following questions:

1. What is the query scalability of ScaleDB when compared to Peloton (§6.1)? We use YCSB to answer this question.
2. How does ScaleDB scalability compare to Cicada when guaranteeing serializability for transactions (§6.2)? Is the transaction abort rate affected? We evaluate TPC-C.

3. Is the ScaleDB asynchronous architecture a scalable design (§6.3)? We evaluate the scalability of indexlets (phantomlets) and system-wide timestamps given that these mechanisms are necessary for a scalable, asynchronous database.

**Testbed.** All machines in the evaluation have 2×18-core Intel Xeon Gold 6154 CPUs with 36 cores. 192GB of memory is divided across two NUMA nodes. Each machine has a Mellanox ConnectX-5 NIC, operating at 100Gb/s. For networked benchmarks, we run a single database server and 4 client machines. Each client machine runs as many processes of the OLTP benchmark suite [13] as needed to saturate the database server. Accordingly, all experiments report peak throughput.

### 6.1 Asynchronous Index Update

We evaluate ScaleDB’s scalability of asynchronous updates to a single range index and compare to Peloton. For this purpose, we use the Yahoo! Cloud Serving Benchmark (YCSB) [40] read-insert workload. To generate enough load, we access the database from 4 networked YCSB benchmark client machines. The YCSB benchmark defines a single table with an integer primary key and 10 string columns, each of size 100 bytes. Peloton uses the lock-free Bw-Tree [77] as the underlying primary range index on the integer key.

All experiments use 36 server threads, with each thread pinned to a separate core. We show scalability by increasing the number of client terminals sending operations to the database server. For ScaleDB, we set the maximum merge epoch duration to 100 ms and the maximum batch size per thread to 1,000 entries. Prior to running each experiment, we load the table with 1 million records. We use a Zipfian distribution for reads with  $\theta = 0.99$  to simulate a skewed workload. For inserts, each client thread adds new records sequentially within its own interval of the primary key space, starting after the already inserted 1 million records, to avoid uniqueness conflicts.

**Mechanism contention.** Figure 7a shows terminal scalability for two points of read-insert intensity. The read-insert workload has only mechanism contention—reads and inserts are to disjoint keys. For 95% reads, both ScaleDB and Peloton scale with similar performance until all server cores are saturated. This is not surprising. Peloton’s range index scales well when a workload is read-intensive. For a write-intensive workload with 50% inserts, Peloton’s throughput collapses, while ScaleDB maintains 9.5× Peloton’s throughput at scale.

To detail this effect, we examine the sensitivity of both systems to increasing write intensity by varying the fraction of inserts in the workload, fixing the number of terminals to 160. Figure 7b shows that Peloton’s throughput quickly collapses with increasing write intensity (knee-point at 20% inserts), while ScaleDB’s throughput gradually declines. ScaleDB loses 46% of its peak throughput when the workload is write-only.

### 6.2 Serializability

We now evaluate asynchronous scalability with serializable transactions on the TPC-C benchmark, which has multiple tables and several primary and secondary range indexes. We compare with the Cicada [62] database. Cicada’s prototype does not have a network layer and it uses a TPC-C implementation linked with the database binary, calling directly into the Cicada function call API as opposed to sending SQL calls across the network. For a fairer comparison, we do the same for ScaleDB. Cicada’s prototype also pre-allocates all of its memory using huge pages. Recent work from Huang et al. [51] has recommended avoiding this strategy since it “changes system dynamics significantly—for instance, pre-allocated indexes never change size”. Further, Huang et al. show that Cicada, with pre-allocation, experiences a performance collapse at high core counts due to memory exhaustion, which we observed as well. Therefore, we modify Cicada to instead use jemalloc [6], which is what ScaleDB uses for memory allocation. Finally, Cicada simplifies multi-column keys by reducing them to 64-bit integers (using assumptions about the maximum range of each column). Thus, all key comparisons in Cicada are between single 64-bit integers, while ScaleDB stores and compares multi-column keys (with possibly varying column types). Hence, the baseline performance in this evaluation is biased against ScaleDB. We report self-normalized scalability, in addition to raw transactional throughput (Figure 8), for a more complete picture.

TPC-C does not run range scans on the WAREHOUSE, DISTRICT and ITEM tables. Cicada uses hash indexes for these tables and we do the same for ScaleDB. For the other tables, ScaleDB’s maximum per-thread batch sizes are calculated using the method outlined in §4.1. The New-Order and Delivery transactions exert a very small W-to-RS latency on the NEW-ORDER table, requiring this table’s maximum batch size to be set to 0 (*i.e.*, synchronous merging into the range index). The remaining tables have a batch size of 2,048.

Figure 8 shows the TPC-C evaluation. The setup for these experiments is the same as that of Figure 2. ScaleDB does not have a partitioned index configuration, so all results for ScaleDB use shared indexes. On the canonical TPC-C benchmark (Figure 8a), ScaleDB scales 22.3× on 36 cores (relative to its single core throughput), which is significantly better than Cicada’s scalability (with shared indexes) of 6.4×. At scale, ScaleDB’s raw throughput is 1.8× higher than Cicada.

Partitioned indexes show the upper bound for Cicada’s scalability. ScaleDB, with shared indexes, achieves better self-normalized scalability than Cicada with partitioned indexes (Cicada scales only 20× over 36 cores). At scale, ScaleDB’s raw throughput is 60% of Cicada. Of course, Cicada’s partitioned indexes do not generalize to skewed workloads.

We also evaluate a workload (NewOrd-Deliv, Figure 8b) consisting of TPC-C transactions New-Order and Delivery in equal proportions. On this more index-contended benchmark,

(a) Throughput.

(b) Write sensitivity.

Figure 7. YCSB read-insert workload. 95-5 is 95% reads and 5% inserts. 50-50 is 50% reads and 50% inserts.

(a) TPC-C.

(b) NewOrd-Deliv.

Figure 8. ScaleDB vs Cicada goodput scalability on the TPC-C benchmark. Goodput counts only committed transactions.

(a) TPC-C.

(b) NewOrd-Deliv.

Figure 9. ScaleDB abort rate.

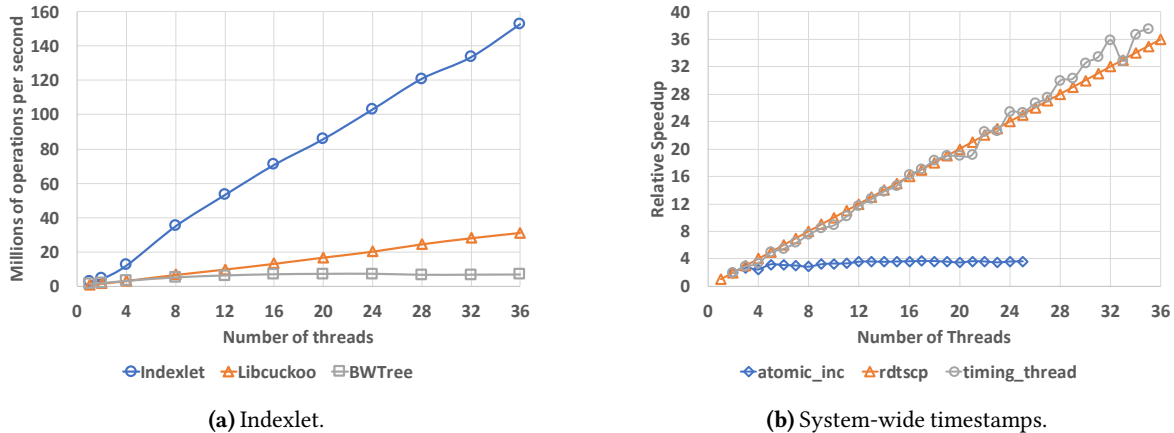

Figure 10. ScaleDB mechanism scalability.

ScaleDB maintains its scalability, while Cicada’s scalability is severely impacted. ScaleDB scales 24× over 36 cores, compared to only 1.6× for Cicada with shared indexes. ScaleDB’s throughput is 4.3× higher than Cicada. With partitioned indexes, Cicada scales 15.5×, still worse than ScaleDB using shared indexes. At scale, ScaleDB (with shared indexes) provides 48% of Cicada’s throughput (with partitioned indexes).

Given ScaleDB’s asynchronous design and the fact that transactions can do stale reads from range indexes in between batch merges, an important concern is how the abort rate behaves with an increasing number of threads. Figures 9a and 9b show this evaluation. On the canonical TPC-C benchmark, only the Delivery and StockLevel transactions have a non-negligible abort rate. The Delivery abort rate stabilizes at 3.5% around 20 cores (for both workloads), which implies that ScaleDB continues scaling even beyond 36 cores. The Stock-Level abort rate stays under 1%, even for 36 cores.

We also evaluated sensitivity of the abort rate to batch size, but found that our workloads were not very sensitive to even significant variations around the initial batch size—calculated according to the expected write rate for the corresponding table (§4.1). Accordingly, we omit those results for brevity.

### 6.3 ScaleDB Mechanisms

**Indexlets.** We evaluate the scalability of indexlets against libcuckoo [7], an optimized concurrent hash table, and the BwTree [61, 77], a recent, lock-free range index structure. This evaluation is performed on a microbenchmark (included with libcuckoo) with a 50% read and 50% insert workload consisting of 64-bit integer keys and values. As Figure 10a shows, indexlets achieve nearly 5×libcuckoo and 25×BwTree throughput at 36 cores. Open addressing in indexlets provides better scalability than cuckoo hashing and the flat structure of hash tables scales better than tree indexes.

**Memory Overhead.** Indexlets have low memory overhead. Each indexlet entry only contains the primary key, a reference to the actual database row, and a small amount of meta-data (e.g., a spinlock). For primary keys composed of integer columns, such as those in TPC-C tables, an indexlet entry can fit within a cache line (i.e. 64 bytes). As a result, the maximum size of an indexlet in our benchmarks was ~60MB, even for tables (e.g. the TPC-C Orderline table) which absorbed millions of record inserts per second at peak. For phantomlets, the memory overhead is even more modest, as their entry count is sized according to the expected number of leaf index nodes used for inserts per epoch. Accordingly, the maximum size of phantomlets in our benchmarks was lower than 1MB.

**System-wide timestamps.** We evaluate the TSC and timing thread approach (§5) and compare with an atomic increment as a global timestamp. As Figure 10b shows, both timing thread and TSC approaches scale linearly to 36 cores, while the atomic increment does not scale beyond 4 cores.

## 7 Conclusion

ScaleDB is an asynchronous in-memory database that provides scalability and serializability for ACID transactions. ScaleDB asynchronously updates range indexes by temporarily holding writes in indexlets that are merged periodically into range indexes. ScaleDB uses asynchronous consistency control (ACC) to provide transaction serializability. ACC extends OCC with asynchronous phantom detection via phantomlets and atomic transaction commit using locks in indexlets, rather than range indexes. For durability, ScaleDB uses system-wide time stamp counters for scalable redo logging. ScaleDB achieves 9.5× better query throughput than Peloton on the YCSB benchmark and 1.8× better transaction throughput than Cicada on the TPC-C benchmark.

## Abstract

Approximate similarity queries on high-dimensional vector indices have become the cornerstone for many critical online services. An increasing need for more sophisticated vector queries requires integrating vector search systems with relational databases. However, high-dimensional vector indices do not exhibit monotonicity, a critical property of conventional indices. The lack of monotonicity forces existing vector systems to rely on monotonicity-preserving tentative indices, set up temporarily for a target vector's TopK nearest neighbors, to facilitate queries. This leads to suboptimal performance due to the difficulty to predict the optimal  $K$ .

This paper presents VBASE, a system that efficiently supports complex queries of both approximate similarity search and relational operators. VBASE identifies a common property, *relaxed monotonicity*, to unify two seemingly incompatible systems. This common property allows VBASE to circumvent the constraints of a TopK-only interface to achieve significantly higher efficiency, while provably preserving the semantics of TopK-based solutions. Evaluation results show VBASE offers up to three orders-of-magnitude higher performance than state-of-the-art vector systems on complex online vector queries. VBASE further enables analytical similarity queries that previous vector systems do not, and shows  $7,000\times$  speedup with 99.9% accuracy of exact queries.

## 1 Introduction

Recent advances in deep learning (embedding) models map almost all types of data (*e.g.*, images, videos, documents) into high-dimension *vectors* [60, 66, 88]. Queries on high-dimensional vectors enable complex semantic-analysis that was previously difficult if not impossible, thus they become the cornerstone for many important online services like search [25, 51], eCommerce [54], and recommendation systems [49, 53, 56, 84]. The “online” nature of these

services requires vector search to complete in milliseconds [31, 36, 42, 64]. Such a strict latency conflicts with the inherently high cost of exact search algorithm [28], which forces end-users to settle on approximate query results on high-dimensional vectors. With emerging new vector search applications, queries on vectors become increasingly more complex, which often involve hybrid search on both scalar and vector data (§2.1). This naturally motivates an integration of vector search systems and relational databases.

Vector search and database systems differ in their ways of using the index, a critical structure to speed up queries. An important property of conventional indices like B-tree [22] is *monotonicity*. This property ensures that a query can traverse the data-set guided by an index monotonically along a certain direction. This often avoids total data scan, therefore enables efficient query execution. However, it is prohibitively expensive for high-dimensional vector indices [5, 25, 43, 55, 57, 85] to preserve monotonicity, because of the curse of dimensionality [28]. Instead, they are often organized as a graph or cluster-based irregular structure, which follows monotonicity *approximately*. Traversing such vector indices does not guarantee a strict monotonic order in terms of distances to a target vector, but it enables a system to efficiently determine when it is *unlikely* for new traversals to reach closer vectors to a target than the current  $K$  ones. Therefore, modern vector indices only support approximate TopK, *i.e.*, to find  $K$  nearest neighbors approximately. A TopK query traverses a vector index for a sufficiently large number of steps, until it determines that a neighbor closer than the current  $K$  nearest ones is unlikely to be found.

To integrate vector search and database systems, existing vector database systems [76, 80, 86] choose to conform with *strict* monotonicity. To support similarity queries other than TopK, they first leverage TopK to collect  $K$  vectors, and sort the  $K$  vectors according to distances to a target vector, which sets up a *temporary index preserving monotonicity*. Complex relational operators can therefore execute on the temporary index in the traditional way. Consider the following vector search query, “find  $X$  number of products most similar to an

\*Corresponding author.

image but under a certain price”. A database planner would first run a vector search operator on the vector attribute of image embedding to find  $K$  nearest tuples, then apply a filter operator on the price attribute. But it is impossible to predict exactly how many tuples will pass the filter operator, which could be much less than  $K$ . Therefore this practice has the inherent difficulty of identifying the optimal  $K$  that produces exact  $X$  results. As a result, it resorts to either a setting of a conservatively large  $K$  or a trial-and-error of many  $K$ s, which both lead to suboptimal query performance.

In this paper, we present VBASE, a new system capable of efficiently serving complex online queries that involve both approximate similarity search and relational operators on scalar and vector data-sets. VBASE identifies *Relaxed Monotonicity* as the common property abstracted from the two seemingly different systems: vector search systems and relational databases. *Relaxed monotonicity* requires index traversals to only follow monotonicity *approximately*. We observe that state-of-the-art vector indices all follow relaxed monotonicity property in a two-phase pattern: an index traversal first locates the nearest region to a target vector approximately, and then moves away from the target region progressively in an approximate way. Based on the observation, we formally define *Relaxed Monotonicity* property, which abstracts the core index traversal pattern that most existing vector indices already have (§3.1). *Relaxed monotonicity* can be viewed as a generalized form of monotonicity, thus it is also applicable to conventional scalar indices, such as B-trees. Therefore, *Relaxed Monotonicity* can serve as the common foundation of vector search and database systems.

With relaxed monotonicity, VBASE builds a unified query execution engine to support a wide range of queries both on scalar and vector data, including queries across multiple heterogeneous indices. VBASE’s unified engine is based on a *Next* interface, instead of *TopK*, to support traversal in both vector and scalar indices. Meanwhile, the engine allows the derivation of a generalized termination condition from relaxed monotonicity to stop a query’s execution timely.

A unique characteristic of VBASE is that its relaxed-monotonicity-based query execution engine can *provably* achieve *equivalent* query results to those produced by *TopK*-only solutions of the *optimal  $\tilde{K}$*  (§3.3). This powerful property allows VBASE to circumvent the constraints of a *TopK*-only interface to achieve significantly higher efficiency, while preserving the semantics of *TopK*-based queries. In particular, based on the derived generalized termination condition, VBASE is able to detect the  $\tilde{K}$  during index traversal without an prediction of  $\tilde{K}$ . This allows VBASE to achieve similar performance to the well-optimized *TopK* vector search. For more complex queries than *TopK* searches, VBASE can achieve up to three order-of-magnitude lower average and tail query latency over state-of-the-art systems under similar result accuracy (i.e., same or even better recalls).

Moreover, with relaxed monotonicity, VBASE can even

Table 1: Online Similarity Query Support for Vectors

	S1	S2	S3	S4
ANN systems [25, 43, 46]	✓	✗	✗	✗
AnalyticDB-V [80]	✓	✓	✗*	✗*

Milvus [76]	✓	✓	✓	✗
Elasticsearch [4]	✓	✓	✗ <sup>o</sup>	✗

\*: Some systems can support these queries through exhaustive linear scan, but this cannot meet the requirements of online services.

<sup>o</sup>: Only support one inverted index and one vector index.

support approximate query types that previous systems do not, and show superior query performance and accuracy. For example, VBASE can finish a *join*-based vector query in 16 seconds with 99.9%+ recall rate, which is 7000× faster than a brute-force table scan.

In summary, we make the following contributions:

1. VBASE identifies and defines formally “*Relaxed Monotonicity*”, a property that reveals, for the first time, the core of well-designed vector indices and why they work effectively in practice.
2. VBASE builds a *Unified Database Engine* based on *relaxed monotonicity*, which enables powerful complex queries leveraging both vector and scalar data indices.
3. We prove that VBASE’s unified engine produces equivalent results to *TopK*-only methods using vector indices, with a much more efficient execution plan than that of *TopK*-only methods.
4. We implement VBASE based on PostgreSQL with 2000 lines of additional code, and show an end-to-end evaluation of eight complex SQL queries on a hybrid one million recipe data-sets [59] with both vector and scalar attributes.

We plan to make VBASE open-source to satisfy the emerging important vector analytic applications in the era of AI.

## 2 Background

### 2.1 Emerging Online Vector Queries

Vector has become a key form of data representation in the AI era. Deep learning has enabled a growing number of vector-centric online applications, including embedding-based retrieval [25, 87], face recognition [69], code retrieval [37], question answering [52, 63], Google Multisearch [7], Facebook near-exact duplicates detection [6], etc. More recently, AI applications have leveraged ChatGPT’s retrieval plugin [10] to convert their proprietary knowledge, personal documents, and chat contexts into vectors. This enables the retrieval of relevant vectors with price, category, location, or time constraints to construct prompts in the chat.

Traditional applications also benefit from vectors empowered by AI. For example, search engine turns web documents into both bag-of-words sparse vectors and deep learning em-

bedding dense vectors to improve the relevance of search results. And recommendation systems turn images, videos, and descriptions of items into different vectors. Combined with scalar data like item price and category, these vectors are used to enhance recommendation experiences.

All these call for a general system to run sophisticated vector and scalar queries efficiently. In summary, these vector scenarios can be categorized into the following types.

**S1: Single-vector TopK.** embedding-based retrieval [25], recommendation [87], and question answering [52, 63] essentially search a vector data-set for the  $K$  closest vectors, given a query vector. Such queries can be naturally expressed by a TopK operator on a single-vector column.

**S2: Single-vector TopKplus scalar attribute filtering.** There are also requirements to find TopK results under certain scalar attribute constraints. Google Multisearch [7] belongs to this category. It allows users to provide additional text hints during a similarity image search.

**S3: Multi-column TopK.** Some vector analytics require intersecting results of multiple TopK searches over different vector attributes. For example, image-recipe retrieval [68] is a recipe search on multi-modal data attributes of both (vectorized) ingredient keywords and a sample dish image. Recent work [70, 83] shows that multi-column TopK search can boost result quality in applications such as question-answering.

**S4: Vector similarity filter.** Similarity filtering is a typical vector analytics scenario. For example, face recognition [69] and Facebook’s near-exact duplicates detection [6] search for similar images (given an image) from a data-set with a similarity threshold. To support such applications, one could use vector filtering based on distance similarity between two images, i.e., distance-based range query.

All these vector query types have a strict latency requirement (e.g. milliseconds). Unfortunately, no existing systems can support all these online similarity queries comprehensively and efficiently (see Table 1).

## 2.2 The Division Between Databases and Vector Search Systems

Although databases can express the above queries through relational algebra, the division in the semantics between vector and conventional database indices makes it difficult to provide a unified system that efficiently runs various types of sophisticated online vector queries as shown in Table 1.

**Relational database.** A relational database is one of the most prominent tools to run sophisticated queries [16, 24, 29, 40]. In order to meet the low-latency “online” requirement, indices are widely adopted by databases to expedite query executions, such as B-tree [22], B+-tree [75] and more. These indices demonstrate *monotonicity*, a property that allows a query to traverse an index monotonically along a certain direction, e.g., in a descending or ascending order.

One of the most important types of online queries in the context of emerging vector scenarios is TopK query (§2.1). And a conventional database index can speed up TopK by traversing the index in the ascending or descending order and terminating the query as soon as it collects  $K$  results. This optimization applies to many TopK variants, such as TopK + filtering, and multiple-column TopK queries [33].

However, the effectiveness of such optimization relies on the assumption of monotonicity, which high-dimensional vector indices do not follow. We elaborate next.

**Approximate vector search.** The recent eruption of AI models has been generating a large and growing amount of high-dimensional vector data. For better learning representation, a vector can have hundreds of dimensions [60, 66, 88]. Due to the curse of dimensionality [28], no solutions can complete a high-dimensional vector query in sub-linear time. To address “online” scenarios, modern vector search systems resort to approximation to lower query latency dramatically (milliseconds) while maintaining a relatively high result accuracy (90%+ recall). These systems are often referred as *approximate nearest neighbor search* (ANNS) systems [5, 25, 43, 55, 57, 85].

Like relational databases, vector indices are adopted to facilitate approximate vector search. Representative vector indices are either organized as *partitions* (clustering-based [5, 17, 19, 25, 44, 45, 48, 90]), hash-based [30, 41, 79, 81, 85]), high-dimensional tree-based [23, 57, 62, 78]), or *neighborhood graphs* [32, 39, 43, 55, 58, 77]. The difficulty of locating a vector in the high-dimensional space forces these vector indices to optimize for approximate TopK. In a TopK query, index traversal is guided by a query vector  $q$  approximately towards the nearest neighbors tortuously based on the distance between  $q$  and some anchor points (e.g. cluster centroids, or sampled graph vertices). During the traversal, the direction to  $q$  may change dramatically, thus the process does not guarantee to approach  $q$  in every traversal step and the vector index traversal is not monotonic.

The lack of monotonicity in vector indices bars database systems from directly using vector indices to expedite queries, which is the primary source of *the division between databases and vector search systems*.

**TopK-based solutions to eliminate the division.** Because vector indices are optimized for TopK, ANNS systems expose only a TopK interface. To close the monotonicity gap between databases and vector search systems, the current practice is to use ANNS TopK interface to create tentative indices based on  $K$  vectors sorted according to the distance to the target vector. Such tentative indices preserve monotonicity, which enables fast vector query processing in databases [76, 80, 86].

However, TopK-based tentative index solutions are unsatisfactory. It is difficult, if not impossible, to predict the right size of  $\tilde{K}$  for the tentative index for queries, where a subsequent relational operator with a filter constraint can collect just the right number of results. This limitation universally applies

to TopK + filter queries, vector similarity filter queries, and more. Thus TopK-based tentative indices inevitably lead to choosing a conservatively very large  $K$  [80, 86] or performing trial-and-error with different sizes of  $K$  [76], both incurring excessive data accesses and computations.

### 3 VBASE Design

#### 3.1 Relaxed Monotonicity

Unlike conventional scalar indices, high-dimensional vector indices are designed for approximate TopK and do not follow monotonicity. Figure 1 shows the TopK traversal patterns of two popular vector indices, FAISS IVFFlat [5] and HNSW [89]. As illustrated, vector index traversal does not comply with monotonicity, the distance towards the target vector oscillates *unpredictably* as the traversal progresses. A lack of monotonicity in these vector indices bars relational databases from directly using them to expedite queries (§2.2).

Figure 1: Traversal patterns of two vector indices.

**The Two-phase Vector Index Traversal Pattern.** Nevertheless, Figure 1 reveals a two-phase index traversal pattern for both vector indices. In the first phase, the index traversal approaches the target vector region approximately in spite of large oscillations in vector distances. In the second phase, the index traversal stabilizes and steadily departs from the target vector region in an approximate way.

This two-phase traversal pattern is common in most vector indices we examine. We believe that the essence of well-designed vector indices is an effective data-structure that embodies this traversal pattern implicitly. Thus a TopK search query could terminate early when it enters the second phase as further traversals are unlikely to identify more similar vectors.

**The Formal Definition of Relaxed Monotonicity.** Based on the two-phase traversal pattern, we can formally define *Relaxed Monotonicity* which identifies if a vector index traversal has entered the second phase. The definition is built upon the intuition of how a vector TopK search is executed internally.

Figure 2 shows such an intuition by illustrating the process of a general vector search for a query vector  $q$ . The dashed arrow in the figure shows an index traversal path with respect to  $q$ . Following the two-phase pattern, the query first approaches the *neighborhood* of  $q$  gradually. In a high-dimensional space, the neighborhood of  $q$  is defined by a neighbor sphere centered around  $q$ , illustrated as a circle in Figure 2. Afterward,

Neighbor sphere of a target vector  $q$  with a radius  $R_q$ , which contains  $E$  nearest vectors to  $q$ .

Figure 2: An Illustration of *Relaxed Monotonicity*'s intuition. A vector query  $q$  discovers  $q$ 's neighborhood with  $E$  nearest vectors along the progression of a traversal path.

the index traversal leaves the sphere and enters phase two, where the query can terminate in this phase.

Figure 2 suggests that, to determine whether it enters phase two, a query needs to understand  $R_q$ , the radius of the neighbor sphere centered around  $q$ , and whether  $M_q^s$ , the distance between the query's current index traversal position (denoted as traversal step  $s$ ) and  $q$ , is greater than  $R_q$ , i.e., it is traversing beyond the neighborhood of  $q$ .

Formally,  $R_q$ , the radius of  $q$ 's neighborhood, is defined as:

$$R_q = \text{Max}(\text{Top}E(\{\text{Distance}(q, v_j) | j \in [1, s-1]\})), \quad (1)$$

where  $\text{Top}E$  denotes the  $E$  nearest neighbors of  $q$  observed during the traversal, supposing that the traversal has reached step  $s$  so far. For a  $K$  nearest vector search query, it requires  $E \geq K$  in order to produce sufficient final results. In Figure 2, the  $E$  vectors within the circle are the nearest neighbors of  $q$  of all the  $s$  vectors visited so far. During an index traversal, the sphere's radius  $R_q$  would gradually decrease during phase 1, and becomes stable during phase 2.

Given the definition of  $R_q$ , the system needs to define  $M_q^s$ , the distance measurement between the target vector  $q$  and the current index traversal position, denoted as traversal step  $s$ .  $M_q^s$  is then used to determine whether the traversal enters phase 2, i.e., leaving the neighbor sphere.

Mathematically,  $M_q^s$  is defined as the median distance to  $q$  of all vectors traversed in the most recent  $w$  steps, i.e., the traversal window.

$$M_q^s = \text{Median}(\{\text{Distance}(q, v_i) | i \in [s-w+1, s]\}), \quad (2)$$

where  $\text{Distance}(q, v_i)$  denotes the distance between  $q$  and vector  $v_i$ , traversed in the past traversal window. Note that we use *median* instead of *mean* to disregard any outlier vectors in the traversal window, which has exceedingly large or small distances to  $q$  than others. For example, the two outlier vectors in the leftmost and rightmost positions in the traversal window shown in Figure 2.

Taking Eq.1 and Eq.2 together, we define *Relaxed Monotonicity* as:

**Definition 1 Relaxed Monotonicity**

$$\exists s, M_q^s \geq R_q, \forall t \geq s. \quad (3)$$

In other words, Def. 1 determines that a vector index follows *relaxed monotonicity* if there exists a certain index traversal step  $s$ , where all traversal steps  $t$  after step  $s$  transcends into a region ( $M_q^t$  as the region's distance to  $q$ ) that is outside  $q$ 's neighborhood sphere, defined by  $q$ 's  $E$  nearest neighbors.

**Importance of Relaxed Monotonicity.** Relaxed monotonicity is the key for the database to circumvent the inefficient constraint of TopK-only interfaces, and to generate an efficient execution with on-the-fly early termination. When subsequent database operators following the vector index scan can determine that vector index traversal has entered the second phase, one would know that we are veering away from the target vector steadily. In such cases, we could early terminate the query if sufficient results have been collected, because new tuples with closer vector attributes are unlikely to be found.

**Generality of Relaxed Monotonicity.** All mainstream vector indices listed in ANN Benchmarks [2] perform vector search using four general components: 1) *index traversal* to navigate the vector data-set; 2) *termination check* to detect query termination signal; 3) *monotonicity check* to determine if a query enters Phase 2; and 4) *priority queue* for keeping  $K$  nearest vectors so far. Often in ANNS indices, *monotonicity check* is a necessary condition for the *termination check*.

Although vector indices implement these four components in different ways, their monotonicity check satisfies Def. 1. For example, Figure 1 shows that index traversal patterns of IVFFlat and HNSW follow *relaxed monotonicity* obviously. And Def. 1's parameters, i.e., the traversal window  $w$  and the neighborhood of  $q$   $R_q$ , are able to capture the internal characteristics of index traversal patterns of these popular vector indices as well as conventional indices. Next, we elaborate on the setting of these parameters for representative indices.

- **Graph-based Vector Indices**, such as HNSW [89], follow the two-phase pattern using graph data-structures. In the first phase in Figure 1b, HNSW quickly navigates the traversal to the neighborhood of  $q$  through hierarchical coarse-grained to fine-grained navigating graphs. When it reaches the fine-grained graph, the traversal enters the second phase where it has found the neighborhood of  $q$  and departs away. Vector search using a graph-based index use best-first (BF) graph traversal from a fixed starting point. BF search maintains a *sorted candidate queue* with the size  $ef$ . This queue essentially represents the neighborhood sphere in Eq. 1 with  $ef$  vectors. Therefore  $E$  equals  $ef$  for HNSW. BF traversal explores the graph through the vectors in the candidate queue and expands the exploration by visiting their neighbors. If a neighbor is *unvisited* and its distance to the target vector  $q$  is smaller than the farthest vector in the sorted queue (i.e.  $R_q$ ), the traversal replaces the farthest vector with the new one and resorts the queue. Because the traversal only compares the traversed vector itself with  $R_q$ , the traversal window  $w$  in Eq. 2 equals one.
- **Partition-based Vector Indices**, such as FAISS IVFFlat [5] and SPANN [25], divide vectors into multiple clus-

ters where nearby vectors are conglomerated. During the traversal in the first phase in Figure 1a, IVFFlat traverses over the centroids to identify the  $m$  closest clusters, and then in the second phase it goes over the vectors in  $m$  clusters and terminates when all vectors in  $m$  clusters are traversed, which indicates Eq. 3 of *Relaxed Monotonicity* has been satisfied after the vector search visits  $m$  clusters. With this observation,  $E$  in Eq. 1 is set to  $K$  of the TopK query, and the traversal window  $w$  in Eq. 2 is set to the number of total vectors in  $m$  clusters.

- **Scalar Indices**, such as B-Tree, follow strict monotonicity. It is a special case of relaxed monotonicity, where  $w$  and  $E$  are both set to 1 and Eq. 3 is always true.

Note that it is our observation that well-designed indices should satisfy *Relaxed Monotonicity*. VBASE abstracts and formalizes this property that most indices already preserve, and encapsulates it with mathematical terms such as  $E$  and  $w$  in Eq. 1 and 2. It is the responsibility of individual indices to guarantee relaxed monotonicity by tuning the corresponding hyperparameters like  $ef$  and  $m$ , which can be transformed to  $E$  and  $w$ , as discussed above.

## 3.2 Unified Query Execution Engine

With relaxed monotonicity, VBASE builds a unified query execution engine modeled after a traditional database engine with minimum changes. VBASE's unified engine is built on Volcano Model (i.e. Iterator Model) [35], where 1) a relational operator in a given query produces a stream of tuples iteratively that are consumed by downstream operators, and 2) the iterative execution stops if a termination condition is met.

**Iterative Execution Model.** VBASE fully complies with the Volcano Model. It reuses the traditional `Open`, `Next`, and `Close` interfaces to leverage index traversal so that no change is required for conventional indices. For vector indices that traditionally expose TopK interfaces only, VBASE performs a simple adaptation to expose their internal index traversal process, to conform to VBASE's `Next` interface. We will discuss the details of implementing `Next` for vector indices in §4.2.

**Generalized Termination Condition Check.** VBASE modifies the termination condition based on relaxed monotonicity. In particular, VBASE extends the original termination condition with *relaxed monotonicity check*. In addition to the original query termination condition, VBASE performs relaxed monotonicity check by inspecting Eq. 3. Because VBASE requires a vector index guarantees *Relaxed Monotonicity*, an inspection of Eq. 3 could be reduced to  $M_q^s > R_q$ , where *relaxed monotonicity* checks beyond step  $s$  are all assumed to be true.

The query execution would only stop if both the original termination condition and *relaxed monotonicity* check were passed. Please note for the traditional index, the *relaxed monotonicity* check is always true, which reduces to the termination check of the convention iterative model.

Next, we describe how VBASE’s termination conditions work for TopK and distance-based ranger filter, two operators used by vector queries.

- **OrderBy with limit:** In traditional databases, TopK is usually expressed by an OrderBy operator with limit  $K$ . The traditional TopK query terminates immediately once  $K$  results have been collected, because all indexed tuples are ordered. For an approximate TopK query on vectors, VBASE need to check if the relaxed monotonicity check (i.e., reduced Eq.3) is passed, in addition to collecting  $K$  vectors. When *relaxed monotonicity* check is true, the index traversal has entered phase 2 (§3.1), which indicates it is veering away from the target vector steadily. And we can terminate the query after collecting  $K$  nearest vectors, because it is unlikely to find new vectors closer than the collected ones.
- **Range filter:** Distance-based range filter returns tuples whose values or distances to a target are within a range  $R$ . For a conventional query, the query stops when a tuple being traversed goes beyond range  $R$ , because monotonicity guarantees we have visited all tuples within  $R$ . For a vector query, the execution only stops if both a vector along the traversal path exceeds distance  $R$  and the relaxed monotonicity check is passed, which indicates we are in a stable phase (phase two) moving away from a target vector.

**Advantages of a Unified Engine.** The unified engine enables VBASE to preserve full compatibility with traditional databases and supports all the vector query types discussed in §2.1. It also creates new optimization opportunities for vector queries. For example, instead of filtering after TopK, VBASE can perform filtering during index traversal with flexible termination conditions (for TopK or range query). This optimization is one of the key reasons VBASE outperforms TopK-based solutions (§5.3). Moreover, the unified engine allows the incorporation of a refined NRA algorithm [33], which can significantly improve the performance of multi-column vector query (§4.4).

Interestingly, VBASE’s unified engine also supports vector Join. Although not an online query, vector Join is useful in scenarios such as document auto-tagging [26, 72], where a small labeled (tagged) document set is used to identify a tag for each document in a large unlabeled document set by finding the document pair with the closest document embeddings (vectors). This can be thought of as running a Join operator on a document table and a label table with a distance-based match, which can be achieved in VBASE by an index join based on a range filter. Because such a Join can only be achieved by a full table scan in existing solutions, VBASE can outperform the baseline by over  $7000\times$  (§5.3).

### 3.3 Result Equivalence

In this section we demonstrate a powerful property of VBASE’s unified query execution engine based on *Relaxed Monotonicity*, that it produces the equivalent results as a TopK

method based on a tentative monotonicity-preserving index with the optimal  $\tilde{K}$ . The optimal  $\tilde{K}$  is the minimal  $K'$  for the index traversal to satisfy  $K$  results in a TopK query. As  $K'$  is the minimal satisfactory value, the query latency is minimized. We rely on the quality of individual indices to ensure recalls.

Next, we formally prove the result equivalence for TopK+filter and range filter [20] queries, which are major types of similarity searches supported by existing TopK-based vector systems (Table 1). The proof also reveals the reason of VBASE’s superior performance.

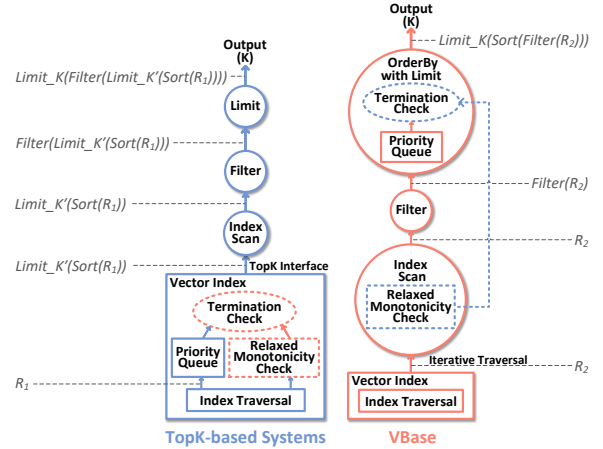

Figure 3: Result Equivalence

**TopK +filter.** To find  $K$  vectors matching the filter, a TopK-based system first collects  $K'$  vectors by calling TopK ( $K'$ ) and sorts the collected  $K'$  vectors. To achieve this, the system needs to traverse  $R_1$  vectors through the underlying vector index. The query then runs on the sorted  $K'$  vectors by applying the filter and the  $K$  limit operators, producing the final results, denoted as  $r_1$ . Eq.4 formulates the above process, illustrated on the left in Figure 3.

$$r_1 = \text{Limit}_K(\text{Filter}(\text{Limit}_{K'}(\text{Sort}(R_1)))). \quad (4)$$

We define *filter\_selectivity* as the ratio of the output set on the input set of the filter operator. Eq. 4 can then be transformed to:

$$r_1 = \text{Limit}_{K''}(\text{Filter}(\text{Sort}(R_1))), \quad (5)$$

where  $K'' = \min(K, K' \times \text{filter\_selectivity})$ .

Assuming the TopK-based system can predict the optimal  $\tilde{K}$ , i.e.,  $K' = \tilde{K} = K / \text{filter\_selectivity}$ , execution will get exactly  $K$  results, and Eq. 5 reduces to Eq. 6

$$r_1 = \text{Limit}_K(\text{Filter}(\text{Sort}(R_1))). \quad (6)$$

In comparison, VBASE traverses  $R_2$  vectors via the same vector index as the TopK-based system, and gets results  $r_2$ . Eq. 7 formulates this process, shown on the right of Figure 3.

$$r_2 = \text{Limit}_K(\text{Sort}(\text{Filter}(R_2))). \quad (7)$$

We show in §3.2 and §4 that TopK-based systems and VBASE use the same vector index, follow the same index traversal algorithm, and are based on the same relaxed monotonicity check to terminate queries. Therefore both systems traverse the exact same set of tuples, i.e.,  $R_1 = R_2$ .<sup>1</sup> Because  $R_1 = R_2$  and *Filter* and *Sort* are commutative, from Eq. 6 and 7 we conclude  $r_1 = r_2$ . **Q.E.D.**

It is difficult for a TopK-based solution to predict  $K'$  to get both correct results and high query efficiency. If  $K' \times filter\_selectivity < K$  in Eq.5, the system cannot get enough results, leading to poor accuracy. If  $K' \times filter\_selectivity > K$  in Eq. 5, the result is accurate at the expense of splurging extra index traversal. Some TopK-based system [76] performs trial-and-error with many values of  $K'$  until  $K' \times filter\_selectivity \geq K$ , which results in excessive duplicated data access and processing. In contrast, VBASE determines  $\tilde{K} \times filter\_selectivity = K$  on-the-fly, therefore achieving both high query accuracy and performance.

**Range Filter Query.** A range filter query based on TopK can be formulated as

$$r_1 = Filter(Limit\_K'(Sort(R_1))), \quad (8)$$

Where  $R_1$  stands for the traversed vectors by the underlying TopK primitive. Similar to Eq.4 vs. Eq.5, Eq. 8 can be transformed to

$$r_1 = Limit\_K''(Filter((Sort(R_1)))), \quad (9)$$

where  $K'' = K' \times filter\_selectivity$ .

Under the assumption of optimal  $\tilde{K}$ , assuming the query produces  $T$  vectors, we have  $\tilde{K} = K' = T / filter\_selectivity$ . Based on  $\tilde{K}$ , Therefore,

$$r_1 = Limit\_T(Filter(Sort(R_1))) = Filter(Sort(R_1)). \quad (10)$$

In comparison, VBASE traverses  $R_2$  vectors via the same index and gets results  $r_2$ , which can be formulated as

$$r_2 = Filter(R_2). \quad (11)$$

Since the traversal algorithm and the termination condition are exactly the same as the TopK-based solution, both systems visit the same set of vectors, i.e.,  $R_1 = R_2$ . As the filter conditions are not sensitive to order,  $r_1 = r_2$ . **Q.E.D.**

## 4 VBASE Implementation

### 4.1 Relaxed Monotonicity Check

We implement a common relaxed monotonicity check for all vector indices based on Definition 1 in §3.1. Specifically, we implement two queues to track the current traversal state: 1)

<sup>1</sup>We assume vector index traversal is deterministic, true for most vector search systems.

a priority queue with size  $E$  called `smallestQueue`, to keep the visited nearest neighbors of a target vector  $q$  during the traversal; 2) `recentQueue` of size  $w$  to track the most recent traversal window. When a new vector  $v$  is visited via index traversal, `smallestQueue` and `recentQueue` are updated accordingly. And the relaxed monotonicity check is performed by calculating the current traversal state according to Eq.(3) based on vectors in `smallestQueue` and `recentQueue`.

Note that  $E$  and  $w$  are sensitive to data distribution and specific indexing algorithms. Increasing them tends to improve query accuracy at the expense of longer latency. In practice, they can be tuned to trade off query accuracy and latency.

### 4.2 Query Execution Engine

VBASE's unified query engine is implemented based on PostgreSQL, with minor extensions to modules regarding index traversal and termination conditions.

**Vector index integration.** Existing high-dimensional vector indices only expose TopK interface and keep the index traversal and relaxed monotonicity check internally to the system. VBASE re-architects the vector indices systems by exposing the internal index traversal algorithms with `Open`, `Next`, and `Close` interfaces, which can then be integrated into Volcano Model seamlessly.

VBASE has incorporated several state-of-the-art vector indices, including HNSW [89], IVFFlat [5] and SPANN [25], where SPANN is shown effective for billion-scale vector datasets. Next, we introduce the integration of HNSW and IVFFlat, a graph-based index and a partition-based index, respectively. Other algorithms can be integrated in a similar way.

HNSW [89] is a graph-based vector index consisting of hierarchical neighborhood graphs where the upper-layer graph keeps coarse-grained samples of the lower-layer graph. A query traverses the graphs from upper-layer to lower-layer following the best-first manner. The approximate nearest point found in the upper-layer graph is the entry point of the lower-layer graph. In VBASE, we remove the implementation regarding TopK, e.g., a priority queue to record the top  $k$  results, and only keep states necessary to carry on the index traversal algorithm. The relevant states include a bitmap to record previously visited vectors, the current vector being visited, and the candidate vectors to be visited next. These states will be kept during the query life cycle. To initiate a query on a vector index, VBASE calls `Open` to search on high-layer graphs. During query execution, each call to `Next` will return the current closest unvisited node, records it, and expands its neighbors into candidate vectors in the state. The state will be cleared in `Close` function. Overall, we modify less than 200 lines of code to integrate HNSW.

IVFFlat [5] is a partition-based index, which clusters vectors into lists and chooses the centroid as the representative of each list. In the `Open` interface used to initiate index traversal, VBASE sorts all the lists from near to far based on the dis-

tance between the target vector and the centroids. Upon calls to `Next`, the vectors in the corresponding nearest lists are read one by one. The query execution state in a partition-based index includes sorted lists and the current read position, which will be destroyed by a `Close`.

**Index scan operator.** We add a new “vector index” type using the index extension interface in PostgreSQL [12] to implement index scan. It forwards function calls to `Next` to the underlying vector index within the iterative interface. We use `array` to store high-dimensional vectors in the table and record their tuple addresses in the table as the vectors’ metadata in the index. Once a vector is read from the underlying vector index, its metadata will also be returned so that VBASE can find the corresponding tuple in the main table.

Note that the relaxed monotonicity check described in §4.1 is implemented in the index scan operator so that multiple indices do not need to duplicate the implementation.

**OrderBy with limit.** VBASE implement `TopK` using `OrderBy` with `limit` plus an index scan operator. The system uses a priority queue to keep the candidate results. The `TopK` query terminates once the index traversal passes the relaxed monotonicity check in the upstream index scan operator and  $K$  vectors have been filled in the priority queue.

Note that vector indices are used for similarity queries, i.e. search closest vectors to the target vector. If a user would like to query the farthest `TopK` results from the target vector, the distance calculation method needs to be reversed before creating the indices.

**Range filter and Join.** VBASE implements an efficient range filter by concatenating it with an index scan operator. Only vectors passing the distance filter condition can be returned to the subsequent operators. The index traversal stops when the distance between the current vector to the target vector is larger than the filter constraint and the relaxed monotonicity check is passed in the index scan operator.
