**Expressiveness of Brainstorm.** Brainstorm’s abstraction can express various dynamic neural networks in a simple and concise manner. Table 3 shows the lines of code for porting the six dynamic neural network models to Brainstorm. Brainstorm unifies the API of expressing routing logic through *Router* and *Cell*. This only adds a marginal extra coding effort to porting existing models and building new dynamic models. Brainstorm eases the programming by providing common

Figure 11: Latency of Brainstorm with or without profiling.

(a) Variable Branches (b) Variable Cell Sizes

Figure 12: Performance comparison of sparse all-to-all between PyTorch and Brainstorm.

router\_fns (e.g., Top-K) and allows model developers to construct more complex ones atop them.

**Overhead of Tracing Dynamic Cell-level Dataflow.** This micro-benchmark presents the overhead of tracing dynamic Cell-level dataflow. Figure 11 shows the latency variation when tracing is on and off. The latencies of all models are almost equal before and after tracing is enabled. The average overhead is less than 1.0% for all models.

When routing actions are calculated at GPU, major overhead comes from GPU kernels for statistics. The synchronization overhead is negligible because Brainstorm dumps profiles to the CPU periodically and asynchronously.

**Effectiveness of Cell Routing.** Brainstorm’s Router decouples routing logic from execution. Brainstorm has efficient implementations to conduct dynamic data movement for sparse communication. Figure 12 demonstrates two micro-benchmarks for sparse communication, which is a multi-gpu experiment. We randomly generate 1024 Cells routed from one GPU to multiple GPUs. Figure 12a measures the latency of PyTorch’s all-to-all collective (nccl [45] as backend) and Brainstorm’s sparse communication with varied numbers of branches and GPUs. Each Cell has 512 Float32 values (same as TransformerBase [46]). Brainstorm achieves 1.88× to 2.78× speedup from 2 to 8 GPUs. Figure 12b shows Brainstorm’s speedup with a varied Cell size from 32 to 2048 Float32 values, with 4 branches on each GPU. Brainstorm achieves 2.13× to 2.66× speedup on 2 to 8 GPUs. Overall, Brainstorm performs better than PyTorch in all experiments. The root cause is the extra communication for padding using PyTorch’s all-to-all communication, which is avoided by Brainstorm’s sparse communication.

Figure 13: Latencies of serial execution, vertical fusion, and dynamic horizontal fusion with variable branches

### 7.3 Micro Benchmarks

**Dynamic Horizontal Fusion.** In the micro-benchmark of Brainstorm’s dynamic horizontal fusion, we build a simple multi-branch network, each of which contains a Conv2D operator. A Router dispatches 32x32 image patches to different branches based on image content. Brainstorm tunes kernels from 4 patches to 9 patches based on the collected Router profiles. It is conducted on the single-GPU server.

Figure 13 presents the latencies of PyTorch’s serial execution (Torch), Brainstorm’s serial execution but with tuned kernels (BRT+VF), and Brainstorm’s dynamic horizontal fusion (BRT+HF).

Vertical fusion (VF) is the commonly used fusion of consecutive operators to reduce kernel launching overhead [39, 47]. Compared to Torch, BRT+HF achieves up to 41.8× speedup. The improvement comes from two sources: the improved CU utilization with concurrent execution of multiple branches, and efficient kernels tuned for frequently appeared Cell loads. By comparing BRT+VF and Torch, we identify the statistically tuned GPU kernels that bring 13.1× speedup. The concurrent execution of multiple branches further brings 3.18× speedup (BRT+HF/BRT+VF). Since dynamic horizontal fusion has an overhead of extra GPU kernels to calculate input pointer addresses, we find BRT+HF performs slightly worse than BRT+VF (12.3μs on average) when the number of branches is small.

**Profile-Guided Placement.** In §4.2, we show that profile-guided model placement can save inter-GPU communication for dynamic NNs. In this micro-benchmark, we compare the communication latency of default placement in PyTorch with Brainstorm’s optimized placement. We conduct this experiment on the multi-GPU server. We replace PyTorch’s communication with Brainstorm’s sparse communication to isolate the improvement from efficient sparse communication. In the default placement, each GPU-*i* routes 1024 tokens to each branch on GPU-*(i + 1)* and 10 tokens per each other branch. In the optimized placement, Brainstorm can route 1024 tokens to the same GPU without inter-GPU communication. In Figure 14a, the Cell size is fixed to 512 Float32 values for evaluation with variable branches. Brainstorm achieves 2.45× to 6.23× speedup on 2 to 8 GPUs. In Figure 14b, the number

(a) Variable Branches (b) Variable *Cell* Sizes

(a) Variable *Router* latencies (b) Variable weight sizes

Figure 15: Performance comparison of default execution and hit/miss cases in speculative optimizations.

of branches on a single GPU is fixed to 4 with variable *Cell* sizes. Brainstorm achieves  $3.89\times$  to  $6.65\times$  speedup on 2 to 8 GPUs. Brainstorm achieves the improvement due to reduced communication in the optimized placement. More branches and larger *Cell* further increase inter-GPU communication volume amplifying the gap between the default placement and Brainstorm’s optimized placement.

**Hit or Miss of Speculative Optimization.** §4.3 and §4.4 introduce two speculative optimizations for dynamic NNs, i.e., speculative routing and weight preloading. The following two micro-benchmarks demonstrate a comparison between default execution and Brainstorm’s speculative optimization, conducted on the single-GPU server. We build a simple network routing an input tensor to 8 branches. Each branch has 20 `gemm` operators. Brainstorm speculatively executes Branch-0 or loads Branch-0’s weights in the speculative routing and weight preloading, respectively. Figure 15a shows inference time with varied *Router* latency. When prediction hits, *Router* latency can be hidden by `gemm` operators on the correct branch. When prediction misses, these `gemm` operators will be unrolled. Brainstorm achieves a constant inference time when prediction hits, and a similar inference time with the default execution when prediction misses.

Figure 15b shows weight preloading overhead of the same model but with varied weight sizes. Since only weights of the activated branch are loaded, the GPU memory requirement is reduced by  $8\times$ . When Brainstorm’s prediction hits, the

Figure 16: Latencies of SwitchTransformer.

weights are speculatively preloaded before *Router*, whose latency is hidden by previous computation and *Router* latency. When prediction misses, Brainstorm falls back to the default execution that loads weights of the correct branch. Brainstorm achieves a consistent latency when prediction hits, and similar latency with the default execution when prediction misses.

## 7.4 End-to-end Model Execution

### 7.4.1 SwitchTransformer

In SwitchTransformer, each expert has a capacity of 64 tokens for each sentence. By analyzing *Router* profiles, we find an imbalanced distribution of the number of tokens routed to each expert (shown in Figure 2a). This motivates us to apply dynamic horizontal fusion to execute experts in parallel with GPU kernels tuned for different loads. We use the official weights trained by Google with 8 to 256 experts per MoE layer. The batch size is 8, and each sentence has 128 tokens. The experiment is conducted on the single-GPU server.

Figure 16 shows latencies of SwitchTransformer with official implementation in PyTorch (*Torch*), replacing MoE layers with an optimized implementation from Tutel (*Tutel*), and Brainstorm with dynamic horizontal fusion. The official implementation executes experts in serial. Tutel runs experts concurrently with `BatchMatmul`, which requires padding to the same number of tokens for all experts. Brainstorm outperforms by  $3.63\times$ , and  $3.33\times$  compared to *Torch*, and *Tutel*, respectively. The speedup increases with more experts in each MoE layer. In addition to improved utilization of concurrently executed experts, Brainstorm also benefits from imbalanced token distribution. Because many experts only receive a few tokens, Tutel pads many dummy tokens in all paths, leading to vast wasted computation on padding. The excessive padding also uses more GPU memory leading to out-of-memory in Tutel when there are 256 experts. By analyzing loads of different branches, Brainstorm compiles multiple GPU kernels to minimize the padding.

### 7.4.2 LiveSR

LiveSR is our internal model for super-resolution, which slices a single image into  $32\times 32$  patches and routes them to different branches. It uses a ResNet-18 model to extract patterns, which are then routed by K-nearest neighbor (kNN) to multiple branches. By collecting the routing distribution of patches,

Figure 17: Latencies of LiveSR in Brainstorm with vertical fusion and dynamic horizontal fusion.

we find a distribution in the number of patches routed to each branch (as shown in Figure 2b). This creates the opportunity for Brainstorm to tune GPU kernels for frequently *Cell* loads. Also, since different patches of an image are routed to different branches, Brainstorm can horizontally fuse these branches to concurrently execute them to improve CU utilization.

Figure 17 shows latencies of LiveSR with different optimizations, while being executed on the single-GPU server. BRT+HF applies dynamic horizontal fusion of both multiple branches and multiple tuned kernels of different loads. To dissect the improvement of both types of fusion, we evaluate BRT+VF that only fuses Conv2D, BatchNorm, and ReLU operators in each branch but with statistically tuned GPU kernels. In Figure 17, we vary both the number of branches with a fixed number (8) of channels and the number of convolution channels with a fixed number (10) of branches.

Overall, BRT+HF achieves up to  $8.62\times$  speedup compared to BRT. BRT+VF brings a speedup up to  $3.5\times$  compared with BRT. BRT+HF further brings  $1.79\times$  to  $2.48\times$  gains over BRT+VF with an increasing number of branches because of the improved CU utilization with more branches. When increasing the number of channels, we find the latency of BrainstormBRT+HF remains the same until it reaches 20 channels as it goes beyond the upper bound of GPU CUs.

### 7.4.3 TaskMoE

TaskMoE routes input tensors at the granularity of the sentence. Each MoE layer has 16 experts. Each sentence is routed to 2 experts. The key difference of TaskMoE is its routing algorithm: it decides expert of a sentence based on *task type*. Sentences of the same task will be routed to the same expert branches. Therefore, as we have shown in Figure 2c, TaskMoE has a strong inter-layer expert correlation that experts of the same task are activated together with a high probability, which brings the opportunity for profile-guided placement.

Brainstorm optimizes placement by reordering experts of MoE layers for the most efficient communication. Brainstorm’s *Routers* are aware of reordering and dispatch sentences to correct GPUs in the optimized placement. We conduct this experiment with three input settings: 256 sentences on each GPU with 32/64 tokens in each sequence; 512 sequences on each GPU with 32 tokens in each sequence. The

Figure 18: Throughput of TaskMoE. Torch: routing with PyTorch’s native communication primitive. BRT: routing with Brainstorm’s sparse communication primitive. BRT+P: placement optimized routing over BRT.

Figure 19: Throughput of SwinV2-MoE. G: the number of GPUs. E: the number of experts per GPU.

task ID of each sequence is randomly generated. Since routing of TaskMoE only works on task ID, the synthetic dataset does not affect the optimal placement and evaluation conclusion.

Figure 18 shows the per-GPU throughput on 2-8 GPUs. The experiment is conducted on the multi-GPU server. Compared with Torch, BRT first brings up to  $1.17\times$  speedup with efficient sparse communication. The speedup of BRT grows with more GPUs because of the increased data volume for inter-GPU transmission. Brainstorm’s sparse communication saves unnecessary communication due to padding. On top of this, BRT+P further achieves up to  $1.34\times$  speedup with the optimized placement. The optimized placement derived from runtime profiles helps BRT+P to reduce  $42\sim 87\%$  inter-GPU communication, speeding up routing of MoE layers.

### 7.4.4 SwinV2-MoE

SwinV2-MoE is the MoE-version of SwinTransformer [41] for image tasks, introduced in Tutel [22]. It defines tokens as *Cells*, each of which contains  $384 \text{ float}_{32}$  values tokenized from a  $48\times 48$  image patch. SwinV2-MoE uses a capacity factor to control the number of patches each expert receives. When the capacity is exceeded, extra patches are dropped during routing. The capacity factor varies in  $[1.25, 2.0, 3.0, 4.0]$  in the experiments. We evaluate SwinV2-MoE with 16 experts on the multi-GPU server by evenly placing the experts on each GPU with 128 images for each inference.

Figure 19 shows throughput of four approaches: a PyTorch

Figure 20: Gaps between the *best* and the *worst* placement for MoE Layers in SwinV2-MoE with varied capacity factors.

implementation using DeepSpeed-MoE [48] (DeepSpeed), optimized version with Tutel’s MoE kernels [22] (Tutel), optimized version with Brainstorm’s Router (BRT), and Brainstorm’s profile-guided placement optimization (BRT+P). Brainstorm’s efficient Router first brings up to  $5.04\times$  and  $1.52\times$  speedup over DeepSpeed and Tutel, respectively. Both BRT and Tutel use custom GPU kernels for efficient routing inside a GPU, thus greatly outperforming DeepSpeed, which uses `einsum`. With an increased capacity factor, BRT brings higher speedup over Tutel because of saved inter-GPU communication due to increased padding.

By optimizing expert placement via runtime profiles, we find BRT+P only brings marginal improvement. After using Brainstorm’s efficient Router, SwinV2-MoE model only spends up to 35% of time on inter-GPU communication, which reduces the potential by further reducing communication overhead. Similar to TaskMoE, we do observe different expert placements have greatly varied efficiency. Figure 20 shows our evaluation of a single SwinV2-MoE layer to compare the performance of the best placement and the worst placement with 8 GPUs and 2 experts per GPU. The gap is up to  $1.26\times$  speedup for ten SwinV2-MoE layers. The smaller the layer id is, the more imbalance appears in token distribution, creating more space for improvement by placement. It shows great potential for larger MoE models with more experts, whose communication latency dominates [22].

#### 7.4.5 MSDNet

MSDNet [1] is a dynamic network that can adapt this execution path to the computational resource limits at test time. The network contains 5 exits that allow the inference of an image to end in the middle, if the output quality is higher than the predefined thresholds. Users can configure the threshold of each exit to control the inference cost. For instance,  $[0, 0, 0, 0.4, 0.6]$  represents that 40% of the inferences in the dataset end at the 4th exit and 60% end at the last exit. There are no inferences ending at the other exits.

Figure 21 shows the experiment results with 6 kinds of exit configurations applying different optimizations, running on the single-GPU server. We set the batch size to a single image at inference. We first tune the GPU kernels with vertical fusion (BRT+VF) as the baseline. On top of that, we first

Figure 21: Latencies of MSDNet with vertical fusion, speculative routing, and dynamic horizontal fusion.

Figure 22: Latencies of DynamicRouting.

apply speculative routing (BRT+SP) and then dynamic horizontal fusion (BRT+HF) to evaluate the benefits of dynamic optimizations. Compared with BRT+VF, Brainstorm achieves up to  $8.44\times$ ,  $11.7\times$  speedup by BRT+SP and BRT+HF, respectively. We observe BRT+SP reduces higher latency when the inferences end at either very early exits or very last exits, due to the speculative routing making more correct predictions. If the inference has a similar opportunity to end at each exit, BRT+SP has a similar performance with BRT+VF (e.g., for  $[0.1, 0.1, 0.2, 0.3, 0.3]$ ). For dynamic horizontal fusion (BRT+HF), Brainstorm performs better when the inferences prefer ending at the last exits, further bringing up to  $1.57\times$  gain over BRT+SP. The root cause is the uncertain routers break many horizontal fusion opportunities. MSDNet has some operators that can be executed in parallel if the inference does not end at an exit. If a Router may terminate in the middle, Brainstorm cannot determine whether it is safe to horizontally fuse them, thus falling back to BRT+VF.

#### 7.4.6 DynamicRouting

DynamicRouting [28] is a semantic segmentation model for images that introduces a lot of Routers. It contains 186 Routers and 186 computation operators, leading to a very high routing overhead. At each Router, input images are routed to 1 or 2 branches among 3 designed branches with convolution operators for down-sampling, up-sampling, or keeping-resolution, respectively. DynamicRouting proposes four architecture configurations (A, B, C, and Raw for short, in order of growing computation). By analyzing Routers’ runtime profiles collected by Brainstorm, we find many Routers exhibit a high probability of making consistent routing decisions, which brings opportunities for speculative optimizations. The following experiments are conducted on the single-GPU server.

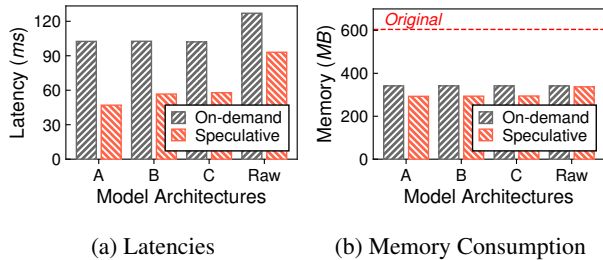

Figure 23: Speculative weight preloading of DynamicRouting with variable model architectures.

Figure 22 presents the latency of four configurations optimized by Brainstorm’s speculative routing (BRT+SP), where batch size is set to a single image. Brainstorm achieves up to  $1.7\times$  speedup compared to the official implementation in PyTorch (Torch). BRT+SP achieves  $1.7\times$ ,  $1.58\times$ ,  $1.57\times$ , and  $1.29\times$  speedup compared with Torch in the four architecture, respectively. With statistical distribution derived from the runtime profiles, BRT+SP can predict the routing decisions of the 186 routers with an accuracy of 90% ~ 95%. This greatly reduces the routing overhead in the four model architectures. As we have shown in the micro-benchmark of Figure 15a, the overhead of speculative routing is negligible even when the prediction is wrong.

Figure 23 shows the inference latency and the GPU memory usage of DynamicRouting optimized by Brainstorm’s speculative weight preloading. In the baseline (on-demand loading), Brainstorm only loads the weight of a branch after the routing decision is made. Brainstorm will preload the weights of the branch to be activated with the highest probability, and falls back to on-demand loading if the prediction is wrong. Because the weight loading latency is hidden, Brainstorm’s speculative optimization can accelerate the model inference by up to  $1.97\times$  than on-demand loading. Moreover, the official implementation needs to load all model weights to the GPU memory for single-image inference (i.e., 604.5MB of Original in Figure 23). With on-demand loading and speculative preloading, memory usage is greatly reduced by 50.7% and 43.5%, respectively. This creates the opportunity to infer large models on GPUs with limited GPU memory. Brainstorm’s speculative weight preloading requires slightly lower GPU memory than on-demand loading. This is because speculative weight preloading also releases some GPU memory in advance speculatively.

## 8 Discussion

**Handling distribution drift.** The profiling data is analyzed offline by dynamic optimization policies. Profiling data should be statistically representative of reality; otherwise, it could mislead Brainstorm’s optimization and result in reduced or even negative gain. As shown in Figure 24, the impact de-

Figure 24: Speedup of Brainstorm’s dynamic horizontal fusion when the distribution of branch loads drifts from the statistics used for tuning GPU kernels.

pends on the models and the degree of drifts.

Figure 24 evaluate the impact of distribution drift on dynamic horizontal fusion. Based on the collected profiles, Brainstorm only tunes Conv2D kernels with 4 and 27 patches. Therefore, when a branch receives more than 4 patches, it needs to be padded to 27 patches running with the non-optimal 27-patch kernel. An initial dispatch of 4 patches per branch is made so that no padding is needed. To simulate increasing distribution drift, we add loads of some branches to 8 patches, which are less frequently appearing in the profile and thus not tuned by Brainstorm. We define the *distribution drift ratio* as the fraction of branches whose received patches differ from the tuned shapes (4 and 27 in this experiment). In Figure 24, we find the speedup of Brainstorm’s dynamic horizontal fusion BRT+HF diminishes with an increasing drift ratio, from  $4.65\times$  to  $2.11\times$ , compared with applying only vertical fusion. This is due to the wasted computation from the padding on branches receiving 8 patches.

The optimization policy needs to monitor profiles continuously collected by Brainstorm and triggers re-optimization when distribution drifts. It takes time for re-optimization (usually a few minutes), e.g., searching for a new placement, and tuning new GPU kernels. Therefore, during cold-start or re-optimization, the model execution does not use dynamic optimization. Currently, Brainstorm focuses on the mechanisms of enabling dynamic neural optimizations. We hope to inspire more advanced solutions to be robust to distribution drifts.

**More dynamic optimization opportunities.** Brainstorm can also be applied to training. When fine-tuning MoE-based Large Language Models, the statistics of expert activation can be leveraged similarly with inference, e.g., re-arranging the expert placements across GPUs to reduce communication volume. Moreover, many algorithms in Neural Architecture Search also design dynamic architectures (e.g., DARTS [49], SPOS [50]), whose activation is known only at runtime. Their latter stage of training may show more stable branch activation, which can be potentially exploited by Brainstorm.

To support training, there are still some engineering efforts that need to be resolved. Firstly, backward propagation

is needed for automatic differentiation in training, which is missed in the current implementation. Secondly, some operators may invalidate Brainstorm’s tracing for dynamic optimization. For instance, `Batchnorm` performs cross-*Cell* computing different from the *Cell*-level computation at inference, which requires manual specification.

Brainstorm can also be applied to dynamic sparsity, which uses different value/block-level sparsity patterns for different inputs (e.g., Longformer). To optimize their execution, Brainstorm needs to collect pattern statistics at a fine granularity. Then we can compile multiple specialized GPU kernels for different sparsity patterns (e.g., using SparTA [51]), and activate the most efficient one at runtime.

## 9 Related Works

**Deep Learning Frameworks for Dynamic NNs.** Popular DL frameworks can express dynamic neural networks via control-flow operators in static DFGs (e.g., TensorFlow 1.x [52]) or Python native control-flows (e.g., PyTorch [32], JAX [53], TensorFlow Eager [54]). They are capable of expressing dynamic neural networks in very flexible ways. However, their tensor-centric DFGs are hard to be analyzed at the sub-tensor level. As shown in §5.1, many dynamic NNs require *Cell*-level dataflow analysis, which the tensor-centric programming model misses. Brainstorm unifies how dynamic NN should be expressed so that the required information for dynamic optimization can be easily traced.

Optimization of dynamic NNs has also been studied in recent years, which mainly focuses on specific types of dynamism. Cava [55], DyNet [56], BatchMaker [57], TensorFlow Fold [58], DVABatch [59], ICE [60], and PAME [61] focus on dynamic batching [62] for the cases when the batch size is dynamic. Cortex [63] is a framework for recursive neural networks with compiler optimization. DietCode [64] is an auto-scheduler framework for optimizing dynamic shapes. Nimble [65] and DISC [66] are compilers to express and execute dynamic neural networks. Brainstorm is orthogonal to them by exploring a new optimization space that leverages runtime statistics of *Cell*-level dynamism.

**Optimization of deep neural networks.** Most optimizations of existing DL compilers and frameworks are proposed for optimizing static neural networks. TVM [39] expresses operators as loop optimization schedule primitives and search for efficient kernels. Anso [67] enlarges the search space via a hierarchical representation of the search space. Roller [68] uses a cost model to reduce the overhead of searching efficient kernels. XLA [47], Rammer [33], TASO [69], Tacker [70], TVM [39] also performs graph-level optimization on static DFGs, e.g., operator fusion. Pathways [71] proposes asynchronous distributed dataflow for large-scale distributed training. Brainstorm differs from these works in that it introduces

new optimization spaces for dynamic NNs through sub-tensor-level profiling. Brainstorm’s dynamic optimizations focus on exploring the runtime dynamism distribution of dynamic NNs, which are orthogonal to these works.

Moreover, Brainstorm’s *Router* separates the dynamic control flow from the dataflow graphs, which makes it easier to extract the static sub-networks for applying existing static optimizations. Brainstorm focuses on optimizing dynamic fragments in dynamic NNs and leaving optimizations of static sub-networks to existing compilers. With statistics of sub-tensor-level profiles, Brainstorm employs TVM [39] for kernel autotuning. Brainstorm can also leverage Pathways [71] to build an efficient execution plan to better fit the runtime dynamism, e.g., partition models with better affinity.

**Profile-guided optimization in modern programming languages.** Compilers for programming languages, e.g., HotSpot JVM [16], Dot-Net Core 2.0 [17], Clang [25], have supported dynamic optimization by collecting runtime statistics of programs and then compiling new optimized versions for future execution. Brainstorm is inspired by them and identifies new dynamic optimizations specific for dynamic NNs.

## 10 Conclusion

In this paper, we identify a new space of dynamic optimizations for dynamic NNs by collecting and analyzing runtime profiles to specialize the model execution to dynamism distribution. We propose Brainstorm, the first deep learning framework that optimizes the execution of dynamic NNs. The core of Brainstorm is *Cell* and *Router*, that lets model developers express dynamic NNs at the granularity of dynamism so that the necessary information for dynamic optimizations can be traced. Model developers can focus on designing the dynamic model architecture while leaving the optimization to the Brainstorm framework. In Brainstorm, we propose four dynamic optimizations leveraging the runtime profiles at different granularity. Our evaluation shows Brainstorm can accelerate popular dynamic neural networks by up to  $11.7\times$  ( $3.29\times$  on average) or reduces GPU memory usage by 42%.

## A Artifact Appendix

### Abstract

Brainstorm unifies the programming of dynamic NNs with *Cell* and *Router* abstraction which enables a new space of dynamic optimizations for dynamic NNs. This artifact reproduces the main results of the evaluation in both single-GPU and multiple-GPU environments.

### Scope

This artifact will validate the following claims:

1. **Effectiveness of Brainstorm Abstraction:** By reproducing the experiments of [Figure 12](#), we can validate the effectiveness of Brainstorm's abstraction.
2. **Micro Benchmarks:** By reproducing the experiments of [Figures 13–15](#), we can validate the proposed dynamic optimizations with micro benchmarks.
3. **End-to-end Model Execution:** By reproducing the experiments of [Figures 16–23](#), we can validate the end-to-end latency of Brainstorm claimed in §7.

### Contents

In this artifact, we will reproduce the [Figures 12–23](#). Each figure has a shell script to reproduce and visualize the evaluation results automatically. In addition, we also provide a pre-built Docker image hosted on [Github Container Registry](#). Users can quickly initiate a container with this image, which has preconfigured experimental environments.

### Hosting

The artifact is hosted at <https://github.com/Raphael-Hao/brainstorm/tree/osdi2023ae>. To get the code, please git clone the Brainstorm repository and checkout to the `osdi2023ae` branch.

### Requirements

1. **Hardware Requirements:** [Figures 13, 15–17](#) and [21–23](#) requires a server with a NVIDIA A100 (80GB) GPU, [Figures 12, 14](#) and [18–20](#) requires a server with eight NVIDIA V100 GPUs.
2. **Software Requirements:** Please use docker to build the `docker/Dockerfile.update` to setup the environment for single and multiple-GPU experiments. A one-click script `python scripts/docker_gh_build.py -type latest` is also provided to build the image.
3. **CUDA Driver:** Larger than 11.3

## Tutorial

Please follow the instructions in `README.md` to reproduce the main results.

# AdaEmbed: Adaptive Embedding for Large-Scale Recommendation Models

## Abstract

Deep learning recommendation models (DLRMs) are using increasingly larger embedding tables to represent categorical sparse features such as video genres. Each embedding row of the table represents the trainable weight vector for a specific instance of that feature. While increasing the number of embedding rows typically improves model accuracy by considering more feature instances, it can lead to larger deployment costs and slower model execution.

Unlike existing efforts that primarily focus on optimizing DLRMs for the given embedding, we present a complementary system, AdaEmbed, to reduce the size of embeddings needed for the same DLRM accuracy via in-training embedding pruning. Our key insight is that the access patterns and weights of different embeddings are heterogeneous across embedding rows, and dynamically change over the training process, implying varying embedding importance with respect to model accuracy. However, identifying important embeddings and then enforcing pruning for modern DLRMs with up to billions of embeddings (terabytes) is challenging. Given the total embedding size, AdaEmbed considers embeddings with higher runtime access frequencies and larger training gradients to be more important, and it dynamically prunes less important embeddings at scale to automatically determine per-feature embeddings. Our evaluations in industrial settings show that AdaEmbed saves 35-60% embedding size needed in deployment and improves model execution speed by 11-34%, while achieving noticeable accuracy gains.

## 1 Introduction

Deep learning recommendation models (DLRMs) are important to many online services, including Google advertisement display [9, 10], Netflix movie recommendations [15, 27], and Amazon e-commerce [40], and comprise up to 65% of AI cycles in Meta’s datacenters [13, 18]. Unlike conventional machine learning (ML) counterparts that train models on continuous input features (e.g., color values of images), DLRM inputs consist of continuous dense features (e.g., timestamp) and categorical sparse features (e.g., video genres). Each sparse feature is often associated with an embedding table, where each instance of that feature is represented by a trainable embedding row (weight vector). In the forward and backward

passes of model execution, the model reads and updates the embedding weights of accessed rows.

Because the accuracy of a DLRM typically increases with larger embeddings (e.g., by considering more feature instances), modern DLRM embedding size is ever growing (up to terabytes and billions of embeddings [13, 50]). This introduces multiple challenges. First, DLRMs often have stringent throughput and latency requirements for (online) training and inference [26, 45], but gigantic embeddings make computation [34], communication [4, 39] and memory optimizations [13, 52] challenging. To achieve desired model throughput, practical deployments often have to use hundreds of GPUs to hold embeddings [35]. Meanwhile, designing better embeddings (e.g., number of per-feature embedding rows and which embedding weights to retain) remains challenging because the exploration space increases with larger embeddings and requires intensive manual efforts [32, 49].

Unlike existing DLRM efforts that have primarily focused on optimizing the model’s execution speed for the given embeddings – e.g., by balancing embedding sharding [35, 52], accelerating embedding retrieval [39, 44], compressing embeddings [19, 48], or elastic resource scaling [45, 51] – we explore a complementary opportunity: *Can we fundamentally reduce the size of embedding needed for the same accuracy, by dynamically optimizing the per-feature embedding during model training?* Or, equivalently, *can we improve model accuracy for the given embedding size?* This is because unlike classic ML models, the DLRM model output (accuracy) is determined by the input data (e.g., accessed instances) and their embedding weights, and the input data is typically organized chronologically during training to account for the diverse and non-stationary user preferences [53]. Therefore, the access patterns and the weights of embeddings vary across embeddings rows and the training process (§2.2). This implies an opportunity to admit and prune embedding rows based on their heterogeneous importance to improve model accuracy.

In this paper, we introduce an *automated in-training pruning system* to Adaptively optimize per-feature Embeddings (AdaEmbed) for better model accuracy. For the given embedding size, AdaEmbed scalably identifies and retains embeddings that have larger importance to model accuracy at particular times during training. As a result, not only does it reduce human effort in embedding design, but it also cuts down the embedding size, thus the computational, network,

\*Work done while the author was working at Meta.

and memory resources, needed to achieve the same accuracy. AdaEmbed is complementary to and supports existing DLRM efforts with a few lines of code changes (§3).

Unfortunately, identifying important embeddings out of billions is non-trivial. To maximize the overall model accuracy, we should retain the embedding rows that affect model inputs more often (e.g., are frequently accessed) and that affect model outputs the most (e.g., have larger weights) (§4.1). However, the non-stationary data distribution during training leads to the spatiotemporal variation in the access frequency of different embeddings. e.g., new videos are posted and become popular, while some old ones lose popularity. Moreover, embedding weights change over training iterations and so does their impact. Once we prune an embedding’s weights from the GPU memory, we cannot accurately capture their importance to model accuracy as training moves on. Based on our analytical insights, embeddings with larger runtime gradients and higher access frequencies tend to accumulate larger embedding weights, and AdaEmbed prioritizes them when deciding which ones to retain. Moreover, we group features with similar feature-level characteristics (e.g., vector dimensions), and then identify important embeddings across feature groups to optimize the per-feature embedding size and which embedding to retain (§4.1).

Enforcing in-training pruning after identifying important embeddings is not straightforward either. Pruning for practical DLRMs can require reallocating millions of embedding rows and tens of gigabytes of embedding weights per training iteration, whereas each iteration takes only a few hundred milliseconds [4, 35]. While frequent pruning allows admitting important embeddings in a timely manner, thereby improving model accuracy, it can slow down model training by many hundred times (§4.2). To achieve a sweet spot between timely pruning and low overhead, AdaEmbed initiates pruning selectively when perceiving big changes in the importance distribution of all embeddings, thus reducing the number of pruning rounds needed while ensuring high accuracy. However, existing DLRM systems face difficulty in dynamically admitting and pruning embeddings at scale because they often rely on static and/or fixed-size embedding storage [1–3, 44]. AdaEmbed introduces a shim layer, Virtually Hashed Physically Indexed (VHPI) embedding, to support various embedding designs. VHPI decouples the management of embeddings from their physical weights, whereby it recycles the weight vector of embeddings to avoid intense memory allocation (§4.3).

We have implemented a system prototype of AdaEmbed (§5) and evaluated it using five industry models and months of data across hundreds of GPUs (§6). Our evaluations show that AdaEmbed can reduce 35-60% embedding size, implying comparable resource savings, and improve model execution speed by 11-34% without compromising model accuracy. Meanwhile, it achieves noticeable accuracy gains under the same embedding size, thus being able to reducing manual efforts by automatically finding better per-feature embeddings.

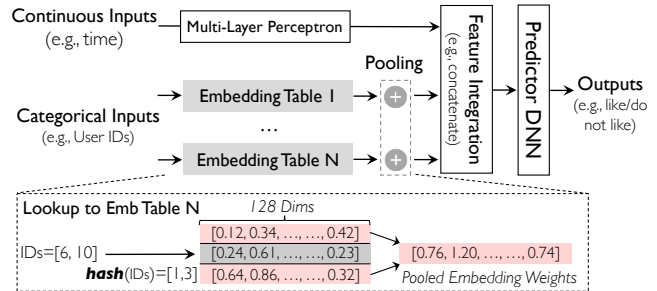

Figure 1: DLRM models consist of large embedding tables.

Overall, we make the following contributions in this paper:

1. We propose an in-training pruning system, AdaEmbed, to automatically optimize DLRM embeddings.
2. We introduce embedding importance to capture important embeddings and employ VHPI embedding to enforce scalable pruning, with few changes to existing designs.
3. We evaluate AdaEmbed in various real-world settings to show its resource savings and accuracy gains.

## 2 Background and Motivation

We start with a quick primer on DLRMs (§2.1), followed by the challenges it faces and inefficiencies of the state-of-the-art based on our analysis of real-world experiments (§2.2). Next, we highlight the opportunities that motivate our work (§2.3).

### 2.1 Deep Learning Recommendation Models

As shown in Figure 1, a DLRM consists of a combination of fully connected multiple-layer perceptrons (MLPs) to capture continuous dense features (e.g., timestamp), and a set of embedding tables to map various categorical sparse features (e.g., user and video IDs) to a dense representation. DLRMs can contain up to thousands of sparse features: each feature is typically associated with an embedding table, and each table can have millions of rows [15, 35, 52]. Each embedding row is a multi-dimensional weight vector (e.g., 128 floats) corresponding to a specific feature instance (e.g., a specific user ID of feature "User IDs").

DLRMs differ from traditional computer vision (CV) and natural language processing (NLP) models in that they require training on large volumes of data organized chronologically, to keep up with the latest recommendation trends. Hence, the distribution of training data changes over the training process. In the forward pass of model computation, each input sample includes a set of embedding IDs for each table to extract the corresponding embedding weights (vectors). To reduce the computation complexity, embedding weights of a sample will be pooled per table using the element-wise *pooling* operator, which typically takes the sum or maximum along each vector dimension (Figure 1). The pooled embedding weights of mini-batch samples are packed together with their intermediate outputs of dense features, forming a batch input to deeper layers. In the backward pass, the weights of the accessed embeddings are updated using the gradient.

**Figure 2: The number of sparse feature instances (IDs) increases rapidly over time, while the lifespan of instances is heterogeneous.**

Due to the enormous number of sparse feature instances, their embedding weights can occupy more than 99% size of a commonly used model (up to several terabytes) [21]; so DL-RMs exhibit much larger memory intensity than conventional ML models (e.g., ResNet). As such, practical DLRM deployments use a combination of model parallelism for sparse feature layers and data parallelism for MLPs. The former allocates different embedding partitions across workers to avoid replicating them, and the latter enables concurrent processing of dense feature inputs [13]. Even so, model deployments often require hundreds of GPUs to achieve the desired model throughput (a few hundred milliseconds per iteration) [4, 35].

## 2.2 Challenges in DLRM Deployment

Due to its significant impact on revenue and numerous iterations needed to train a DLRM model, DLRM deployments follow the “achieve better accuracy and run as fast as possible” paradigm [35, 45, 52]. The execution speed and accuracy of a DLRM model are respectively measured by Query-Per-Second (QPS) throughput and Normalized Entropy (NE) loss [22]. Larger QPS and smaller NE indicate better performance, and any relative  $> 0.02\%$  NE gain is considered to be significant [13, 46]. However, optimizing both aspects leads to novel tussles and challenges in real-world deployments.

**Larger embedding sizes improve NE** Embedding size of modern DL-RMs is ever-growing to accommodate more embedding rows for sparse features and their instances [35, 44]. Figure 2 reports the size of the instance set over 15 days’ data in a real-world DLRM system. We observe that even though a small portion of the trained instances will seldom be accessed again in later days (Figure 2(a)), the total number of unique instances increases by  $1.5\times$  every week (Figure 2(b)). As DL-RMs are often trained on 1.5 months of data and retrained over time, the size of the instance set will eventually far exceed the embedding size. To cap the embedding size, existing designs often perform hashing on the raw instance IDs, and then use the hashed IDs to access their embedding rows [3].

Intuitively, using more embedding rows implies more instances are considered, thus enabling better data coverage for better NE. Figure 3(a) reports the impact of the embedding size on the NE regression at different times of training. NE regression denotes the accuracy degradation of using a smaller

(a) Large embeddings improve NE. (b) Large embeddings hurt QPS.

**Figure 3: Compared to the full ( $1\times$ ) model, smaller embedding sizes hurt model NE (i.e., larger NE regression), but improve QPS.  $0.25\times$  and  $0.5\times$  denote using 25% and 50% of the full model size.**

embedding size w.r.t. the full-size model. We notice that (i) using a smaller embedding size can greatly hurt NE. For example, reducing the number of embedding rows by 75% (i.e.,  $0.25\times$  model) results in  $\sim 0.02\%$  NE regression on Day 2; Worse, (ii) this NE regression inflates as the training evolves over time as more instances are spawned.

**Large embedding sizes hurt QPS** However, using more embeddings can slow down model execution and consume more machine resources in multiple execution phrases: (i) slower embedding access if we can not retain all embeddings in high-bandwidth GPUs; (ii) longer communication as we may need to transfer more embeddings over the network [4, 50]; and (iii) longer computation as more embeddings need to be computed on. Figure 3(b) shows, compared to the full model,  $0.5\times$  model achieves  $1.4\times$  QPS speedup in the same resource setting. Here, we note that state-of-the-art DLRM optimizations [35, 44], which cache and prefetch the embeddings to be accessed in future batches, cannot eliminate the QPS drop (Figure 3(b)). More importantly, they can be insufficient for online training and model serving as we may not know the input data in advance.

## 2.3 Opportunities for In-Training Pruning

For a given DLRM, recent advances have made considerable progress for efficient communication [4, 19, 39] and/or computation [13, 26, 35]. Instead, we focus on a complementary opportunity that *reduces the embedding size needed without NE regression, by adaptively pruning embeddings during model training*. Our approach is based on the following observations.

**Handcrafted embeddings are suboptimal** Designing optimal embeddings (e.g., deciding the number of per-feature embedding rows and which embedding weights to retain) is as yet an open problem in the ML community [14]. Hence, DLRM systems often decide the embedding size using human-defined rules, e.g., by estimating the feature popularity [14] and/or hyper-parameter tuning by model experts before training takes place [52]. Not only does this require great human effort and resources to explore, but it can also be suboptimal due to limited adaptivity at runtime (e.g., deciding which instance’s embedding to retain if many instances are generated).

(a) Utilization of embedding tables. (b) Heterogeneous ID access.

**Figure 4: Embedding access varies across IDs and over time, leading to distinct table utilization in existing embedding designs.**

Worse, existing DLRM systems often treat per-feature embedding tables individually for ease of management. This can underutilize or overload individual tables as data distribution changes over time. Indeed, when we analyze the table utilization in a one-day training window (i.e., number of accessed embeddings over the total number of embeddings on that day), we notice large heterogeneity (Figure 4(a)). Intuitively, tables that are fully utilized can degrade NE because many instances are hashed to the same embedding row, leading to hash collisions. However, underutilized tables cannot trade in their space during training because of the suboptimal pre-determined embedding size and inelastic embedding designs.

**Embeddings have heterogeneous characteristics** Figure 4(b) zooms into individual embedding rows, where the sampled IDs (i.e., x-axis) are ordered based on their access frequency on Day 1. We notice that the access frequency of embeddings varies across embedding IDs and over time, since user preferences change over time. We have similar observations on embedding weights too (§4.1). Since the model output (accuracy) is determined by the input instance (e.g., which embedding is accessed) and embedding weights, this implies a potential to identify and retain more important embeddings during training to maximize final model accuracy.

### 3 AdaEmbed Overview

In this paper, we introduce an *automated in-training pruning system*, AdaEmbed, to adaptively optimize per-feature embeddings at scale for better model accuracy. Unlike existing efforts for model pruning, which focus on conventional models [8, 11, 20] and/or prune model size when training completes [32], AdaEmbed automatically identifies and retains important embeddings for the given embedding size to improve performance while training is ongoing. Our evaluations in industrial settings show that in addition to saving resource throughout training, AdaEmbed provides superior model accuracy to its post-training pruning counterparts (§6.4).

AdaEmbed is a complementary system that acts as a shim layer atop today’s embedding designs (Figure 5). It has a central coordinator and a set of distributed on-worker agents:

- *AdaEmbed Coordinator*: It gathers the embedding information from agents, determines the global pruning decision, and orchestrates the agent to enforce the pruning.

**Figure 5: AdaEmbed overview and its in-training execution flow. AdaEmbed components are in red.**

- *Memory Manager*: It is located inside each AdaEmbed agent and manages the physical memory for today’s embedding designs. At runtime, it receives the pruning decision from the coordinator and executes pruning on local embedding weights.
- *Embedding Monitor*: It resides along with the memory manager to track embedding importance and reports the profiling results of the importance to the coordinator.

Figure 6 illustrates the interface of AdaEmbed, which supports existing DLRM systems in a few lines of code.

```

1 import AdaEmbed
2
3 def dlr_model_training():
4     # Wrap existing embedding modules
5     emb_agent = AdaEmbed.create_agent(
6         emb_tables=model.embs, pruning_config=config)
7
8     for _ in range(num_ iterations):
9         input_ids = get_next_data_batch()
10
11        # Look up physical embedding address
12        emb_physical_ids = emb_agent.look_up(input_ids)
13        feedback = model.train_step(emb_physical_ids)
14
15        # Update embedding importance with feedback
16        emb_agent.update_importance(input_ids, feedback)

```

**Figure 6: AdaEmbed supports existing DLRMs with minor changes.**

**Training Lifecycle** Similar to current DLRM deployments, ① each worker is in charge of a subset of sparse features, which is determined by the embedding partition of model parallelism. The worker processes the input data (i.e., a list of embedding IDs) of those features. ② However, the inputs are first forwarded to AdaEmbed agent to look up the physical address of each embedding’s weights (Line 12). ③ The physical address is then used to fetch the embedding weights for read and write operations. The rest of model training adheres to existing designs. ④ After each training iteration, the embedding monitor updates the embedding importance with the training feedback (Line 16). Periodically, it samples the importance of different embedding rows and notifies the coordinator of the profiling results. The coordinator determines how to prune embeddings subject to the total embedding size and guides the

memory manager to admit and prune embeddings at scale.

## 4 AdaEmbed Design

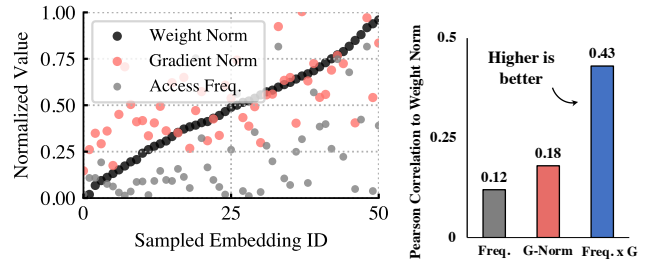

Practical DLRMs often contain hundreds of sparse features and up to billions of embedding rows [13, 50]. They run across hundreds of GPUs on non-stationary model inputs to get the desired model execution speed [4, 35]. These lead to the following challenges toward practical in-training pruning of embedding rows:

- *Heterogeneity*: The characteristics of embeddings (e.g., data distribution and embedding weights) vary across instances of the same feature. This, as well as the physical size of the embedding row, differs across features too. How to measure which embeddings are important to retain for better model accuracy (§4.1)?
- *Dynamics and Scalability*: The importance of individual embeddings varies over iterations at a sub-second speed. As such, improving model accuracy requires pruning in a timely manner to maximize the number of important embeddings. However, identifying important embeddings out of billions distributed across hundreds of workers, and then pruning on terabytes of embedding weights can lead to large overhead. How to orchestrate pruning under training dynamics (§4.2)? Additionally, how to efficiently enforce pruning on each worker’s memory to avoid throughput degradation (§4.3)?
- *Extensibility*: Existing systems are built atop a variety of embedding designs, such as key-value storage [44, 52] or highly optimized but fixed-size tensors [2, 3]. How to provide generic systems support to minimize modifications to existing DLRM systems (§4.3)?

### 4.1 Embedding Monitor: Identify Important Embeddings

Given the embedding size, we aim to trade the less important embedding rows for the more important ones. This requires us to consider the importance of each embedding row in terms of the contribution of its embedding weights to model accuracy, as well as its physical size. However, determining the optimal pruning strategy during training is challenging. First, the model output (accuracy) is affected by the complex interplay between input feature instances (e.g., which item IDs appear) and their embedding weights. Even with full model information after training completes, pruning is still a fundamental open problem in the ML literature [11, 32]. Second, during model training, this interplay becomes more intractable because of the large spatiotemporal variations in the distribution of model inputs and embedding weights (Figure 7(a)). Worse, once we prune an embedding’s weight vector, it is difficult to assess its impact on model accuracy as training moves on. These challenges are amplified by the need to account for feature-level heterogeneity too (e.g., different weight vector sizes across features).

AdaEmbed employs the embedding monitor to capture the

(a) Heterogeneous emb. characteristics. (b) Pearson analysis.

**Figure 7: (a) Embedding gradient and access frequency are heterogeneous, (b) while their combination reports a larger correlation to the embedding weights. A correlation value > 0.4 indicates a positive and medium to strong association.**

embedding importance of individual rows within the feature, and then extends it to identify important rows across features.

**Intra-Feature Embedding Importance** For embeddings of the same feature, we introduce a data- and model-aware importance metric  $EI(i)$  to capture the importance of each row  $i$  to model accuracy. Instead of relying on the embedding weights that become stale after being pruned,  $EI(i)$  is the runtime combination of access frequency and gradient, i.e.,  $EI(i) = freq_t(i) \times \|\nabla g_t(i)\|$ .  $\|\nabla g_t(i)\|$  is the L2-norm of  $i$ ’s gradient in iteration  $t$ , and  $freq_t(i)$  is the access frequency. So the embedding with a higher access frequency and a larger gradient norm is deemed more important. Here, collecting  $EI(i)$  introduces negligible overhead, because the embedding gradient is already generated during back-propagation of training regardless of AdaEmbed. Since the gradient is generated and shared by mini-batch samples [35], the importance of pruned-but-accessed embeddings will continue to be updated.

Our importance design is motivated by multiple factors:

- Intuitively, the output of sparse feature layers (i.e., pooled embedding weights) is often derived by taking the sum or maximum of input embedding weights (§2.1); so we should retain the embeddings that affect many model inputs (i.e., frequently accessed) and that affect model outputs more (i.e., larger weights). While we do not have information about future weights after pruning an embedding, we observe a strong correlation between our frequency-gradient combined metric and the final embedding weights when training converges (Figure 7). This is because frequent weight updates with large gradients typically result in larger weights.
- Theoretically, embedding rows are designed for training different bins of data instances: each bin holds only one type of category instance (i.e., a specific ID), and bins can have different data volumes (i.e., different access frequencies of IDs). Now, we want to select and retain certain bins (embeddings). This, in concept, is similar to the importance sampling problem in the ML literature [17, 25]: To improve model convergence by selecting the right bins to train the model, the optimal solution is to select bin  $i$  with a probability proportional to the aggregate gradients

(a) Heter. frequency. (b) Heter. grad. norms. (c) Heter. dimensions.

**Figure 8: Magnitudes of embedding access frequencies and gradients vary across features, making it hard to compare  $EI(i)$ .**

of training all that bin’s data. In our formulation, the training samples within the same bin are identical, because they correspond to the same specific ID. Therefore, the aggregate gradients herein is equivalent to the product of the number of training samples and the gradient of the individual sample (i.e.,  $EI(i) = freq_t(i) \times \|\nabla g_t(i)\|$ ).

Empirically, our fleet-wide evaluations show that our importance design outperforms its alternatives (§6.4).

Since the gradient and access frequency can fluctuate during training (e.g., due to the randomness in sampling mini-batches), we need to account for these uncertainties in  $EI(i)$ . Here, the embedding monitor considers  $EI(i)_t = freq_t(i) \times \|\nabla g_t(i)\| + EI(i)_{t-1}$ , whereby we reduce uncertainties in individual iterations and only need to update the importance of accessed embeddings. This is because the importance of not accessed embeddings remains unchanged as  $freq_t(i) = 0$ . In reality, only a subset of embeddings are accessed, so we can reduce the overhead significantly (§4.2). Moreover, to account for the temporal variation, we use a moving average that decays  $EI(i)$  by a factor of 0.8 every  $T$  iterations.

**Inter-Feature Group Pruning** Retaining important embeddings subject to the total size naturally leads to a global pruning design, in which we hope to allocate different embedding sizes to individual features. However, the values of embedding importance can vary across features by orders of magnitude. This can be due to features with fewer instances often having larger average access frequencies per embedding, and/or different initialization mechanisms of the embedding weights leading to gradients of different magnitudes (Figure 8). As such, directly using the intra-feature embedding importance for comparison across features can result in a large bias, as embeddings with greater importance values are not necessarily more important than those of other features. Moreover, as the dimension of embedding vectors of different features can vary (Figure 8(c)), deciding which embeddings are more valuable to retain becomes intricate when large embedding importance and vector size are in conflict.

Because we rely on the relative ranking of importance to determine pruning (e.g., prune the tail 40% less important embeddings), we can tackle the comparison bias across features using the popular normalization philosophy [16]; i.e., by normalizing each embedding’s importance by that

(a) Number of accessed IDs. (b) Size of weights to prune.

**Figure 9: (a) Each iteration accesses millions of embeddings. (b) Pruning needs to reallocate a large amount of embedding weights.**

feature’s distribution of all embeddings’ importance. This way, the embedding importance of different features takes on similar ranges of values, and the more important embeddings of each feature are still prioritized because of having larger relative importance values after normalization. The embedding monitor normalizes the embedding importance of each feature by the 95th percentile of its distribution (i.e.,  $EI(i)/EI_{95th}(feature(i))$ ) to avoid outliers.

Next, to account for different weight vector sizes across features, AdaEmbed groups features with the same embedding dimension and then performs global pruning within the feature group. In reality, DLRMs are configured with only a handful of distinct embedding dimensions (Figure 8(c)) to reduce hyper-parameter tuning and/or to achieve better parallelism (e.g., balancing embedding sharding [35, 52]). This implies a big opportunity to group many features, which already forms a large shared embedding size for inter-feature group pruning. By default, AdaEmbed initializes the per-group embedding size based on the number of in-group features and the total embedding size (i.e.,  $\frac{num\_group\_features \times group\_feature\_dim}{num\_features \times avg\_feature\_dim} \times total\_size$ ) to uniformly allocate the space to each dimension. Note that unused embedding storage will be picked up by other groups (§4.3). When developers have more advanced information about features (e.g., feature importance), AdaEmbed provides APIs for customizing feature groups and sizes (§5).

Our evaluations show that with importance normalization and group pruning, AdaEmbed achieves better resource savings and model accuracy (§6.3).

## 4.2 AdaEmbed Coordinator: Prune at Right Time

In real-world DLRM systems, each training iteration involves updating the importance of millions of embedding rows in terabyte-sized models (Figure 9(a)). At that scale, orchestrating hundreds of workers to prune leads to a trade-off between the pruning overhead and quality. Frequent pruning allows for better decision quality, i.e., maximizing the number of important embeddings all the time for potentially better model accuracy. Yet, pruning can require cleaning up and creating tens of gigabytes of embedding weights, which can take many seconds and significantly slow down the sub-second training iterations (Figure 9(b)). This trade-off becomes more

**Algorithm 1:** Pseudo-code of AdaEmbed runtime

```

1: weight_table ← EmbWeights()    ▷ Physical weight tables
2: emb_meta ← Init(weight_table)   ▷ VHPI metadata

   the importance distribution via profiling across
   workers. */
10:  last_dist ← null
11:  while training == true do
12:    if mod(current_time, Δ) == 0 then
13:      cur_dist ← ProfileImportance()
14:      pruning_start ← Diff(last_dist, cur_dist) > p
15:      last_dist ← cur_dist
16: Function EnforcePruning () :
   /* Memory manager: Identify embedding rows to admit
   and prune subject to the given embedding size. */
17:  admit_emb, evict_emb ← IdentifyRecycleEmbs(
18:    emb_meta, weight_table.size)
   /* Redistribute the lookup mapping from the embedding
   ID to the weight vector, whereby admitted embedding
   rows can recycle the weight vector of pruned ones. */
19:  RedistLookup(emb_meta, admit_emb, evict_emb)
   /* Reset embedding weights for admitted embeddings. */
20:  weight_table.ResetEmbs(admit_emb)

```

intractable as a result of training dynamics; e.g., stochastic gradient descent can introduce large noise to embedding gradients, thus the embedding importance. As such, pruning too frequently can also be suboptimal (§6.4).

To find the sweet spot between pruning overhead and quality, AdaEmbed Coordinator decides the right time to prune to reduce the number of pruning rounds needed, and instructs the memory manager to minimize the overhead in each pruning round when pruning embedding weights (§4.3). Algorithm 1 outlines how AdaEmbed Coordinator orchestrates efficient embedding pruning. The embedding monitor updates the importance of accessed embeddings after each training iteration (Line 4), and periodically profiles embedding importance (Line 9). The results of the profiling will be sent to the coordinator. In the event of big changes in the importance distribution, the coordinator initiates a new pruning round and notifies the memory manager of the pruning decision (Line 9). The memory manager on each worker then executes pruning and admits new embedding weights at scale (Line 16).

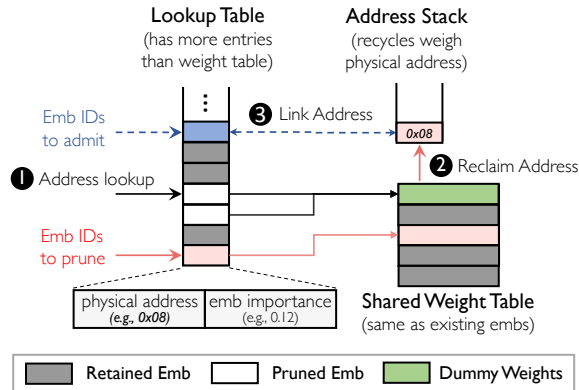

Figure 10: Profiling can get accurate results with little overhead.

Intuitively, pruning cares about the importance ranking of individual embeddings instead of their dynamic importance. Therefore, AdaEmbed coordinator relies on the importance distribution of all embeddings again, and initiates pruning if the importance distribution has changed greatly since the last pruning round. To effectively gather the importance distribution across hundreds of machines, each local agent samples a small portion,  $P$ , of embedding importance values on that agent. The coordinator then can estimate how many embeddings have crossed the pruning boundary, i.e., the number of embedding rows whose importance ranking has fallen below or risen above the  $X_{th}$  percentile of the distribution since the last pruning round.  $X_{th}$  is the cut-off importance boundary determined by the size limit (i.e.,  $\sum_{emb \in top\_X_{th}} size(emb) < total\_size$ ), and the agent will prune the weight vector of the embeddings whose importance value is smaller than the cut-off importance.

As shown in Figure 10, while more samples,  $P$ , allow for a more precise estimate of  $X_{th}$  importance, this will also increase the coordination overhead, such as in collecting importance distributed across hundreds of machines and then computing distribution changes. In fact, we can use the concentration theorem in the probability sampling [47] to decide the right number of samples.<sup>1</sup> This gives us  $\sim 5M$  embedding rows out of billions to sample on each machine, in order to ensure a deviation from the global ground truth of less than 1%. In addition to having a smaller computation overhead, this results in negligible network traffic,  $5M \times 4bytes \sim 20$  megabytes as  $EI(i)$  is a 4-byte float, over tens of Gbps network to the coordinator. As suggested by today’s data validation systems [7, 33], we consider a big change to have occurred and initiate pruning when more than  $c=5\%$  of the total embeddings cross the boundary (i.e., we need to prune and admit more than  $c\%$  embeddings), and issue this lightweight profiling per minute. This avoids the large overhead caused by pruning in each training iteration, while ensuring that the current embedding allocation is at most  $c\%$  worse than what we can achieve through pruning in each iteration. We show that profiling achieves a small deviation and little overhead (i.e., the 5M sample size in Figure 10).

**Convergence Analysis** As described in §4.1, our design of embedding importance draws inspiration from importance

<sup>1</sup>The minimum number of samples  $P$  needed to ensure  $Pr[|\bar{X} - E[\bar{X}]| < \epsilon] > \delta$  is  $P = \frac{(X_{max} - X_{min})^2 \ln(2/\delta)}{2\epsilon^2}$  for the distribution of variable  $X$ .  $E[\bar{X}]$ ,  $X_{max}$  and  $X_{min}$  are the expectation, maximum and minimum of  $X$ , respectively.

**Figure 11: VHPI employs lookup table to link each embedding to the weight vector, and recycles the vector of pruned embeddings without intense memory allocation.**

sampling, which has been shown in ML theory [17, 25, 31] for its ability to reduce gradient variance and accelerate training convergence. Empirically, our extensive evaluations using months of real-world data and models demonstrate that AdaEmbed consistently improves model accuracy by pruning at the right time, as opposed to pruning too frequently or infrequently (§6.4).

### 4.3 Memory Manager: Prune Weights at Scale

As the reallocation of embedding weights is hundreds of times slower than each training iteration (Figure 9(b)), reducing the number of pruning rounds needed is still far from achieving negligible overhead in practice (§6.2). To avoid intense memory reallocation, the memory manager of AdaEmbed employs a Virtually Hashed Physically Indexed (VHPI) design to decouple the management of embeddings from their physical weight vectors, whereby AdaEmbed can recycle the weight vectors of different embeddings to enable efficient pruning for a variety of existing embedding designs.

VHPI primarily consists of two parts (Figure 11):

- **Lookup table:** It stores the metadata information of each embedding instance, including the embedding importance (a `float32`), and the physical address (a `int64`) to that embedding’s weight vector. Compared to the weight vector, often a vector of 128 `float`, this payload information introduces a negligible memory footprint ( $\frac{3}{128} \sim 2\%$ ).
- **Weight table:** It is a monolithic physical table for embedding weight vectors. It remains the same as the embedding table of today’s DLRM systems, but it is shared across features under the orchestration of the memory manager.

Weights vectors of the pruned embeddings are not retained, while the metadata of all embeddings is always maintained in the lookup table. So the lookup table can include more entries (i.e., embedding IDs) than the weight table. This allows us to adaptively determine the link between embeddings and weight vectors to recycle weight vectors. Moreover, this can improve model accuracy by reducing hash collision (§6.4), as we can make the lookup table very large to accommodate

**Figure 12: Zero initialization performs better (0.5× model).**

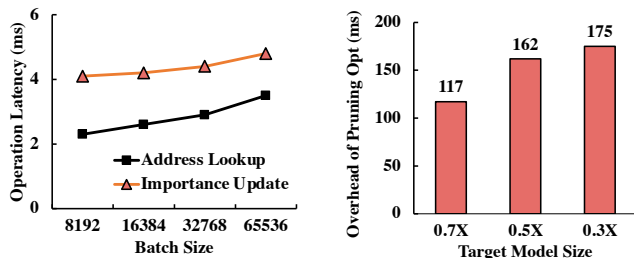

many embedding entries without expanding the weight table.

The memory manager performs two primitive operations for weight pruning at runtime (Figure 11):

- **Address lookup:** It looks up the physical weight address for each embedding ID to access its embedding weights. ① If that embedding row is pruned, to avoid breaking existing designs (e.g., missing weights due to pruning), lookup returns a shared physical address that points to a weights vector containing constant zeros. Access to this dummy vector will be folded on the execution backend due to the same entry, reducing redundant execution.
- **Weight allocation:** It executes the pruning decision to prune and admit embeddings. ② To prune an embedding row, VHPI first de-links and reclaims the current physical address of that embedding’s weight. It then sets the address of the pruned embedding’s lookup entry to the address of the shared dummy vector, redirecting the future access. ③ To admit an embedding, VHPI pops an available physical address and links this address with the lookup entry, thereby recycling the physical memory. Meanwhile, the memory manager resets the weight vector values to clean up the previously pruned weight state.

However, it is not straightforward to reset (i.e., reinitialize) the weight values for admitted embeddings, because the model herein is partially trained and the values of embedding weights already differ by orders of magnitude (Figure 7(a)). Improper initialization (e.g., random initialization) can introduce a large amount of noise to the retained embeddings. Eventually, this will hurt model accuracy, especially considering the noise from millions of admitted embeddings in each pruning round.

Here, we investigated four popular strategies to reset weight vectors (Figure 12): (1) *w/o reset*: inherit the weights of pruned embeddings without resetting them; (2) *weight restore*: evict previously pruned weights to extra storage (e.g., disk) and reinstate the weights when that embedding is reclaimed; (3) *original initialization*: randomly initialize embedding weights as at the start of training; and (4) *zero initialization*: reset embedding weights to zeros. Intuitively, the restored weights will become too stale since they were pruned (often thousands of iterations ago). Original initialization and w/o reset can introduce large noise, as the weights have already been of differing magnitudes. Here, we advocate resetting the weight vector values to zeros, as this can avoid large noise while allowing the admitted embedding to learn from scratch. Indeed, our real-world evaluations report that zero initialization outperforms its alternatives (Figure 12).

(a) Control-plane overhead. (b) Data-plane overhead.

**Figure 13: VHPI operations introduce little overhead.**

**Overhead Analysis** Among all the operations involved in VHPI, address lookup and importance update to the lookup table take place every iteration and consume a few milliseconds (Figure 13(a)). Weight pruning to the weight table consumes a few hundred milliseconds (Figure 13(b)), but it occurs every hundreds of iterations. Overall, these operations lead to little end-to-end overhead in large-scale deployments (§6.2).

## 5 Implementation

We implemented a system prototype of AdaEmbed to support distributed DLRM deployment across GPUs. Our implementation requires minor changes to existing DLRM systems.

**AdaEmbed Backend** AdaEmbed backend is implemented as GPU operators for fast execution. The VHPI metadata (e.g., embedding importance and weight address) are hosted on GPUs to process embeddings in parallel. The address lookup and importance update operations require no change to existing DLRM systems. As we need to reset the weight vector, the weight allocation operation requires existing frameworks to expose an API to access their weight table, but this requires a few lines of code change. The local agent interacts with the coordinator via TCP connections.

**Fault Tolerance** As a shim layer, AdaEmbed can be integrated into existing DLRM checkpoints by adding its state information to the model state. This not only minimizes the modification to existing designs, but also ensures that the saved AdaEmbed state conforms to the embedding weights at that time. When training is resumed, the model reloads the checkpoint, which restores the AdaEmbed state too. At runtime, AdaEmbed runs a lightweight daemon to back up VHPI metadata after each pruning round, and to resume its components if the current instances crash.

**Interfaces** AdaEmbed exposes Python APIs as the frontend (Figure 6), and it can also take *json* as input (Figure 14).

## 6 Evaluation

We evaluate AdaEmbed in real-world DLRM systems across hundreds of GPUs. Our evaluation results on different industrial models and months of data are summarized as follows:

- AdaEmbed can reduce 35-60% embedding size and improve model execution speed by 11-34% without compromising model accuracy (§6.2).

```

1  "adaembed_configs": {
2    "total_emb_size": "1 TB", // Total embedding size
3    "feature_configs": {
4      "default_group": {...},
5      "group_1": { // Features to use group pruning
6        "features": ["feature1", ...],
7        "total_emb_size": "200 GB",
8      } ... // Other feature groups
9    }
10 }

```

**Figure 14: Example embedding configuration in AdaEmbed.**

- AdaEmbed can reduce manual efforts by automatically finding better per-feature embeddings, achieving noticeable accuracy improvements (§6.2-§6.3);
- AdaEmbed improves performance over a wide range of settings and outperforms its design counterparts (§6.4);

### 6.1 Methodology

**Experimental setup** We use models and data from industry DLRM systems in the evaluation. Table 1 depicts high-level statistics of the model. They span different scales and recommendation tasks, including click-through rate prediction and ranking. We train each model on 14 days’ data to obtain the model *lifetime NE*, which indicates the cumulative model accuracy throughout training, and then test the model on the 15th day’s data to get the *evaluation NE*. Each day has many terabytes of data input.

The training batch size of each model is 65536, requiring tens of GPU nodes for the desired QPS. Each GPU node has 8 A100 GPUs with 40 GB of GPU memory. The GPUs are interconnected using 200 Gbps RoCE NICs.

**Baselines** To the best of our knowledge, AdaEmbed is the first system to support in-training embedding pruning, and is complementary to existing DLRM efforts. Our evaluations cover two primary baselines: (i) *w/o AdaEmbed*: an industry DLRM system without AdaEmbed support. Based on the access frequency of embedding rows in previous days, rows that are less frequently accessed are removed before training starts. This generates a pruned model derived from the full model; and (ii) different variants of AdaEmbed with changes in the pruning algorithm (§6.4). Here, we focus on the performance improvement of the *w/ AdaEmbed* setup, i.e., the setup using AdaEmbed.

**Metrics** We care about the (i) *memory saving* to achieve the same model accuracy as with the full model (i.e., without NE regression)<sup>2</sup>, because we want to minimize the embedding size for better model throughput and resource savings in deployment; (ii) *NE gain* that we can achieve using the same embedding size, since it not only minimizes manual efforts in configuring DLRM embeddings, but also implies higher revenues; and (iii) *overhead* that AdaEmbed introduces in model execution speed (i.e., QPS).

<sup>2</sup>A smaller Normalized Entropy (NE) loss indicates better model accuracy.

Model	# of Sparse Features (Approximate Value)	Raw Emb Size (Approximate Value)	# of GPUs	w/ Same Model NE		w/ Same Emb Size	
				Memory Saving	QPS Speedup	Avg. NE Gain (%)	QPS Overhead
Model-XS	1000	200 GB	32	≈ 35%	1.1×	0.015	0.4%
Model-S	600	350 GB	32	≈ 45%	1.2×	0.018	0.2%
Model-M	1000	1 TB	64	≈ 40%	1.2×	0.028	1.6%
Model-L	1000	1.1 TB	64	≈ 55%	1.3×	0.021	1.3%
Model-XL	800	1.5 TB	128	≈ 60%	1.3×	0.026	1.1%

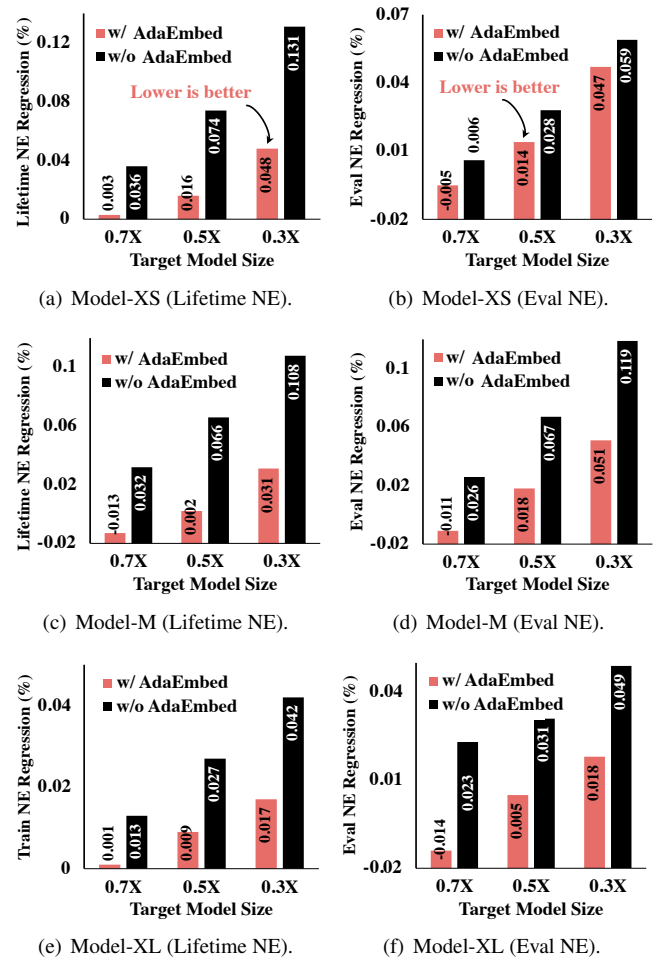

**Table 1: Summary of improvements. AdaEmbed reduces the embedding size needed for the same model accuracy (NE), while improving NE using the same embedding size. We report the approximate memory saving, since evaluating all memory settings is unaffordable.**

## 6.2 End-to-End Performance

Table 1 summarizes the key memory saving, NE gain, and overhead of five models at different scales. Meanwhile, Figure 16 zooms into three representative models and reports their performance under different target embedding sizes. In our evaluations, NE regression measures the accuracy loss w.r.t. the full model (i.e., 1× model), and any > 0.02% NE gap is considered to be significant [13, 30, 52].

**AdaEmbed cuts resource needs and improves QPS** We first evaluate how many embedding sizes we can reduce without sacrificing model NE. Yet, evaluating all embedding sizes to get accurate memory saving is unaffordable because training with each setup takes thousands of GPU hours. So, we enumerate 0.7× (i.e., cut the embedding size by 30%), 0.6×, 0.5×, 0.4×, and 0.3× of the full model size to approximate this embedding saving with no accuracy drop. Table 1 reports that (i) AdaEmbed reduces the model embedding size by 35-60% with no reduction in model accuracy. This implies that we can reduce the machine usage by nearly the same amount (e.g., using 50% fewer GPUs); (ii) the resource savings are more encouraging for large models (e.g., Model-XL vs. Model-XS). One reason behind this is that large models provide gigantic GPU memory for AdaEmbed to reallocate embeddings via inter-feature group pruning (§6.3); and (iii) alternatively, reducing the fundamental embedding size provides 1.1-1.3× faster model execution speed (i.e., QPS) when running the model on the same machines.

**AdaEmbed achieves better NE under the same size** Figure 16 illustrates that with AdaEmbed, models can achieve 0.011-0.077% better NE using the same embedding size. We notice that (i) AdaEmbed achieves consistently better NE across models and under different target embedding sizes than the baseline; (ii) we can achieve NE gains with smaller embedding sizes (e.g., 0.7× models) even when compared to the full model. This is because AdaEmbed can automatically learn better per-feature embeddings, like the size and which embeddings to retain. Meanwhile, pruning less important embeddings can reduce model overfitting, thereby improving model generalization (accuracy) [6]; and (iii) the lifetime NE

**Figure 16: AdaEmbed achieves better lifetime NE and evaluation NE. Better lifetime NE implies potentially better model accuracy for online learning deployment, while better evaluation NE indicates better accuracy after offline training (i.e., prior to launching online training). Both NEs are important metrics.**

gain is more prominent than that of the evaluation NE, because the former is closer to the online deployment (i.e., retraining on real-time data), where AdaEmbed is able to adapt to the latest data distribution.

**AdaEmbed introduces negligible overhead** As shown in Table 1, compared to the same-size model in the baseline,

Figure 15: Models with AdaEmbed achieve consistently better NE over time. Troughs are due to data distribution shifting over days.

Figure 17: For the same NE w.r.t.  $1\times$  model, AdaEmbed learns better per-feature embedding configuration using smaller size.

AdaEmbed introduces negligible ( $< 2\%$ ) QPS overhead across scales of the deployment (e.g., from 32 to 128 GPUs and 200 GB to 1.5 TB models), because (i) AdaEmbed largely parallelizes operations (e.g., asynchronous importance update and multi-threading); (ii) coordinator selectively initiates pruning rounds; and (iii) the memory manager introduces VHPI to avoid intense reallocation of the physical weight. Note that the memory overhead is  $\sim 2\%$  as AdaEmbed introduces only two small buffers (i.e., the lookup address and embedding importance) in VHPI lookup table (§4.3).

### 6.3 Performance Breakdown

We next break down AdaEmbed performance by time, the characteristics of sparse features, and design components.

**Breakdown by Time** Figure 15 breaks down model NE by time, with each data point on the line representing the moving average of the NE over hourly data (i.e., window NE regression). The training encompasses 14 days of data. We observe that with AdaEmbed, we can achieve consistently small NE regression than the baseline over time.

Moreover, we notice that this NE regression exhibits diurnal variation (e.g., in Model-XS and Model-M). This is because the data distribution (e.g., user preference) of recommendation tasks can change drastically over days. As such, at the beginning of training on a new day’s data, the smaller model (e.g.,  $0.3\times$  model) will experience a larger NE regression as it has less space to accommodate new embedding IDs. However, as the model gradually adapts to the new distribution, this regression tones down. We note that AdaEmbed experiences less NE fluctuation due to its ability to identify

Figure 18: For the same size ( $0.5\times$  model), AdaEmbed retains more important embeddings to achieve better NE (Model-XS).

Figure 19: Performance breakdown of AdaEmbed (AE) design.

and retain important embeddings on the fly.

**Breakdown by Embedding Features** We next investigate whether AdaEmbed can reduce manual efforts by learning to use better embedding configurations. First, in achieving the same NE as the  $1\times$  model, AdaEmbed learns to use smaller embeddings for many features (Figure 17). Moreover, using the same embedding size w.r.t. the  $0.5\times$  model, AdaEmbed gathers larger average embedding importance on each feature than the handcrafted setup (Figure 18), implying that more important embeddings are retained under the same total size. More importantly, we notice that (i) our group pruning shares similar preferences to the handcrafted configuration. Specifically, AdaEmbed tends to allocate more embeddings to those features that the model expert also values highly. However, (ii) some features are allocated fewer embeddings but AdaEmbed eventually achieves better NE, indicating that AdaEmbed can automatically find better embedding configurations.

**Breakdown by Components** We break down our design into two variants (i) (AdaEmbed w/o Norm): disable importance normalization in group pruning; and (ii) (AdaEmbed

(a) Impact of pruning interval.

(b) Impact of dataset.

Figure 20: *AdaEmbed* achieves improvement across settings.

Figure 21: *AdaEmbed* outperforms importance alternatives.

Figure 22: *AE* outperforms post-training pruning (PTP).

w/o Group): completely disable group pruning, so the per-feature embedding size is resized to X% of the full model. We notice that both normalization and group pruning contribute to better NE (Figure 19). This is because (i) group pruning allows greater flexibility to resize the per-feature embedding using the shared gigantic weight table; and (ii) importance normalization helps to reduce the inter-feature heterogeneity by prioritizing important embeddings of each feature when comparing embedding importance globally.

## 6.4 Sensitivity and Ablation Studies

**Impact of pruning frequency** *AdaEmbed* Coordinator initiates a pruning round when the importance distribution radically changes. Next, we evaluate the impact of pruning frequency by deterministically enforcing pruning after training every-minute ( $\sim 50$  training iterations) and every-day data ( $\sim 70K$  training iterations). Figure 20(a) reports that pruning too frequently and infrequently (i.e., pruning every one-minute and one-day data) both lead to suboptimal NE. The former is due to large training noise affecting instantaneous embedding importance, while the latter is due to *AdaEmbed* missing to admit important embeddings in a timely manner. Instead, the selective pruning of *AdaEmbed* achieves better performance by relying on the overall importance distribution at runtime.

**Impact of different data** Figure 20(b) reports the NE performance of model-S on three distinct datasets. Each training spans 10 days’ training data, and we report the evaluation NE on the data of day 11. While the NE gain varies slightly as the data distribution varies across dates, *AdaEmbed* consistently achieves 50% memory savings with no NE regression.

**Alternatives of embedding importance** We next experiment with different embedding importance designs in training 10 days’ data. Here, we consider using the frequency, gradient, and their combination (i.e., *AdaEmbed* design) as the embedding importance. We notice our frequency-gradient combination outperforms the alternatives. We note that this is consistent with the results of our Pearson analysis too, i.e., their combination has a stronger correlation to final embedding weights (Figure 8(b)). Instead, the access frequency and gradient only consider the data distribution and model characteristics, respectively, while DLRM accuracy depends on both aspects.

**In-training vs. post-training pruning** We compare *AdaEmbed* to its post-training pruning (PTP) counterpart like [20]. After model training is complete, PTP reduces the embedding size by pruning less important embeddings, as measured by our importance design. In fact, deploying PTP in real is often impractical (e.g., due to the need for online learning), and cannot achieve memory savings and/or QPS improvement during model training. Moreover, Figure 22 reports that *AdaEmbed* (i.e., in-training embedding pruning) can achieve better NE than PTP under the same embedding size, as the in-training design can adapt to the model performance at runtime and continuously optimize embeddings.

## 7 Related Work

**Deep Learning Recommendation Systems** Existing systems primarily focus on accelerating DLRM execution. NEO [18] co-optimizes embedding sharding and data parallelism. AIBox [52] and HierPS [51] overlap training execution on CPUs (using solid-state drives) and GPUs. Ekko [39] accelerates DLRM training over wide-area networks. TT-Rec [48] replaces embedding tables with matrix products to reduce memory footprints. Check-N-Run [13] reduces the bandwidth consumption for model checkpoints. Fleche [44] and Kraken [45] share the idea of sharing the weight table across features, but they focus on caching frequently accessed embeddings. *AdaEmbed* goes one step further by identifying the heterogeneous embedding importance to improve model accuracy during model training.

**Optimizations for Deep Learning** Recent ML advances have proposed various innovations for deep learning. TASO [23] and PET [41] perform tensor optimizations to improve model computation. Superneurons [42] and PipeSwitch [5] optimize instantaneous GPU memory by prefetching model layers based on their computation order. Similarly, ByteScheduler [37] and BytePS [24] accelerate the communication of distributed DNN training. Model-Keeper [28] warms up model training to reduce the amount of training execution needed. Egeria [43] adaptively freezes the training of model layers and bypasses their computation. These existing works focus primarily on conventional models, whereas DLRM models are often bottlenecked by memory-

intensive embeddings. Moreover, AdaEmbed is complementary to these efforts as AdaEmbed can further improve their optimized DLRM models.

**Model Pruning** Model pruning has been extensively studied to reduce model computation during training [11, 32], or to generate smaller models after training completes [8, 38]. Importance sampling [17, 29] performs weighted sampling on training data to achieve faster training convergence. Existing pruning systems and theories primarily focus on conventional CV and/or NLP counterparts by pruning only the dense layers [12, 20, 36]. However, in DLRMs, the gigantic embedding tables have become the bottleneck. This difference introduces novel challenges since the dense layers and embedding tables are distinct components with unique characteristics. For instance, dense layers are shared and accessed by all input samples, whereas each embedding row corresponds to a specific feature instance and is only accessed by it, leading to the heterogeneous importance of embeddings. Therefore, existing solutions are ill-suited for DLRMs.

## 8 Conclusion

This paper introduces AdaEmbed, an in-training embedding pruning system for better DLRM accuracy. AdaEmbed identifies embedding rows with larger importance to model accuracy, and then adaptively prunes less important embeddings to cap the total embedding size at scale. Our evaluations demonstrate that AdaEmbed can reduce manual efforts by automatically learning to use better per-feature embeddings, whereby it saves 35-60% embedding size needed in deployment, and achieves noticeable improvements on model accuracy and model execution speed.

## Abstract

Work stealing is a widely-used scheduling technique for parallel processing on multicore. Each core owns a queue of tasks and avoids idling by stealing tasks from other queues. Prior work mostly focuses on balancing workload among cores, disregarding whether stealing may adversely impact the owner’s performance or hinder synchronization optimizations. Real-world industrial runtimes for parallel processing heavily rely on work-stealing queues for scalability, and such queues can become bottlenecks to their performance.

We present Block-based Work Stealing (BWoS), a novel and pragmatic design that splits per-core queues into multiple blocks. Thieves and owners rarely operate on the same blocks, greatly removing interferences and enabling aggressive optimizations on the owner’s synchronization with thieves. Furthermore, BWoS enables a novel probabilistic stealing policy that guarantees thieves steal from longer queues with higher probability. In our evaluation, using BWoS improves performance by up to 1.25x in the Renaissance macrobenchmark when applied to Java G1GC, provides an average 1.26x speedup in JSON processing when applied to Go runtime, and improves maximum throughput of Hyper HTTP server by 1.12x when applied to Rust Tokio runtime. In microbenchmarks, it provides 8-11x better performance than state-of-the-art designs. We have formally verified and optimized BWoS on weak memory models with a model-checking-based framework.

## 1 Introduction

Many language runtimes and similar systems (*e.g.*, JVM [104], Go [36], Rust’s Tokio [38]) divide their work into smaller units called *tasks*, which are executed asynchronously on multiple cores and whose execution can generate further tasks. To achieve good performance, the task scheduler has to ensure a

\*Ming Fu (ming.fu@huawei.com) is the corresponding author.

Figure 1: Profiling results for *go-json* complex object decoding ( $\sim 1\mu\text{s/op}$ ) benchmark [9], with the original work stealing queue (up) and with BWoS (down).

good *workload distribution* (preventing idle cores while there are pending tasks) with a low *scheduling overhead*.

Achieving these goals, however, is non-trivial. Storing the tasks in a single queue shared by all cores achieves optimal workload distribution, but incurs a huge overhead due to contention. Using per-core task queues minimizes the overhead per operation, but can easily lead to a skewed workload distribution, with some cores remaining idle while others have queued work.

*Work stealing* [51] is a trade-off between these two extremes: each core owns a queue (*owner*) and acts as both the *producer* and the *consumer* of its own queue to put and get tasks. When a core completes its tasks and the queue is empty, it then steals another task from the queue of another processing core to avoid idling (*thief*). A number of stealing policies [69, 76, 77, 83, 88, 100] have been proposed to choose the proper queue (*victim*) to steal from, which can bring significant speedups depending on the use-cases. Due to these features, work stealing is widely used in parallel computing [22, 35, 56, 64, 65, 85, 93, 97], parallel garbage collection [60, 68, 69, 96, 101], GPU environment [52, 54, 99, 102, 103], programming language runtimes [26, 36, 38, 50, 63, 80, 81], networking [86] and real-time systems [82].

However, as parallel processing is applied to more workloads, current implementations of work stealing become a bottleneck, especially for small tasks. For example, web frame-

works running over lightweight threading abstractions, such as Rust’s Tokio and Go’s goroutines, often contain many very small tasks, leading the Tokio runtime authors to observe that “the overhead from contending on the queue becomes significant” and even affects the end-to-end performance [28]. Similarly, high-performant garbage collectors, such as Java G1GC [13], rely on work stealing for parallelizing massive mark/sweep operations, which comprise only a few instructions. The work stealing overhead becomes a performance bottleneck for GC [68, 69, 96, 101].

As a third example, in Fig. 1, we profile the GoJson object decoding benchmark, which uses goroutines both for GC workers and for parsing complex objects. Only 51% of all CPU cycles constitute the useful workload (JSON decoding). The remaining cycles are spent on the runtime code, including 7% on lightweight thread scheduling, 20% on GC, 5% on kernel code idling the CPUs, *etc.* As both the scheduler and the GC code rely on work stealing, improving its performance can result in massive efficiency gains. Furthermore, the benefit is not limited to the above-mentioned scenarios, but expands to all fine-grained tasks parallel processing scenarios. Thus, we ask the following question: *How can we improve performance of work-stealing queues for fine-grained tasks to the benefit of a large range of common applications?*

Existing work-stealing queues suffer from four main sources of inefficiency:

**P1: Synchronization overhead.** Due to the possibility of a steal, local queues must use stronger atomic primitives (*e.g.*, atomic compare-and-swap and memory barriers) than a purely sequential queue. Queues with a FIFO policy are generally implemented as single-producer multiple-consumer (SPMC) queues [8, 17, 39, 47], thereby treating *steal* similarly to *get*, and thus distributing the costs of stealing equally between owner and thieves. This also applies to the existing block-based queues [106], which lack any optimizations specific to the work-stealing use case to achieve high performance in the presence of thieves (§6.2, §7). Queues with a LIFO policy, such as the well-known and widely-used ABP queue [35, 48, 104], suffer from memory barrier overhead [83, 98] to avoid the conflict between the owner and thieves, even when they operate on different tasks.

**P2: Thief-induced cache misses.** Since steals update the metadata shared between the owner and the thieves, they cause cache misses on subsequent accesses to the queue by its owner. This problem is especially apparent on unbalanced workloads, which feature high steal rates—for example, in the JVM Renaissance benchmarks [95], 10% of all items are stolen on average. Although strategies such as batching (*e.g.*, *steal-half* [66]) can reduce the frequency of steals, they often cause *overstealing* which introduces additional overhead (§2.1.3).

**P3: Victim selection.** To improve the workload distribution, advanced policies for selecting the victim queue to steal from require scanning the metadata of several queues, *e.g.*, to

find the longest queue. Doing so, however, causes contention for its owner and severely limits the improvement from advanced victim selection policies (§2.1.3).

**P4: Correctness under weak memory models (WMMs).** Correctly implementing concurrent work-stealing queues on weak memory architectures, such as Arm servers for datacenters [46, 70], is very challenging because it requires additional memory barriers to prevent unwanted reordering. Using redundant barriers can greatly reduce the performance of work-stealing [79], while not including enough barriers can lead to errors, such as in the C11 [6] version of the popular unbounded Chase-Lev deque translated from formally verified ARMv7 assembly [90]. Even the popular Rust Tokio runtime required a fix to its implementation of work stealing [2].

**Contribution.** In response, we introduce BWoS, a *block-based work stealing* (BWoS) bounded queue design, which provides a practical solution to these problems, drastically reducing the scheduling overhead of work stealing. Our solution is based on the following insights.

First, we split each per-core queue into multiple blocks with independent metadata and arrange for the owner and the thieves to synchronize at the block level. Therefore, in the common case where operations remain within a block, we can elide synchronization operations and achieve almost single-threaded performance (§3.2). Similarly, since a queue owner and the thieves share only block-local metadata, they do not interfere when operating on different blocks (§2.1). We can arrange for that to happen frequently by allowing stealing tasks from the middle of the queue.

Second, we improve victim selection with a *probabilistic policy*, which approximates selecting the longest queue (§3.4), while avoiding the severe interference typical of the prior state-of-the-art (§2.1), to which we can integrate NUMA-awareness and batching.

Finally, we ensure correctness under WMMs by verifying BWoS with the GenMC model checker [74, 75] and optimizing its choice of barriers with the VSync toolchain [92] (§5).

As a result, BWoS offers huge performance improvements over the state-of-the-art (§6). In microbenchmarks, BWoS achieves up to 8-11x throughput over other algorithms. In representative real-world macrobenchmarks, BWoS improves performance of Java industrial applications by up to 25% when applied to Java G1GC, increases throughput by 12.3% with 6.74% lower latency and 60.9% lower CPU utilization for Rust Hyper HTTP server when applied to the Tokio runtime, and speeds up JSON processing by 25.8% on average across 9 different libraries when applied to the Go runtime.

Returning to our motivating example (Fig. 1), applying BWoS to the Go runtime removes 29% of scheduling time, 55% of GC time, and 40% of CPU idle time, while increasing the CPU time ratio for useful work from 51% to 71%.

Figure 2: Motivating benchmarks: (a) Sequential performance of state-of-the-art work stealing algorithms. (b,c) Performance of the ABP queue owner depending on the frequency of (b) steal and (c) getsize operations. (d) Hyper HTTP server performance with different stealing batch sizes with the original Tokio work stealing queue:  $S$  is the victim queue size and  $S/2$  refers to the default steal half policy [66]. (e,f) Interference between two threads for two sizes of cacheline sets.

## 2 Background

**Task processing.** Tasks vary a lot among benchmarks. Their processing time ranges from a few nanoseconds (e.g., Java G1GC [13]), to microseconds (e.g., RPC [55, 73, 108]), and even to seconds (e.g., HPC tasks [35]). In this paper, we mainly focus on the nanosecond- and microsecond-scale tasks. Ignoring steals, tasks may be processed either:

- in FIFO (first-in-first-out) order, when minimizing processing latency is important (e.g., network connections), or
- in LIFO (last-in-first-out) order, when only the overall execution time matters, as is often the case with multithreaded fork-join programs [57].

We use the term *queue* to refer to the instances of work stealing data structures without implying a specific task ordering.

**Victim selection.** There are multiple policies for selecting the victim queue to steal from. *Random* [51] chooses one of the remaining queues uniformly at random: it has the least complexity but achieves poor load balancing. Size-based policies (e.g., *best of two* [88] and *best of many* [69]) scan the queues’ size to improve the load balance by stealing from a large queue. The NUMA-aware policy [77] was proposed to optimize the remote communication cost, by tending to steal from the queues in the local cache domain. Batch-based policies (e.g., *steal half* [66] is used in Go and Rust’s Tokio runtimes) allow thieves to steal multiple tasks at once to reduce their interference with the owner. Later in this section (§2.1.3), we will quantify these overhead sources to guide our queue design.

### 2.1 Performance Overhead Breakdown

Next, we analyze the state-of-the-art work stealing algorithms to dissect their performance issues, and motivate the design decisions of BWoS. Fig. 2 contains our experimental results on an x86 server [71].

#### 2.1.1 Cost of Synchronization Operations

As steals may happen at any time, strong atomic primitives are introduced for local queue manipulation. To quantify their cost, we first measure the throughput of the state-of-the-art

	Thief: cost of communication		Victim: cost of interference		Overhead reduction $1 - \frac{C_s + I_s}{C_d + I_d}$
	same node ( $C_s$ )	diff node ( $C_d$ )	same node ( $I_s$ )	diff node ( $I_d$ )	
abp	15ns	141ns	170ns	278ns	56%
ideal			–	–	90%

Table 1: Reducing the stealing overhead with a NUMA-aware policy.

work stealing algorithms on a sequential setup where an owner puts and gets data from its local queue, without any tasks ever being stolen (§6.2). We compare the results with the theoretical performance upper bound: a single-threaded FIFO (FIFO\_seq) or LIFO (LIFO\_seq) queue implementation [72] without support for steals. Although there is no owner-thief interference, these synchronization operations pose a huge overhead (Fig. 2a): throughput of these work stealing algorithms is less than 0.25x for FIFO-based (0.19x for LIFO-based) compared to the upper bound.

#### 2.1.2 Interference Cost with Thieves

To estimate how thieves affect the throughput of the owner, we consider an ABP queue benchmark with an owner and one thief, which steals tasks from the queue with various frequencies (one queue and two threads in total). As the “ideal” baseline, we take the single-threaded performance of the ABP queue (i.e., with no steals). To account for any NUMA effects in this measurement, we use two configurations, running the thief in the same or in different NUMA nodes.

As we can see in Fig. 2b, the thief significantly degrades the owner’s throughput: e.g., by stealing only 1% of the tasks, the owner’s throughput drops by 17.8% when the thief is in the same NUMA node, and by 25.2% when it runs in a different NUMA node. This degradation happens because of the cache interference between the owner and the thief on the shared metadata. We will further explain this in §2.2.

#### 2.1.3 Overhead due to Victim Selection

There are two main sources of stealing overhead: first, a sub-optimal victim selection can lead to workload imbalance trig-

gering more stealing; second, the cost of steal operations.

**Size-based policies.** Policies like *best of two* [88] or *best of many* [69] read global metadata of multiple queues (their length) to determine the victim. Somewhat surprisingly, as shown in Fig. 2c, these reads introduce significant overhead for the owner, especially in the cross-NUMA scenario: even with a *getsize* frequency of only 1%, the owner throughput drops by 34.4%. This is further amplified as *getsize* is called multiple times for a single steal.

Therefore, for size-based policies, although reading more queues' sizes (e.g., *best of many* [69]) can achieve better load balance, it inevitably induces more slowdown to the owners of these queues (§6).

**NUMA-aware policies.** NUMA-aware policies [77] try to reduce the overhead of each steal by prioritizing the stealing from queues in the same NUMA node. We observe that although such NUMA-aware policies can reduce the overhead of steals by 56% in the case of our ABP queue benchmark, they fail to achieve their full potential.

In Table 1, we break down the overhead of stealing in the ABP queue into its two main parts: the thief's communication cost and the owner's interference penalty. The former is 141ns when the thief and owner run on different NUMA nodes (measured by Intel MCA [21]), and reduces to 15ns (consistent with the L3 cache access latency [7]) when they are at the same NUMA node. The victim's interference penalty is 170ns and 278ns for cases of thief and victim running on the same ( $I_s$ ) and different ( $I_d$ ) NUMA domains respectively. NUMA-aware policies with existing queues can typically eliminate the first communication overhead, while leaving the second interference overhead not sufficiently optimized.

With long enough queues, steals could ideally happen at a different part of the queue and cause no interference to the victim. This would reduce  $I_s$  and  $I_d$  to zero, resulting in a 90% improvement due to NUMA-awareness (rather than 56%).

**Batch-based policies.** Batch-based policies steal more tasks at once with the aim of reducing the frequency of steals. Indeed, in the Hyper HTTP server benchmark (see Fig. 2d), choosing larger batch sizes leads to a reduction in the number of steal operations. These larger steal operations, however, make the workload even less balanced (i.e. percentage of stolen tasks increases), which results in additional overhead (e.g., task ping-pong), canceling out the overhead reduction due to the fewer steals: the end-to-end throughput remains roughly the same.

## 2.2 Recap to Motivate BWoS

In summary, the owner's performance suffers both from the synchronization cost, and the interference with thieves (due to victim selection and task stealing). This interference occurs because of cache contention on the queue metadata: write-write interference with *steal*, and read-write interference with *getsize* in size-based stealing policies.

To better understand the effects of these types of cache contention, we conduct a simple microbenchmark with two threads: thread  $t_0$  continuously writes to a cacheline, while thread  $t_1$  either reads or writes to a cacheline with a specified frequency (Figs. 2e and 2f). The cachelines for  $t_0$  and  $t_1$  are independently and randomly chosen on each iteration out of the cacheline sets of two sizes: 1 or 64.

In both cases, the cache contention on a single cacheline significantly harms the throughput of  $t_0$ , regardless of the NUMA domain proximity. Introducing multiple cachelines (64 in this case) reduces the contention and significantly improves the throughput. Therefore, in the design of BWoS we separate the metadata.

## 3 Design

BWoS is based on a conceptually simple idea: the queue's storage is split into a number of blocks, and the global mutable metadata shared between thieves and owner is replaced with the per-block instances.

The structure of BWoS queue facilitates abstracting the operations into *block advancement* that works across blocks, and *fast path* that operates inside of the block chosen by the block advancement (§3.1). Moving most of the synchronization from the fast path to the block advancement allows BWoS to fully reap the performance benefit indicated by our previous observation (§2.1.1) thus approaching the theoretical upper bound. *get* and *steal* always happen on different blocks. We carefully construct the algorithm such that thieves cannot obstruct the progress of *get*, while *get* can safely *takeover* a block from thieves operating on it without waiting for them. For complexity consideration, we don't prohibit *put* and *steal* in the same block<sup>1</sup>, as they can synchronize with the weak barriers without losing performance (§6.2).

As metadata is also split per block, thieves and the owner are likely to operate on different blocks and thus update different metadata. As explained in §2.2, this reduces the interference between thieves and the owner. For FIFO-based BWoS, block-local metadata allows stealing from the middle of the queue, without enforcing the SPMC queue restriction of always stealing the oldest task, which is not required by the workloads.

BWoS can benefit from NUMA-aware policies more than other queues because the reduction in interference for the victim makes both constituents of cross-NUMA-domain stealing overhead negligible (Table 1). Furthermore, unlike batch-based policies, stealing policies integrated with BWoS can focus on balancing the workload itself without worrying about the interference from frequently called *steal*.

<sup>1</sup>Nevertheless, it is guaranteed automatically in LIFO BWoS.

```

1  bool queue<E>::put(E e){
2  again:
3    blk = blk_to_put();
4    switch(blk.put(e))
5    case success():
6      return true;
7    case blk_done(rnd):
8      if (adv_blk_put(blk, rnd))
9        goto again;
10     else return false;
11  }
12  E queue<E>::get(){
13  again:
14    blk = blk_to_get();
15    switch(blk.get())
16    case success(e):
17      return e;
18    case empty:
19      return null;
20    case blk_done(rnd):
21      if (adv_blk_get(blk, rnd))
22        goto again;
23     else return null;
24  }
25  E queue<E>::steal(){
26  again:
27    v, blk = blk_to_steal();
28    switch(blk.steal())
29    case success(e):
30      return e;
31    case empty:
32      return null;
33    case conflict:
34      goto again;
35    case blk_done(rnd):
36      if (adv_blk_steal(v,
37        blk, rnd))
38        goto again;
39     else return null;
40  }

```

Figure 3: Pseudocode of put, get, and steal operations.

### 3.1 Bird’s-Eye View of the Queue

To better understand the block-based approach, let’s consider the *put*, *get*, and *steal* operations of the BWoS queue (Fig. 3). For each of these operations, the first step is to select a block to work on (lines 3, 14, and 27). The owner uses the *top* block for put and get for the LIFO BWoS, and gets from the *front* block and puts to the *back* block for the FIFO BWoS. In this case, top, back, and front block pointers are owner-exclusive metadata which is unavailable to the thieves. For *steal*, the choice of the block is more complicated and we will explain it in a later section (§3.4).

After selecting the block, operations execute the fast path (lines 4, 15, and 28), which may return one of the three results: (1) The fast path succeeds, returning the value for *get* and *steal*. (2) The fast path fails because there is no data to consume (lines 18 and 31) or because a thief detects a conflict with other thieves or with the owner due to the takeover (line 33). In case of a conflict, the fast path is retried (line 34), otherwise null value is returned. (3) The *margin* (beginning or end) of the current block is reached (lines 7, 20, and 35). In this case, the operation tries to move to the next block by performing the block advancement, and retries if it succeeds, otherwise returns the empty or full queue status.

Splitting the global metadata into block-level instances enables splitting the operations into the fast path and block advancement, which increases the performance by keeping the fast path extremely lightweight. However, the lack of global mutable metadata shared between owner and thieves raises additional challenges, which are mostly delegated to the block advancement—it is now responsible for maintaining complex block-level invariants. We introduce the following invariants:

- (1) *put* never overwrites unconsumed data;
- (2) *steal* and *get* never read the same data;
- (3) *steal* and *get* never read data that has been read before;
- (4) *steal* in progress cannot prevent *get* from reading from a thieves’ block. Before explaining fast path and block ad-

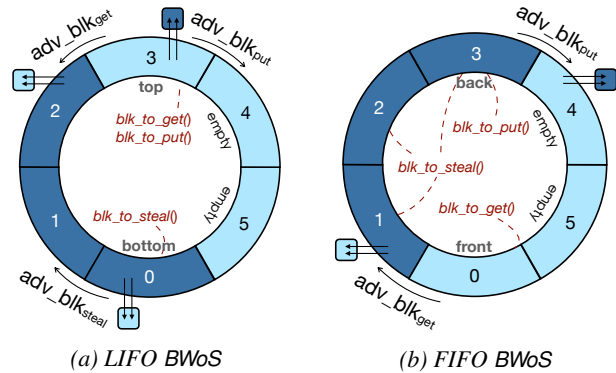

Figure 4: Block-level synchronization in BWoS.

Figure 5: Update of round numbers in each block.

vancement implementations, we introduce two key concepts we rely on to ensure that the abovementioned invariants hold: *block-level synchronization* (§3.2) and *round control* (§3.3).

### 3.2 Block-level Synchronization

Block-level synchronization is the key responsibility of the block advancement and ensures that thieves never steal from the block currently used for get operations. Each block is owned either by the owner or by the thieves. For example, in Fig. 4, blocks with lighter and darker colors belong to the owner and thieves respectively. The owner grants a block to the thieves, or takes a block back from them with block advancement. More specifically, for LIFO BWoS, *get* advances to the *preceding* block (3 to 2) and takes it over from thieves; *put* grants the current one and advances to the *following* block (3 to 4). For FIFO BWoS, *get* (resp. *put*) advances and takes over (resp. grants) the following block.

The grant and takeover procedures are based on the *thief index*—an entry in the block metadata that indicates the stealing location inside the block. Takeover sets this index to the block margin with an atomic exchange, and uses the old value as the threshold between the owner and the ongoing thieves in this block. This ensures that owner is not blocked by thieves when it takes over the block. Moreover, concurrent owner and thieves never read the same data because the threshold between them is set atomically. Similarly, the grant procedure transfers the block to thieves by writing the threshold to the thief index. We will introduce the details in §4.2.1.

### 3.3 Round Control

Each block also records *round numbers* of the last data access. When advancing block, the current block’s round is copied over to the next block; except in the case of a wrap-around,

where the block number is increased by 1 (Fig. 5).

In fact, there are producer, consumer, and thief round numbers in each block. When the producer tries to write round  $r$ 's data into a block, the consumer and thieves must have finished reading all data with round  $r - 1$  from that block; so that the producer never overwrites any unread data. Similarly, when the consumer or a thief tries to read round  $r$ 's data from a block, the producer's round at that block must already be  $r$ ; this prevents reading any data twice, or reading data that was never written. Details can be found in §4.2.2.

### 3.4 Probabilistic Stealing

As discussed in §2.1.3, size-based policies can achieve better load balance at the cost of degrading the performance of the owner of each queue. Calculating the size is even harder in our setting because the appropriate metadata is distributed across all blocks. However, BWoS brings an opportunity to have a new size-based, probabilistic stealing policy, which can provide strong load balance without adversely affecting the owner's performance.

We ensure strong load balancing by making the probability of choosing a queue as a victim proportional to its size. We implement this approach with a two-phase algorithm: the  $P_{select}$  phase first selects a potential victim randomly, and then the  $P_{accept}$  phase decides whether to steal from it with probability  $S/C$ , where  $S$  is the selected queue's size and  $C$  is its capacity; otherwise (with probability  $1 - S/C$ ) it returns to  $P_{select}$  for a new iteration.

Therefore, given a pool of  $N$  queues each with the same capacity and a selector in  $P_{select}$  that selects each queue with equal probability,  $P_{accept}$  can guarantee that the probability of a thief stealing from a queue is proportional to its size.

To minimize the impact on the owner's performance, instead of measuring  $S$ , we estimate  $S/C$  directly by sampling. The thief chooses a random block from *all* blocks of the queue and checks if it has data *available for stealing*, where the probability of returning true is close to  $S/C$ . As the thief reads only one block's metadata, its interference with the owner is minimal (cf. §2.2).

For FIFO BWoS, the above approach can achieve zero-overhead for steals: after the estimation returns true, we can steal from the block used for estimation directly, as block-local metadata enables thieves to steal from any block which has been granted to thieves. We call this instance of applying our probabilistic stealing policy to FIFO BWoS a randomized stealing procedure.

For LIFO BWoS, stealing still happens from the *bottom* block (Fig. 4). Thieves advance to the following block when they finish the current one. For FIFO BWoS, thieves do not advance block when randomized stealing is enabled, and fall back to the stealing policy for selection of the new queue and block instead (§3.4). In this case, the operation to advance to the next block on stealing (Fig. 3 line 36) becomes a no-op.

Figure 6: Put, get, and steal operations inside the block.

Moreover, we can further combine the probabilistic stealing policy with a variety of selectors for  $P_{select}$  phase (e.g., from NUMA-aware policy), to benefit from both better workload balance and reduced stealing cost. Results show that the hybrid probabilistic NUMA-aware policy brings the best performance to BWoS (§6).

## 4 Implementation

### 4.1 Single-Block Operations (Fast Path)

Let's consider how *put*, *get*, and *steal* operations inside the block are implemented (lines 4, 15, and 28 in Fig. 3). Because *get* and *steal* always happen on different blocks, we only need to consider two cases of multiple operations in a block: producer-consumer and producer-thieves (Fig 6).

To support these cases, each block has 4 metadata variables: entries which are ready for the consumer in the block are between the *front position* ( $f\_pos$ ) and *back position* ( $b\_pos$ ), while thieves use the *stealing position* ( $s\_pos$ ) and a counter of *finished steals* in the block ( $s\_cnt$ ) for coordinating among themselves and with the producer respectively.

To produce a value, *put* first checks whether it reaches the block margin NE (number of entries), if not, writes the data into the producer position ( $b\_pos$ ), and lets it point to the next entry.

To consume a value, there are two *get* operations,  $get^f$  and  $get^b$ , which correspond to the FIFO and LIFO BWoS respectively. *get* checks whether the block margin has been reached, or if the block has run out of data ( $f\_pos$  has reached  $b\_pos$ ), if not, it reads the data and updates the consumer position variable in the block metadata. The two variants of *get* differ in which position variables and boundaries they use.  $get^f$  uses  $f\_pos$  as consumer position variable, NE as block margin, and  $b\_pos$  as boundary of valid data.  $get^b$  uses  $b\_pos$ , zero position of the block, and  $f\_pos$  for the same purposes, respectively.

Thieves follow a similar pattern: *steal* first checks if it has reached the block margin, or if the block has run out of data ( $s\_pos$  has reached  $b\_pos$ ). Then, it updates  $s\_pos$  using an atomic compare-and-swap (CAS) to point to the next entry, reads the data, and finally updates  $s\_cnt$  with an atomic increment. If the CAS fails, *steal* returns *conflict*. (CAS is used because multiple thieves can operate in the same block.)

All of these operations return *block\_done* when they reach a block margin. Otherwise, if the block runs out of data, *get* and *steal* return *empty*.

Figure 7: Takeover and grant procedures in block advancement.

## 4.2 Block Advancement

In case a block margin is reached, *put*, *get*, and *steal* move to the next block: They first check whether advancing is permitted by the round control, and if so, they call takeover (by *get*) or grant (by *put*) procedures, and reset block-level metadata.

### 4.2.1 Takeover and Grant Procedures

We explain the takeover and grant procedures using a queue with 4-entry blocks as an example (Fig. 7).

**LIFO.** Let us assume that 6 elements (a-f) were put into the queue. Thus, the owner is in the block  $b_1$ ;  $b\_pos$  in  $b_0$  and  $b_1$  becomes 4 and 2 respectively, while  $f\_pos$  and  $s\_pos$  remain at the initial value (0) (state ①). Then, two actions happen concurrently: two thieves try to steal entries, updating  $s\_pos$  in  $b_0$  to 2, and start to copy out the data (steal on Fig. 7), while the owner gets 3 values, consuming f, e (state ②), and advancing to  $b_0$ , thus starting the takeover. To perform the takeover, the owner atomically exchanges  $s\_pos$  with the block margin (4), and then sets  $f\_pos$  to the previous  $s\_pos$  value (2) (state ③). After the takeover, the owner gets d and puts g. Meanwhile, one ongoing *steal* completes (steal' on Fig. 7), increasing  $s\_cnt$  by 1 (state ④). It does not matter which of the two completes first. When the owner puts new items h and i, it grants  $b_0$  to thieves and advances to  $b_1$ . To perform the grant, it sets  $s\_pos$  to the  $f\_pos$  value (2), indicating to thieves that the block is available (state ⑤). After thieves steal all entries in  $b_0$ ,  $s\_cnt$  reaches the block margin (state ⑥). Thus,  $b_0$  can be reused in the next round.

**FIFO.** First, the producer puts 7 elements (a-g) into the queue. The producer and the consumer are in  $b_1$  and  $b_0$  respectively, and thieves can steal from  $b_1$  (state ①). Then, the consumer gets all elements in  $b_0$ , and advances to  $b_1$  (state ②). This requires taking over  $b_1$  from thieves: for this purpose, it updates  $s\_pos$  and  $f\_pos$  in the same way as the LIFO BWoS, but also adds the difference between the new  $f\_pos$  (2) and the block margin (i.e. length of the block) to  $s\_cnt$  (state ③). This way, when all thieves finish their operation in  $b_1$ , its  $s\_cnt$  will be equal to the block margin. After that, the producer puts a new item h, and advances to  $b_2$  granting it to thieves (state ④).

Finally, both thieves and the consumer have read all entries from  $b_1$ , its  $f\_pos$  and  $s\_cnt$  are equal to the block margin (state ⑤). The producer uses this condition to check if the block can be reused for producing new values into it.

### 4.2.2 Round Control and Reset Procedure

To implement round control (§3.3), the position variables in block metadata ( $f\_pos$ ,  $b\_pos$ ,  $s\_pos$ ,  $s\_cnt$ ) contain both the index or counter ( $idx$  field) as described in §4.2.1 and the round number ( $rnd$  field). We fit both components into a 64-bit variable that can be updated atomically.

Consider, for example, the put operation of FIFO BWoS (Fig. 8). In *put*, when the producer  $idx$  reaches the block margin NE of the block  $blk$  (step ①), the new round  $x$  of the next block  $nblk$  is calculated as described in §3.3 (step ②). When advancing to the block  $nblk$  with the producer round  $x$ , the producer checks that the consumer and the thieves have finished reading all data from the previous round in  $nblk$  by checking if their  $idx$  fields are equal to NE and their  $rnd$  fields are  $x - 1$  (step ③). When the check succeeds, the new value with the index 0 and the round  $x$  will be written into the producer position variable (step ④), thus *resetting* the block for the next round producing. Otherwise, a “queue full” condition is reported.

The *get* operation of the FIFO BWoS is similar. To decide whether *get* can use a next block, it checks whether the block’s next consumer’s round is equal to the producer round (step ③), and resets the round and index fields if the check succeeds.

Each operation resets only a subset of position variables ( $b\_pos$ ,  $f\_pos$ ,  $s\_pos$ ,  $s\_cnt$ ). We carefully select which variables each operation resets so that takeover and grant procedures by the owner have no write conflict with the reset done by thieves.

## 5 Verification and Optimization

The complexity of the BWoS algorithm necessitates the use of formal verification techniques to ensure that there are no lurking design or implementation bugs, and to optimize the

Figure 8: Round control in FIFO BWOs.

use on WMMs. One can easily imagine several tricky cases with block advancements. For example, for LIFO BWOs, when the owner calls *puts* and *gets* and advances to the next block, it may easily trigger ABA [67] bugs during the round control and takeover.

Unlike simpler algorithms like ABP [79], it is virtually impossible to justify the correctness of an optimal memory barrier placement by inspection. Luckily, model checking tools [62, 74, 84, 92] are widely used to check the correctness of concurrent algorithms and optimize the memory barrier under WMMs automatically, improving both performance and developer confidence. For example, the Tokio library uses the model checker Loom [27, 91], which has helped them find more than 10 bugs [28].

## 5.1 Verification Client

A model checker takes as input a small *verification client* program that invokes queue operations. It verifies that all possible executions of the input program satisfy some generic correctness properties, such as memory safety and termination [45], as well as any algorithm-specific properties that are included in the verification client as *assertions*. Whenever verification fails, the model checker returns a concrete erroneous execution as a counterexample.

To be able to generalize the verification result beyond the specific client program verified, the client program must trigger all possible contending scenarios and cover all desired properties. Because of the symmetry of BWOs (each owner operates on its own queue and steals from others), it suffices to verify the use of one queue owned by one thread and contended by several thief threads.

**Verified properties.** We have verified the following properties with the GenMC model checker [74, 75]:

- Memory safety: The program does not access uninitialized, unallocated or deallocated memory.
- Data race freedom: there are no data races on variables that are marked as non-atomic.
- Consistency: Each element written by the producer is read only once by either the consumer or thieves. No data corruption or loss occurs.
- Loop termination: Every unbounded spinloop and bounded fail-retry-loop in the program will eventually terminate even under weak memory models.

```

1 class stat {
2   u64 sum = 0, buf = 1;
3   void put(queue<u64> q){
4     if (q.put(buf))
5       sum += buf;
6     buf <<= 1;
7   }
8   bool get(queue<u64> q){
9     data = q.get(buf);
10    if (data != null) {
11      sum += data;
12      return true;
13    }
14    return false;
15  }
16  void steal(queue<u64> q){
17    data = q.steal(buf);
18    if (data != null)
19      sum += data;
20  }
21  }
22  stat f, b, s1, s2;

Figure 9: Verification and optimization client code.

	VERI/OPT time	memory barriers				#executions explored
		#SEQ	#ACQ	#REL	#RLX	
LIFO BWOs	62 min.	0	2	2	14	1.39 M
FIFO BWOs	53 min.	0	3	3	16	1.43 M
ABP	16 min.	4	3	1	7	2.05 M

Table 2: Statistics of the verification and optimization.

All possible executions, including those that occur due to weak memory reordering under the IMM [94] and RC11 [78] memory models, have been explored, and the aforementioned properties hold for each of them. With GenMC we were able to verify safety properties and termination of loops, but not the properties of individual operations.

**Contending scenarios.** As in any model checking verification, our models have a limited size within which the above properties hold. The client code for verifying and optimizing *put*, *get*, *steal* operations of BWOs is shown in Fig. 9. We configure the queue to have two blocks, each with the capacity of two entries (line 23). It is thus sufficient to put 5 entries to trigger the queue wraparound. We then launch 3 threads that run in parallel: The owner thread T0 has 3 rounds of *put* and *get* (lines 24-26) with different numbers of entries, trying to trigger block advancement for both producers and consumers in each round. Thief threads T1 and T2 steal one and two entries respectively, and thus together with T0, they trigger the queue empty condition, takeover, grant, and reset procedures, as well as conflicts between thieves.

**Assertion and properties.** After threads T0–T2 exit, thread T3 gets all remaining entries, and asserts that the sum of *put* elements is equal to the sum of elements read via *get* and *steal* (lines 30-31). Notice that the elements are generated as powers of two (line 6), therefore this assertion ensures that *each element written by the producer has been read only once*.

## 5.2 Results

We have optimized and verified the C code of LIFO and FIFO BWOs with the VSync framework and the GenMC model

checker. We have also verified the ABP queue using our verification client as a baseline. The statistics are shown in Table 2, broken down by memory barrier type: sequentially consistent (SEQ), acquire (ACQ), release (REL), and relaxed (RLX, i.e. plain memory accesses).

For BWoS, barrier optimization and verification finished in about an hour on a 6-core workstation [59], with over 1 million execution explorations. For ABP, the checking finishes in 16 minutes. More executions are explored for ABP since thieves and owner synchronize for every operation, which brings more interleaving cases.

**Verification confidence.** By adding one thread and discovering that no further barriers were required, we conclude that further increasing the thread count is unlikely to discover some missing barrier. Hence, we can avoid the state space explosion that happens with larger thread counts. On the other hand, discovering that an existing barrier had to be stronger would have forced us to review the algorithm in general.

**Experience.** Model checking proved itself to be invaluable during BWoS’s development. For example, an early version of LIFO BWoS had a bug where thieves would reset the `s_pos` variable when advancing to their following block (`blk`). In the case when the owner is advancing to its preceding block which also happens to be `blk`, it would update `s_pos` in the takeover procedure, which conflicts with the thieves’ reset procedure, resulting in data loss. This data loss was detected by GenMC with the verification client assertion (lines 30-31). We have fixed it by delegating the thieves’ `s_pos` reset procedure to the owner, thus removing this conflict.

**Optimization.** For BWoS, most concurrent accesses are converted to relaxed barriers, with the few remaining cases being release or acquire barriers. For the owner’s fast path that determines the performance, we have only one release barrier in the FIFO BWoS. In contrast, the highly optimized ABP [79] contains many barriers. In particular, owner operations contain 2 sequentially consistent, 1 acquire, and 1 release barriers, which significantly degrade its performance.

We note that these optimization results are optimal: relaxing any of these barriers produces a counterexample. To further increase our confidence in the verification result, we added another thief thread stealing one entry, and checked the optimized BWoS with GenMC. BWoS passes the check in 3 days with around 200 million execution explorations.

**Barrier analysis.** LIFO BWoS does not contain any barriers in the fast path because the owner and the thieves do not synchronize within the same block. An acquire-release pair is related to `s_pos` in the owner’s slow path and thieves’ fast path that ensures the correctness of the takeover procedure. Another acquire-release pair is related to `s_cnt` which ensures the owner doesn’t overwrite ongoing reading when it catches up with a thieves’ block (wraparound case). For FIFO BWoS, besides the above barriers, since producer and thieves need to synchronize within a block, an additional acquire-release pair

in their fast path is required.

## 6 Evaluation

**Experimental setup.** We perform all experiments on two x86 machines connected via 10Gbps Ethernet link, each with 88 hyperthreads (x86) [71], and one Arm machine with 96 cores (arm) [70]. The operating system is Ubuntu 20.04.4 LTS with Linux kernel version 5.7.0.

### 6.1 Block Size and Memory Overhead

In comparison with other queues, BWoS has extra parameters that the user needs to choose when initializing a data structure, namely the block size and the number of blocks. In our experience with both micro- and macro-benchmarks, the system’s throughput remains mostly constant regardless of the block size or the number of blocks as long as they are above certain minimal values: 8 or more blocks in the queue and 64 or more elements in the block, both for our x86 and arm machines.

The reason for this insensitivity to block size change is twofold: first, since a single thread is responsible for advancing the blocks of its own queue, the block size does not introduce any contention-related overhead. Larger block sizes cause the queue owner to advance the block less often, but after a certain block size, the overhead of advancing the block becomes negligible. Second, since BWoS forbids the owner and thieves consuming items in the same block with block-level synchronization, the contention of them on a queue is largely independent from the number of blocks. These insights guide the block size selection for our benchmarks: we set the number of blocks to 8 and calculated the block size based on the queue capacity.

Therefore, selecting an appropriate block size is straightforward. Further fine-tuning of these parameters may be beneficial for extreme scenarios where memory-size constraints are present or the overly large block size becomes detrimental to stealing (§8).

BWoS contains three pointers for each queue, and four atomic variables, two pointers, and one boolean variable for each block as its metadata. The actual memory usage also includes cache padding added to prevent false sharing. The memory overhead from this metadata is static and thus negligible for most use-cases.

### 6.2 Microbenchmarks

To verify our claims, we have designed a microbenchmark which supports both LIFO and FIFO work stealing and compared BWoS with the state-of-the-art algorithms: an off-the-shelf ABP [48] implementation from Taskflow v3.4.0 [35] with barrier optimization [79] (`abp`), the block-based bounded queue [106] (`bbq`), work stealing queues from Tokio v1.17.0 [38] (`tokioq`), Go’s runtime v1.18 [36]

Figure 10: Throughput of LIFO BWoS and ABP with (opt) or without (sc) memory barrier optimization on x86 and arm running with different stolen percentages.

Figure 11: Throughput of FIFO BWoS and other state-of-the-art FIFO work stealing algorithms.

(goroutineq), Kotlin coroutines v1.6.4 [26] (coroutineq), and Eigen v3.3 [8] (eigenq).

Each queue has a capacity of 8k entries, with 8-byte data items; BWoS is configured to have 8 blocks. We perform the following three experiments:

- Single queue without stealing (§6.2.1): The owner thread executes the workload in a loop: it first puts until the queue is full and then gets until the queue is empty.

- Single queue with stealing (§6.2.2): An additional thief thread calls *steal* operations on the queue in a loop. We adjust the *put/get* ratio, and the idle time between each *steal* to perform the experiment at varying stolen percentages<sup>2</sup>.

- Pool consisting of 8 queues (§6.2.3): 8 threads perform the following operations in a loop: put items to its queue until it is full, then get until it is empty, and then attempt to steal  $k * C$  items from the pool, where  $k$  is the *balancing factor* (in percent), and  $C$  is the queue capacity. The threads are distributed equally between two NUMA domains, and within each NUMA domain between two L3 cache groups [58].

In each experiment, we measure the total throughput: the sum of *put*, *get*, and *steal* operation throughputs (ops/sec).

### 6.2.1 Queue without Stealing

**Overall performance.** Figures 10 and 11 for stolen percentage equal to 0 show the performance of the queue without stealing. BWoS outperforms other algorithms by a significant margin. For example, LIFO BWoS (bwos\_opt) has 4.55x higher throughput than ABP (abp\_opt) on x86, and FIFO BWoS written in C/C++, Rust, Go, and Kotlin outperform bbq in C, eigenq in C++, tokioq in Rust, goroutineq in Go,

<sup>2</sup>The thief thread is located in the same L3 cache group as the owner; the results are similar when putting the thief thread elsewhere.

coroutineq in Kotlin by 8.9x, 10.15x, 3.55x, 1.61x, and 1.82x accordingly.

**Impact of the memory barrier optimization.** abp and LIFO BWoS get 1.65x and 5.39x speedup on x86, and 2.03x and 3.38x speedup on arm respectively due to the memory barrier optimization. We observe similar results for FIFO work stealing algorithms<sup>3</sup>. The much greater speedup of BWoS compared to ABP is possible in particular due to the separation of fast path and block advancement, where most of the barriers in the fast path become relaxed.

**Effectiveness of the block-level synchronization.** Results show that on x86 LIFO and FIFO BWoS are only 10.7% and 5.4% slower than ideal, respectively. On arm the results are similar. Thus, block-level synchronization allows BWoS to approach the theoretical upper bound by removing the consumer-thief synchronization from the fast path.

### 6.2.2 Queue with Stealing

**Overall performance.** As the stolen percentage increases, BWoS continues to outperform other work-stealing algorithms. For example, with 10% stolen percentage, LIFO BWoS outperforms abp by 12.59x, while FIFO BWoS outperforms bbq, eigenq, tokioq, goroutineq, coroutineq by 11.2x, 30.1x, 9.41x, 2.78x, and 1.64x respectively.

**Effectiveness of the block-based approach.** Unlike other algorithms, BWoS suffers only a minor performance drop as the stolen percentage increases. For example, for 20% stolen percentage, the throughput of LIFO and FIFO BWoS drops only by 0.53% and 9.35%, while for abp\_opt, tokioq and goroutineq it degrades by 71.9%, 80.2%, and 59.3% respectively. Note that the BBQ concurrent FIFO queue [106], which is also a block-based design, does not reach performance comparable to BWoS, stressing the importance of our design decisions for the work stealing workloads.

### 6.2.3 Pool with Different Stealing Policies

**Stealing policies.** We perform this experiment with 6 stealing policies, namely the random choice policy (rand), a policy that chooses the victim based on a static configuration (seq), a policy that chooses the last selected one as the victim [104] (last), best of two (best\_of\_two), best of many (best\_of\_many), and NUMA-aware policy (numa). For best\_of\_many we choose best of half (i.e. best of four).

**Overall performance.** In this experiment, we compare BWoS only with the second-best algorithm from the previous experiments: abp and tokioq for LIFO and FIFO work stealing respectively. Fig. 12 shows that BWoS performs consistently better than other algorithms. When the balancing factor is 0%, BWoS outperforms abp by 4.69x and tokioq by 2.68x. As the

<sup>3</sup>Notice here bwos\_go does not have barrier optimization because Go does not expose an interface for relaxed atomics. However, for the macrobenchmarks we apply the barrier optimization by using the Go internal atomic library.

Figure 12: Throughput of the pool (8 queues) with different stealing policies and different balancing factors on x86. rest refers to all non-*numa* policies with and without probabilistic stealing.

Figure 13: Speedup of 23 benchmarks from Renaissance benchmark suite on x86.

balancing factor increases, the throughput of BWoS variants is 7.90x higher than of abp and 6.45x higher than of tokioq.

**Impact of the NUMA-aware policy.** LIFO and FIFO BWoS with *numa* policy outperform BWoS with other policies by at most 2.21x and 1.73x respectively. For other work stealing algorithms, *best\_of\_two* brings the best performance. Thus, BWoS benefits from *numa* policy while other algorithms do not. On the other hand, in many cases *best\_of\_many* brings the worst performance, proving that interference with the owner can outweigh its improvements to the load balance.

**Effectiveness of the probabilistic stealing.** BWoS can additionally benefit from the probabilistic stealing. When the balancing factor is 100%, *numa* with probabilistic stealing (*bwos+numa+prob*) brings 1.34x, 1.53x performance improvement on average to LIFO and FIFO BWoS.

## 6.3 Macrobenchmarks

### 6.3.1 Java G1GC

We replace the task queue [24] in Java 19 HotSpot [37] with LIFO BWoS, and run the Renaissance benchmark suite v0.14.0 [33], which consists of 25 modern, real-world, and concurrent benchmarks [95] designed for testing and optimizing garbage collectors. Two database benchmarks are omitted since they don't support JDK 19. JVM enables `-XX:+DisableExplicitGC` [30,68] and `-XX:+UseG1GC` flags when running the benchmark. All other parameters (e.g., number of GC threads, VM memory limit) are default. We run 10 iterations for each benchmark with the modified and the

Figure 14: Throughput and latency results of Hyper HTTP server with BWoS and the original algorithm.

Figure 15: Throughput and latency of Tonic gRPC server with BWoS and the original algorithm.

original JVM, and measure the end-to-end program run time via the Renaissance testing framework.

Figure 13 shows the speedup of all 23 benchmarks on x86. When BWoS is enabled, 17 of them get performance improvement. The average speedup of all benchmarks is 3.55% and the maximum speedup is 25.3%. The applications that benefit more from concurrent GC also get greater speedup from BWoS. Results on arm are similar where the average speedup is 5.20%, 18 benchmarks are improved and the maximum speedup is 17.2%.

On the other hand, several Renaissance benchmarks did not get any performance improvement from using BWoS. We have investigated this issue by running JVM with flags `-Xlog:gc+cpu` and `-Xlog:gc+heap+exit` to collect GC-related statistics. These experiments have shown that applications that trigger GC often demonstrate improvement from BWoS, while applications that don't trigger GC or triggered it only rarely (e.g. at JVM exit) see no speedup. For the benchmarks which never or seldomly trigger the GC, the slowdown is most likely due to the longer queue initialization.

### 6.3.2 Rust Tokio Runtime

We replace the run queue [39] in Tokio v1.17.0 [38] with FIFO BWoS, and run Hyper HTTP server v0.14.18 [20] and Tonic gRPC server v0.6.2 [40] with the modified runtime. Tokio runtime (also Go runtime) provides a batch stealing interface. Based on observations from benchmarks similar to Fig. 2d, we configured the thief of BWoS to steal all available entries from its block at once. Benchmarks are performed on two x86 machines, one running the server, the other running the HTTP benchmarking tool *wrk* v4.2.0 [43] or the gRPC benchmarking and load testing tool *ghz* v0.017 [14]. All parameters of Hyper and Tonic are default. Each benchmark runs 100 seconds and

Figure 16: Request throughput, average latency, and task stolen percentage comparison results of 5 Rust web frameworks of BWoS (normalized to the original algorithm results) with rust-web-benchmarks workload on x86.

has 10 iterations. The latency and throughput are measured by wrk or ghz, while the CPU utilization of the server is collected through the Python psutil library [32]. wrk and ghz run the echo workload and SayHello protocol respectively and are configured to utilize all hyperthreads of their machine.

Figure 14 shows the throughput-latency and throughput-CPU utilization results of Hyper with different connection numbers (100, 200, 500, 1k, 2k, 5k, and 10k). Before the system is overloaded, BWoS provides  $1.14 \times 10^6$  op/s throughput while dropping 60.4% CPU usage with similar latency, the original algorithm provides only  $9.44 \times 10^5$  op/s throughput. With 1k connections, BWoS increases throughput by 12.3% with 6.74% lower latency and 60.9% lower CPU utilization.

Figure 15 shows the throughput and latency results of Tonic. Using BWoS increases throughput by 32.9%, with 32.8% lower average latency and 36.6% lower P95 latency.

To prove the generality of BWoS when applied to web frameworks, we also benchmark another 5 popular Rust web frameworks [4, 31, 34, 41, 42] that used Tokio runtime with rust-web-benchmarks [5] workload on x86 (Fig. 16). Results show that BWoS increases the throughput by 82.7% while dropping 45.1% of average latency. In addition, the task stolen percentage drops from 69.0% to 49.2%. We have made our implementation for the Tokio runtime available to the open-source community [3].

### 6.3.3 Go Runtime

We replace the runqueue [17] in the Go programming language [36] v1.18.0 runtime with BWoS and benchmark 9 JSON libraries [1, 9–12, 15, 18, 19, 25]. The benchmark suite [16] comes from the go-json library and runs 3 iterations with default parameters. We record the latency of each operation (e.g., encoding/decoding small/medium/large JSON objects) reported by the benchmark suite, and calculate the speedup.

As shown in Fig. 17, when BWoS is enabled, operations get 25.8% average performance improvement on x86. arm produces similar results with 28.2% speedup on average. In general, encoding operations have better speedup compared to decoding operations. We observe no improvement for encoding booleans and integers.

## 7 Related Work

**Block-based queues.** Wang *et al.* proposed a block-based bounded queue [106] (BBQ) that splits the buffer into multiple blocks, thus reducing the producer-consumer interference. BWoS differs from BBQ in the following ways: (1) although BBQ also applies metadata separation, the producer-consumer interference it reduces is not an issue for work stealing as these always execute on the same core. By introducing block-level synchronization, steal-from-middle property, and randomized stealing, FIFO BWoS outperforms BBQ by a large margin (§6). (2) For the round control in BWoS, the new round of a block is determined only by the round of its adjacent block instead of relying on global metadata, as the *version* mechanism in BBQ does. This design simplifies the round updating and reduces its overhead.

**Owner-thief interference and synchronization costs.** Attiya *et al.* proved that work stealing in general requires strong synchronization between the owner and thieves [49]. BWoS overcomes this issue by delegating this synchronization to the block advancement, thus removing it from the fast path. Acar *et al.* used a sequential deque with message passing to remove the owner’s barrier overhead [44]. However, this design relies on explicit owner-thief communication, thus the steal operation cannot run to completion in parallel with the owner’s operations. Dijk *et al.* proposed a deque-based LIFO work-stealing algorithm which splits the deque into owner and thief parts, thus reducing the owner’s memory fences when they do not reach the queue split point [61]. However, the entries read by thieves cannot be reused until the whole deque is empty. Horie *et al.* proposed a similar idea, where each owner has a public queue that is accessible from other threads and a private queue that is only accessible by itself [68]. However, it requires more effort to deal with load balancing, e.g., introducing global statistics metadata which causes more cache misses for the owner. In contrast, BWoS reduces the interference using techniques of block-level synchronization, and probabilistic and randomized stealing. Morrison *et al.* introduced work stealing algorithms which rely on the bounded TSO microarchitectural model, which x86 and SPARC CPUs were shown to possess [89]. Michael *et al.* reduced the thief-owner synchronization by allowing them to read the same task [87], which requires reengineering of tasks to be idempotent. BWoS exhibits correct and efficient execution on a wide range of CPU architectures without any additional requirements.

**Stealing policies.** Yang *et al.* gave a survey of scheduling parallel computations by work stealing [107]. Kumar *et al.* benchmarked and analyzed variations of stealing policies [76]. Mitzenmacher proposed to give the thief two choices for selecting the victim to have a better load balancing [88]. Most of the analyzed policies are size-based, and thus aim to reach the same goal as our probabilistic stealing policy—namely, better load balance. Hendler *et al.* allow thieves to steal half

Figure 17: Speedup in the go-json library benchmark on x86 from using BWoS.

of the items in a given queue once to reduce interference [66]. BWoS supports batched stealing, but the maximum amount of data that can be stolen atomically is a block. However, the stealing policy can be configured to steal more than one block. Kumar *et al.* proposed a NUMA-aware policy for work stealing [77]. This policy is fully orthogonal to BWoS and can be combined with its probabilistic stealing policy.

**Formally verified work stealing.** Lê *et al.* [79] manually verified and optimized the memory barriers of Chase-Lev dequeue [53] on WMMs. Unlike the verification of BWoS which relies on model checking, manual verification is a high-effort undertaking. In the context of concurrent queues, Meta’s FollyQ was verified using interactive theorem prover [105]. While this approach provides the highest levels of confidence in the design, it works only with sequentially consistent memory model, and is also a high-effort endeavor. Recently, GenMC authors have verified the ABP queue as part of evaluation of their model checker [74]. The authors of BBQ have relied on VSync to simultaneously verify and optimize the barrier for weak memory models [106]. BWoS also uses VSync for this purpose, but instead of many hand-crafted tests, which exercise the individual corner cases in BBQ, we create one comprehensive client that covers several corner cases and their interactions at once. We further verify the optimization results by adding one more thief into the verification client and checking it with GenMC.

## 8 Conclusion

To conclude, we explore two of our learnings from this work.

**The benefit of the block-based design is manifold.** First, by replacing the global mutable metadata with block-level metadata, it is possible to eliminate the interference between the owner and the thieves that operate on different blocks. Second, by ensuring exclusive access to a block for owner’s get operation through block-level synchronization, it is possible to relax most of the barriers from the operation’s fast path, increasing its performance up to the theoretical upper bound. Although being unnecessary in our current algorithm, a third benefit is the verification modularity given by the block-based design, *e.g.*, allowing the verification of blocks

and their composition in separate steps. Finally, the block-based design opens possibilities for holistic optimization of the data structure use, as we do with our probabilistic stealing policy.

BWoS can also be applied to GPU and hybrid CPU-GPU computations, as well as in HPC schedulers, where work stealing is common. We plan to explore this direction in the future. More generally, the BWoS design can be applied to other use cases, where the data structure is mostly accessed by a single thread, and only rarely by multiple. In this case, the decisions demonstrated in BWoS can act as design and implementation guidelines.

### Verified software can be faster than unverified software.

The more hardware details and tweaks are mirrored in the software, the more complex and opaque that piece of code becomes. The interaction of this complexity with concurrency and weak memory consistency is a major challenge. We believe that practical verification tools (*i.e.*, tools applied to increase confidence in correctness) are a key enabler in the development of efficient, and inevitably complex, concurrent software such as BWoS.

### Future Work

There are several directions for further work: We plan to contribute BWoS to more open-source projects, *e.g.*, openJDK [23, 29], and Golang, as well as investigate how to use BWoS in HPC runtimes. We also plan to better explore the performance trade-offs for BWoS: if the number of outstanding work items is smaller than the block size, BWoS can prevent stealing and thus limit the achieved parallelism. Furthermore, if the queue capacity has to be very small (due to space requirements), it may be necessary to reduce the block size and thus incur more block advancement that leads to performance drop. These situations would benefit from more exploration in the system design. In other cases, BWoS is expected to outperform existing state-of-the-art work-stealing algorithms due to its implementation of several performance-enhancing techniques.

## Abstract

System software is often large and complex, resulting in many vulnerabilities that can potentially be exploited to compromise the security of a system. Formal verification offers a potential solution to creating bug-free software, but a key impediment to its adoption remains proof cost. We present Spoq, a highly automated verification framework to construct machine-checkable proofs in Coq for system software with much less proof cost. Spoq introduces a novel program structure reconstruction technique to leverage LLVM to translate C code into Coq, supporting full C semantics, including C macros, inline assembly, and compiler directives, so that source code no longer has to be manually modified to be verified. Spoq leverages a layering proof strategy and introduces novel Coq tactics and transformation rules to automatically generate layer specifications and refinement proofs to simplify verification of concurrent system software. Spoq also supports easy integration of manually written layer specifications and refinement proofs. We use Spoq to verify a multiprocessor KVM hypervisor implementation. Verification using Spoq required 70% less proof effort than the manually written specifications and proofs to verify an older implementation. Furthermore, the proofs using Spoq hold for the unmodified implementation that is directly compiled and executed.

## 1 Introduction

System software such as operating systems and hypervisors [7] forms the software foundations of our computing infrastructure. However, modern system software is large, complex, and imperfect, with vulnerabilities that can be exploited to compromise the security of a system. Formal verification offers a potential solution to this problem by mathematically proving that system software can provide critical security guarantees. This typically involves verifying that the software implementation satisfies a formal high-level specification of its behavior, then proving that the specification guarantees the desired security properties.

The former, referred to as functional correctness, is generally the most challenging part to do, given the complexity of system software implementations. Implementations are commonly written in C, which has complex semantics and language features, many unsupported by verification tools. Verification tools powerful enough to verify real-world system software are difficult and tedious to use to write specifications and proofs. Furthermore, a high-level specification that is useful for verifying higher-level properties such as security often has a significant semantic gap from the implementation, requiring substantial manual proof effort to bridge this gap. However, without functional correctness to ensure that the proofs hold on the actual implementation, formally verified guarantees can be meaningless in practice.

We introduce Spoq (Scaling Proofs in Coq), a new verification framework to reduce proof costs for machine-checkable verification of system software. Spoq focuses on simplifying formal verification of functional correctness to reduce proof costs while ensuring that all proofs are machine-checkable by a theorem prover and verified down to the actual software implementation. It operates on widely used unmodified C code and leverages the Coq proof assistant [55] to enable machine-checkable verification of complex systems. Its key feature is making Coq easier to use by automating many aspects of writing Coq specifications and proofs. This reduces the amount of Coq code that needs to be manually written, which significantly reduces the time to conduct machine-checkable verification.

Spoq is the first system that can automatically translate unmodified C systems code, such as found in the Linux kernel, into a Coq representation so that it can be verified. Previous approaches such as CompCert's ClightGen [35] only support a subset of the C language. Systems that use ClightGen such as CertiKOS [18, 20] require significant manual effort to retrofit the systems implementation before it can be verified, extra effort to develop and maintain the retrofitted version, and still cannot provide any verified guarantees on the actual running version. Spoq address this problem by leveraging the widely used Clang compiler front end to parse C code into

LLVM's language-independent intermediate representation (IR). Because LLVM IR represents functions as control flow graphs, Spoq introduces a novel program reconstruction technique that translates control flow graphs back into a Coq representation using program-style functions with if-then-else and loop statements that is more amenable to verification. This approach enables Spoq to support full C language semantics, including GNU C-specific extensions and inline assembly code, yet work with an IR with clean semantics designed for automated translation into another representation.

Spoq then leverages a layering proof strategy based on Concurrent Certified Abstraction Layers (CCAL) [19, 21] to modularize and decompose verification into smaller steps to make each verification step easier. This involves defining the layer structure of the implementation, where each layer consists of a group of functions that define the layer's interface. Higher layers can call the functions exposed by a lower layer's interface, but not the other way around. The top layer is a high-level specification of the behavior of the entire implementation, while the bottom layer is a machine model whose interface is designed to support LLVM IR semantics. Verification involves proving that the layers compositionally refine the top layer specification of the entire implementation. While layering makes each verification step easier to accomplish, if done manually, it has the disadvantage of requiring a user to construct additional layer specifications, including both low-level and high-level specifications, and refinement proofs for each layer, which can involve tediously writing thousands of lines of additional Coq code. That code then has to be manually rewritten each time the program implementation is updated, imposing significant, time-consuming proof costs. Spoq instead takes advantage of layering and the easier verification steps it affords to make it possible to automatically generate the Coq layer specifications and mechanized refinement proofs from the layer structure definition. It is the first system that can automate the generation of layered specifications and proofs in Coq for concurrent system software.

Spoq constructs a machine-checkable proof object for each layer showing its implementation built on top of a lower layer interface refines its own layer interface. It decomposes the proof for a layer into two tasks. The first task is to prove that the layer's implementation, namely its Coq abstract syntax tree (AST) representation, refines a low-level specification that is closer to the source code and independent of the state of the machine model. The second task is to prove that the low-level specification, built on top of a lower layer interface, refines a high-level specification that defines the layer's interface and is self-contained. By self-contained, we mean that the specification does not contain any calls to functions in any other layer other than the bottom layer machine model. Making the high-level specification self-contained simplifies verification because refinement proofs of any layers built on top of this layer can effectively ignore any layers below it.

Spoq introduces a library of Coq tactics to automatically

generate low-level specifications and refinement proofs between the implementation and low-level specification. Functions with loops are synthesized into Coq recursive specifications, then refined to their specifications using an induction proof template. To generate the specification for a function with loops, a ranking function is provided for each loop, which is monotonically decreasing and non-negative during loop iterations. Spoq leverages the ranking functions to generate loop termination proofs.

Spoq introduces transformation rules to automatically generate high-level specifications and refinement proofs between low-level and high-level specifications. Transformation rules include unfolding function definitions, syntactically reorganizing program structures, eliminating pre-determined branches and assertions, and performing mathematical simplification. Refinement proofs are done by introducing automatically generated annotations to track how transformations are applied, then using Coq tactics to prove the sequence of transformations preserves specification semantics. Automatic generation of specifications and proofs is only done for high-level specifications that do not introduce data abstractions to hide low-level data representation details, such as abstracting an array into a Coq `Map`. High-level specifications that introduce data abstractions or have very complex functions require manual assistance from the user to complete the specifications and proofs. Our experience indicates that the vast majority of functions can be automatically specified and refined without manual effort.

Spoq reduces the trusted computing base (TCB) for performing source code-level mechanized verification. There is no need to trust Spoq for generating specifications or proofs. Incorrect specifications will be rejected during refinement proofs, and incorrect proofs will be rejected by the Coq proof checker. Although Spoq relies on Clang which is not verified, most system software already needs to trust either widely used Clang or unverified alternatives such as the GNU C compiler to generate the executable code that actually runs. Using a verified compiler such as CompCert [35] is not viable in practice since it cannot even compile C code such as Linux kernel code. The only part of Spoq that is unverified yet needs to be trusted is its translator from LLVM IR to Coq, which is minimal by design. This TCB is much smaller than CompCert's ClightGen, which is larger and more complex since it has to directly parse and translate C code, a more difficult and involved process.

We have implemented Spoq and evaluated its effectiveness on commodity system software. We show that Spoq automatically translates over 99% of functions in unmodified C systems code into Coq representations, including the source code for the Linux kernel, while ClightGen fails to translate the vast majority of functions, including almost complete failure on the Linux kernel. We use Spoq to verify a multiprocessor KVM hypervisor implementation. Although an older version of the hypervisor was previously verified in Coq without Spoq, the proofs no longer work with the

Figure 1: Spoq workflow.

updated version that supports additional hardware platforms. Previously, using ClightGen to translate the C implementation into a Coq representation required modifications to the source code, creating a gap between the verified and running code. Verifying the updated hypervisor using Spoq required much less proof effort, reducing the amount of manually written Coq code by over 70% compared to the verification of the older implementation. The proofs using Spoq are done on the unmodified source code of the hypervisor that is directly compiled and executed. Spoq even automatically generates the top layer specification, which we then use to verify the overall security properties of the hypervisor hold on the actual running software implementation.

## 2 Spoq Usage Model

To use Spoq, a user compiles the source code into LLVM IR and writes a layer configuration file defining the layer structure for the proof. The layer structure is defined to modularize the proof, with the additional constraint that a layer can only call functions in lower layers. For example, if the source code has three functions A, B and C such that A calls B and B calls C, at least three layers must be used. The configuration file specifies the name of each layer, the name of each function in each layer, the path to the source IR code, and the path to the Coq project. The configuration file should include the bottom layer abstract machine model, including its machine state definition. Spoq then generates the Coq project, including all specifications and proofs for each layer. If the source code or layer structure are changed, the user can rerun Spoq to update the Coq project. Spoq will regenerate the specifications and proofs for the parts affected by the changes, while other parts will remain unchanged.

Spoq guarantees that all generated specifications have exactly the same behavior as their source code implementations, but some generated high-level specifications may be too complex to be useful, and some refinement proofs may fail. Spoq makes it easy to integrate manually written specifications and proofs, which are simply annotated in the layer configuration file so that Spoq uses the provided specifications or proofs instead of generating them directly. If Spoq generates a high-level specification for a layer that is not concise enough, especially in how it updates the machine

state, the user can manually write the specification and rerun Spoq with the provided high-level specification. If Spoq fails in generating refinement proofs for a layer, the user will see the resulting compilation errors of the generated Coq project identifying the specific functions with errors. If the error occurs for a generated specification, it is most likely due to a failed loop termination proof. The user can manually write the loop termination proof that failed and rerun Spoq with the provided termination proof. If the error occurs for a manually written specification, the user can check if there is an error in the specification or if the refinement proof also needs to be manually written, then rerun Spoq again.

Spoq is useful for both verifying functional correctness as well as higher-level system properties such as security. In verifying functional correctness, Spoq can generate the top-level specification, which will be guaranteed to have exactly the same behavior as the source code implementation. This notion of functional correctness ensures that the implementation satisfies the specification, but not necessarily that the code has no bugs. If the code is buggy, the generated top-level specification will still have the same behavior, including any buggy behavior. To provide a stronger notion of correctness, a user can use the generated top-level specification to verify higher-level properties such as security, which will identify bugs in the specification. Alternatively, a user can manually write the top-level specification and leverage Spoq to generate intermediate layer specifications and refinement proofs to verify that the implementation is functionally correct with respect to a manually written specification, though such a specification can also have bugs. The key benefit of Spoq is ensuring that whatever verification is done holds not just for a specification, but all the way down to the source code implementation.

## 3 Spoq Workflow

Figure 1 shows the workflow of Spoq. We use the example in Figure 2 to explain each step in the workflow and show how Spoq scales machine-checkable verification for systems code. This example contains a simplified C function `alloc` to allocate a free page by scanning the array of page descriptors `page`. The main computation is implemented as a statement expression in a macro definition `ALLOC`, in which we use a loop to iterate all elements of `page` and set the page status of

```

// Layer interface L1
uint page[MAX_PAGE];
uint get_page (uint i) { return page[i] }
void set_page (uint i, uint s) { page[i] = s; }
// Layer interface L2
#define ALLOC() ( \
    uint i; \
    for (i = 0; i < MAX_PAGE; i++){ \
        if (get_page(i) == 0) { \
            set_page(i, 1); \
            break; \
        } \
    } \
    i;})
uint alloc() { return ALLOC(); }

```

**Figure 2:** A running example to allocate a free page.

the first free page to 1. The accesses to `page` are encapsulated into functions `get_page` and `set_page`. This coding style is quite common in systems software such as Linux kernel code.

**Generating Coq representations.** To conduct mechanized verification, the first step is to translate the implementation into a representation in theorem provers, which is challenging even for simple and common C systems code like `alloc`; ClightGen cannot parse this simple example. Spoq leverages the Clang compiler front end to parse C into LLVM IR, and provides a code analyzer to parse LLVM IR code into an AST representation defined in Coq (Step 1 in Figure 1). We use LLVM IR because it is language- and machine-independent, supports full C language semantics and most extensions of C, can be easily integrated with assembly code semantics, and is much simpler and more rigorously defined than C. However, LLVM IR does not keep program structures, such as if-then-else and loop statements, making it hard to conduct proofs in a structural and inductive manner. Spoq resolves this issue by analyzing the control flow graphs of the LLVM IR code and reconstructing program structures. For example, Spoq reconstructs the loop, branch, and break statements in the Coq representation for the LLVM IR generated from the `alloc` function in Figure 2:

```

Definition f_alloc :=
  { | fname := "alloc"; rettype := ...; fargs := ...;
    fbody := ... ::
      (ILoop (... :: (IIif ... IBreak) :: ...))... |}.

```

Spoq also models the semantics of Armv8 instructions [4] and parses assembly code into a list of assembly instructions in their Coq representations.

**Defining layer structure.** Spoq takes as input a layer configuration file which it uses to scale constructing mechanized proofs using CCALs. Using CCALs, we can construct a machine-checkable proof object “ $M@L \sqsubseteq_R L'$ ,” showing that the implementation  $M$ , built on top of a lower layer interface  $L$ , refines the interface  $L'$  with the refinement relation  $R$ . The file defines the layers and at which layer each function should be verified (Step 2 in Figure 1). For example, the layer configuration for the running example in Figure 2 defines that `get/set_page` should be verified on top of layer  $L_0$ , while `alloc` should be verified on top of layer  $L_1$ .

The layer structure presumes a bottom layer machine model, which Spoq automatically generates in part by identifying each global memory object in the source code and generating a corresponding machine state in Coq. Spoq also generates memory load/store primitives for each element in the state. The primitives take a memory pointer as an argument and calculate based on offset the array indices and structure elements to be accessed. Index boundary and data range checks are also included. The initial generated machine model does not include concurrency-related structures, such as an event log and oracle [40], which need to be manually added to complete the model to support CPU-local concurrency reasoning.

Given the layer configuration file, Spoq will automate generating the CCALs. It will build a CCAL “ $M_{\text{page}}@L_0 \sqsubseteq_{R_1} L_1$ ” to abstract the `page` array into a Coq Map object from natural numbers to integers, such that its elements can only be accessed through getter and setter methods, `get_page` and `set_page`, respectively, rather than arbitrary memory operations which may lead to unexpected behavior. The refinement relation  $R_1$  defines how the `page` array is abstracted into the Map object. It will then build a CCAL “ $M_{\text{alloc}}@L_1 \sqsubseteq_{id} L_2$ ” to verify the `alloc` function on top of  $L_1$  using the Map object without the need to worry about concrete implementation details of `page`. Here,  $id$  is an identical refinement relation since no data abstraction is needed when verifying `alloc`.

To make building CCALs easier, Spoq decomposes the required proofs into an *identical refinement* and a *lifting refinement*. The identical refinement refines  $M$  to a low-level specification  $S_{low}$  that is closer to the code and does not introduce any data abstraction, i.e., “ $M@L \sqsubseteq_{id} S_{low}$ .” The lifting refinement refines the low-level specification to a high-level specification  $L'$ , i.e., “ $S_{low} \sqsubseteq_R L'$ .” The high-level specification is self-contained and may introduce abstractions to some data in lower layers.

**Synthesizing identical refinements.** Spoq generates low-level specifications and identical refinement proofs for each layer. The low-level specification of a function aggregates the small-step transition of each instruction in the function into a big-step transition of the entire function while preserving the semantics. For assembly code and C code without loops, generating the specifications and proofs is straightforward (Step 3 in Figure 1). Spoq provides a Coq tactic library to generate the identical refinement proofs; a tactic is a pre-defined decision procedure to generate proof scripts in Coq. Neither the specification generator nor tactic library needs to be trusted, since incorrect low-level specifications will be rejected by refinement proofs, and incorrect proofs will be rejected by the Coq proof checker.

For C code with loops, Spoq requires the user to provide a ranking function for each loop, which is non-negative and monotonically decreasing during the loop iterations. This is necessary because a termination proof is needed for each loop to prove refinement, and automating such termination proofs without user input is generally undecidable. With the input

```

Definition rank (i: nat) := MAX_PAGE - i. (*user input*)
Fixpoint alloc_loop_low (r i: nat) (st: ST) :=
  match r with
  | 0 => Some (MAX_PAGE, st)
  | S r' =>
    match get_page_high i st with (* spec from L1 *)
    | Some 0 => match set_page_high i 1 st with
      | Some st' => Some (i, st')
      | None => None
    end
    | Some _ => alloc_loop_low r' (i+1) st
    | _ => None
  end
end.
Definition alloc_low (st: ST) :=
  let r := rank 0 in alloc_loop_low r 0 st.

```

Figure 3: Low-level specification for the alloc function.

ranking function, Spoq automatically synthesizes a recursive function as the low-level specification using the Fixpoint construction in Coq, which requires an argument that decreases for each recursive call. For example, Figure 3 shows a recursive function `alloc_loop_low` synthesized for the loop in the `alloc` function with a user-provided ranking function (`MAX_PAGE-i`) as the decreasing argument for the Fixpoint construction. Note that the low-level specification of `alloc` is not self-contained and depends on functions `get_page_high` and `set_page_high` provided by the high-level specification at a lower layer. Spoq generates the refinement proof using a uniform induction-proof template (Step 4 in Figure 1).

**Synthesizing lifting refinements.** Spoq generates high-level specifications and lifting refinement proofs for each layer. This is done automatically when data abstractions are not used to hide low-level data representation details to simplify proofs at higher layers. If data abstractions are needed, users need to formulate the refinement relations, define abstract operations, and conduct the refinement proofs manually.

For example, the layer  $L_1$  abstracts the array `page` into a Coq Map `st.page`, and transforms the memory operations `load_mem` and `store_mem`—offered by the bottom layer  $L_0$ 's machine model—into Map operations (`st.page#i` and `st.page#i<-s`) with boundary checks:

```

(* Low-level specifications *)
Definition get_page_low (i: nat) (st: ST) :=
  load_mem st ("page", i * 4) u32.
Definition set_page_low (i s: nat) (st: ST) :=
  store_mem st ("page", i * 4) s u32.
(* High-level specifications in L1 *)
Definition get_page_high (i: nat) (st: ST) :=
  if 0 <= i < MAX_PAGE then Some st.page#i else None.
Definition set_page_high (i s: nat) (st: ST) :=
  if 0 <= i < MAX_PAGE then Some st.page#i<-s else None.

```

Because of the data abstraction, the lifting refinement proof for layer  $L_1$  is not automated and has to be provided manually.

On the other hand, the layer  $L_2$  does not use data abstractions. For layer  $L_2$ , Spoq automatically generates the high-level specification of `alloc` from its low-level specification by applying a sequence of *transformation rules*, including unfolding definitions, merging near-duplicate sub-expressions, eliminating pre-determined branches and assertions, and performing mathematical simplification. The latter two rules are ap-

```

Fixpoint alloc_loop_high (r i: nat) (st: ST) :=
  match r with
  | 0 => (MAX_PAGE, st) (* no need of Some anymore *)
  | S r' => if st.page#i =? 0 then (i, st.page#i<-1)
    else alloc_loop_high r' (i + 1) st'
  end.

```

Figure 4: High-level specification for the alloc function.

plied by using the Z3 SMT solver [16]. For `alloc_loop_low` in Figure 3, Spoq first unfolds the definitions provided by  $L_1$  and simplifies the representation as shown below:

```

Fixpoint alloc_loop_low' (r i: nat) (st: ST) :=
  match r with
  | 0 => Some (MAX_PAGE, st)
  | S r' =>
    if 0 <= i < MAX_PAGE then (* <- always true *)
      if st.page#i =? 0 then
        if 0 <= i < MAX_PAGE then (* <- redundant *)
          Some (i, st.page#i<-1)
        else None
      else alloc_loop_low' r' (i + 1) st'
    else None
  end.

```

Spoq then applies rules to eliminate an inner `if` statement which is redundant and eliminate the outer `if` statement by inferring that `i` is always within the range, resulting in the high-level specification in  $L_2$  shown in Figure 4. Unlike the low-level specification, the high-level specification in  $L_2$  is self-contained and does not refer to anything from  $L_1$ . Thus, any modules depending on  $L_2$  can be reasoned about using  $L_2$  alone without the need to look at lower layers. Otherwise, after building dozens of layers, the specification at a higher layer may wrap many levels of definitions from various lower layers, making the verification non-modular and much harder.

Spoq automatically generates refinement proofs to verify the transformations that are applied to transform low-level into high-level specifications (Steps 5-6 in Figure 1). Since all specifications are guarded by machine-checkable proofs in Coq, there is no need to trust Spoq's specification generation algorithms or any Z3 results.

## 4 Generating Coq Representations

Spoq uses Clang to compile C code to LLVM IR, enabling it to support full C semantics and various extensions, including arbitrary type casting, integer-pointer conversion, inline assembly code, C macros that use GNU C extensions, and GNU C compiler directives. Spoq then translates LLVM IR code into an AST defined in Coq. IR code consists of structs, global variables, and functions. Spoq literally translates IR structs, similar to C structs, and global variables into their Coq representations, but does additional program reconstruction for IR functions. An IR function can be viewed as a control flow graph (CFG) over a set of basic blocks with an entry point. All instructions in a basic block are sequentially executed, and the last instruction either jumps to another block or returns from the function. Since systems code may contain goto statements and IR code is compiled with optimizations enabled, the CFG

Figure 5: Rewrite rules for program CFGs without loops.

can be very complex and hard to reason about directly.

Spoq introduces a novel algorithm to merge each function’s CFG of basic blocks into one code block and reconstruct program structure using if-then-else, loop, continue, break, and return statements. Spoq only uses these statements to construct a program structure that is amenable to proof decomposition, which may not be the same as the program structure of the original source code. For example, any goto statements in the original source code will be eliminated. The algorithm reconstructs program structure by repeatedly applying a set of rewrite rules to reduce the size of the CFG by merging blocks and deleting edges. Spoq performs the reconstruction in IR. No attempt is made to reconstruct the original C code, which would bloat an otherwise minimal implementation.

**Reconstructing programs without loops.** For programs without loops, Spoq uses four rewrite rules to reconstruct programs from CFGs, shown in Figure 5. Each node denotes a code block and each edge denotes a change in control flow.  $A, P,$  and  $S$  in the nodes denote the instructions inside the respective blocks.  $c_1, c_2,$  and  $c_3$  at the beginning of edges denote the conditions to jump through the respective edges. Unlike regular CFGs,  $e, e_1,$  and  $e_2$  denote instructions attached to edges which will be executed when jumping through the respective edges. A blue edge ending with a rhombus denotes an edge without a destination, whose attached instructions must end with a continue, break, or return statement.

The CFG of a function without loops has no cycles, so Spoq can repeatedly apply the rewrite rules to reduce the graph to a single node. Rule  $R_1$  deletes a *dangling* node, a node with only one incoming edge  $e$  and no outgoing edge, and moves its instructions  $A$  to its incoming edge, which becomes an edge without a destination and has instructions “ $e; A$ .” Rule  $R_2$  deletes a *bridge* node  $A$ , a node with exactly one incoming edge  $e_1$  and one outgoing edge  $e_2$ , and redirects the incoming edge from its predecessor node  $P$  to its successor node  $S$  with instructions “ $e_1; A; e_2$ .” If all the outgoing edges of a node  $A$  either point to the same node  $S$  or do not have destinations, rule  $R_3$  merges all the edges into one

Figure 6: Rewrite rules for program CFGs with loops.

edge with branch statements. Since only the last instruction in a node changes the control flow, when a node has more than one outgoing edge, each edge must have a condition. If a node has multiple incoming edges but only one outgoing edge, rule  $R_4$  deletes the node and redirects all incoming edges to its successor node  $S$  with aggregated instructions. Rule  $R_4'$  is logically the same as  $R_4$ , but shows the case when the only outgoing edge does not have a destination.

The reconstruction algorithm prioritizes applying the first three rules and only applies  $R_4$  to the farthest valid node from the entry point if no other rules are applicable. We prove that this algorithm can rewrite any CFGs without loops into a single code block. The following example shows a sequence of rewrites to reconstruct the program structure from its CFG:

**Reconstructing programs with loops.** Loops introduce cycles into CFGs. For CFGs with cycles, Spoq computes the strongly connected components (SCCs). An SCC is the largest set of nodes in which every node is reachable from every other node. One node with self-pointed edges can also be an SCC. Spoq then uses four additional rewrite rules shown in Figure 6 to convert SCCs (marked by dotted orange circles) into loop-related statements.

Rule  $R_5$  breaks cycles in an SCC which only has one incoming edge (pointing to node  $A$  in the SCC), and all its outgoing edges point to the same destination (node  $E$  outside SCC). It redirects any edge to  $A$  in the SCC to having no destination, and appends  $Ct(A)$  (a continue statement for the loop  $A$ ) to the edge. It also redirects any edge to  $E$  in the SCC to having no destination, and appends  $Bk(A, E)$  (a break statement from the loop  $A$  to  $E$ ) to the edge. After the rewrite, there is no longer a cycle back to node  $A$  and the size of the SCC becomes smaller. When an SCC has incoming edges from more than one node, rule  $R_6$  duplicates the SCC for each node with incoming edges so that each SCC has only

one incoming edge. For nested loops in which the inner loop may directly jump out of the outer one, rule  $R_7$  converts such an SCC into one in which the jump target remains within the outer loop. Rule  $R_7$  inserts a new node  $F$ , and all outgoing edges from the inner loop are redirected via break statements to  $F$ . Flags are also appended to the outgoing edges. Node  $F$  contains instructions to jump to different destinations depending on the flag. Flag  $A.b$  means breaking the outer loop  $A$ ,  $A.c$  means going back to the beginning of the outer loop  $A$ , and no flag means breaking the inner loop. Once cycles are removed, rule  $R_8$  converts a node's instructions into a single `Loop` statement, and re-establishes the edge from the loop node to its successor indicated by the break statement.

**Assembly code.** Spoq also handles assembly code, representing assembly instructions as parameterized inductive types in Coq. Each instruction corresponds to one construct with the operand as the parameter. Since assembly is not a structured language, Spoq simply translates each assembly procedure or inline assembly statement into a list of assembly instructions in their Coq representation. For inline assembly, LLVM IR already encapsulates it as a function. Spoq extracts the assembly code into a separate assembly procedure, and replaces the original function body with a call to the assembly procedure, decoupling the inline assembly from the LLVM IR in the Coq representation. The current implementation only handles Armv8 assembly code.

**Semantics of Coq representations.** Once LLVM IR and assembly code is translated to its Coq representation, it can then be verified. This requires defining the semantics of LLVM IR and assembly instructions in Coq, to specify the behavior of the Coq representation. Semantics are defined with respect to a layer interface for a bottom layer machine model. The interface contains a machine state `st` and getter and setter methods that access objects in the machine state through object pointers. An object pointer is a pair  $(base, ofs)$ , where `base` specifies the object and `ofs` specifies the field or offset within the object. In other words, the semantics of LLVM IR and assembly instructions define how those instructions use the getter and setter methods and how they update the underlying machine state. The machine state contains memory blocks and registers, as discussed below.

LLVM IR semantics only depend on memory objects, each of which is a set of disjoint memory blocks that can be accessed using `load_mem` and `store_mem` methods through object pointers with boundary checks. A memory block is contiguous and its size is defined by the type of the respective structure or global variable. For example, the `page` array in Figure 2 is a memory block with  $(MAX\_PAGE \times 4)$  bytes and can be accessed using an object pointer  $(\text{"page"}, i)$ , where  $0 \leq i < MAX\_PAGE \times 4$ . The layer interface contains a variable environment providing a one-to-one mapping of variable names to corresponding addresses in memory.

For assembly code, Spoq models the semantics of the

Armv8 instructions based on not only memory block objects, but also register objects. For example, the register objects model that clearing the `VM` bit in `HCR_EL2` register will disable the stage-2 translation for EL1 and EL0. Since an assembly procedure is just a list of assembly instructions, the semantics of an assembly procedure is defined as applying the semantics for each assembly instruction in the list one after the other.

Based on CCALs, Spoq uses CPU-local reasoning and distinguishes memory objects as CPU-private memory, lock-synchronized memory, and lock-free memory. Each CPU-private memory object belongs to and can only be accessed by a particular CPU. Each lock-synchronized memory object is associated with a lock. When accessing a lock-synchronized memory object, Spoq checks that the corresponding lock is held by the local CPU. Accessing a lock-free memory object generates an event appended to a global log, and an event oracle is queried to simulate other CPUs' behavior before generating each event. Correct concurrent behavior is guaranteed in the same way as previous work using CCALs [38,40]. This event-based machine model assumes sequential consistency (SC). To propagate proof results for a system to Arm's relaxed memory hardware, users can follow the methods introduced by VRM [54] to verify that the system satisfies six weak-data-race-free conditions. This implies that the system exhibits no more behaviors when running on Arm relaxed memory hardware versus an SC model. Thus, any guarantees proven using the SC model still hold on Arm's relaxed memory hardware.

## 5 Synthesizing Identical Refinements

**Low-level specifications without loops.** Spoq recursively aggregates the small-step semantics of every IR statement in a function and generates a Coq definition to reflect the entire transition as the low-level specification of the function. Leveraging the reconstructed program structure, Spoq simply scans through the Coq AST representation, conducts case analysis starting with the first statement, and generates the corresponding Coq definition as a string based on the defined LLVM IR semantics. A small piece of Python pseudocode for assignment and branch statements is shown below:

```
def spec_gen (ast, spec):
    for n in range(len(ast)):
        i = ast[n]
        if isinstance(i, IAssign): # Assignment case
            s = f"let {coq_name(i.asg)} := {val(i.v)} in"
            spec.append(s)
        elif isinstance(i, IIf): # Branch case
            spec.append(f"if {coq_name(i.cond)} then")
            spec_gen(i.true_body + ast[n+1:], spec)
            spec.append(f"else")
            spec_gen(i.false_body + ast[n+1:], spec)
        ...
```

For an `IAssign` statement, which assigns a value to a temporary variable, Spoq generates a `let` binding in Coq. For an `IIf` statement, Spoq recursively invokes its specification generator `spec_gen` for each branch in the code and concatenates the branch body with the rest of the AST.

**Identical refinements without loops.** Spoq automatically generates identical refinement proofs by using a Coq tactic `lrefine`. The idea is to do case analysis for each conditional by recursively decomposing each conditional into two sub-proofs, one for when the conditional is true and another for when it is false. Once a branch body is reached with no further conditionals, the proof can simply show that if the low-level specification transforms the machine state from `st` to `st'`, then the small-step semantics of the Coq AST also transforms the machine state from `st` to `st'`. Spoq aggregates the sub-proofs for all the branch cases to form the overall refinement proof. Take the following pseudo-specification generated from an `if` statement as an example:

```
Definition foo_low (st: ST) :=
  if cond then foo_true_low st else foo_false_low st
```

The `lrefine` tactic will conduct case analysis over `cond`, which generates two sub-proof goals. The first goal is to prove that the AST transfers `st` to “`foo_true_low st`” with an additional hypothesis “`H0: cond = true.`” The `lrefine` tactic then executes the semantics of AST for one step by showing that the branch condition will be evaluated to `true` when `H0` holds and finally invokes `lrefine` recursively to prove that the first branch implementation will transfer `st` to “`foo_true_low st,`” a specification generated using the first branch. The second goal can be proved similarly.

**Low-level specifications for loops.** Spoq generates low-level specifications for loops using a recursive `Fixpoint` construction in Coq. A `Fixpoint` definition requires a decreasing argument, which has the type `nat` and decreases for each recursive call of the function. Spoq requires the user to provide a ranking function for each loop as the decreasing argument. It then generates low-level specifications for loops by filling in the parts marked with `{{ }}` in the template below:

```
1 Fixpoint _loop (n: nat) (bk rt: bool) {{Vi Vo}} st:=
2   match n with
3   | 0 => Some (bk, rt, {{Vo}}, st)
4   | S n' =>
5     match _loop n' bk rt {{Vi Vo}} st with
6     | Some (bk', rt', {{Vo'}}, st') =>
7       if bk' then Some (bk', rt', {{Vo'}}, st')
8       else if rt' then Some (bk', rt', {{Vo'}}, st')
9       else {{low-level spec of the loop body}}
10    | _ => None
11    end
12  end.
13 Definition _low {{args}} (st: ST):=
14   {{low-level spec before the loop}}
15   let n := {{rank i_Vi}} in
16   match _loop n false false {{i_Vi i_Vo}} st with
17   | Some (bk, rt, {{Vo}}, st') =>
18     if rt then Some ({{Vo}}, st')
19     else {{low-level spec after the loop}}
20   | _ => None
21   end.
```

For the loop, Spoq generates a `Fixpoint` construction such that one recursive call of the `Fixpoint` construction corresponds to one iteration of the loop, so its body is the low-level specification of the loop body (line 9). Five `Fixpoint` arguments track the state of the loop (line 1). `Vi` are

the input variables initialized before the loop and accessed by the loop body; they have initial values `i_Vi`. `Vo` are the output variables accessed after the loop that were also accessed in the loop body; they have initial values `i_Vo`. For example, the loop in `alloc` in Figure 2 simply has `i` for both `Vi` and `Vo`, with initial values `0` and `MAX_PAGE`, respectively. Spoq determines input and output variables and their initial values from syntactic analysis of the IR code. `n` is the decreasing argument, which is a natural number that is determined by the user-provided ranking function, which takes as input all the input variables of the loop. `n` is initialized using the ranking function over the initial value of input variables `i_Vi`, which sets the maximum number of “loop iterations” (line 15), and decreases by one for each “loop iteration” (line 4). Flags `bk` and `rt` indicate whether the loop has already been terminated by a `break` or `return` statement. The loop body (line 9) sets `bk` to true when executing a `break` statement or exiting when the loop condition becomes false, and sets `rt` to true when executing a `return` statement. `Fixpoint` will not make further changes once `bk` or `rt` is set to true (lines 7 and 8).

For the function containing the loop, Spoq generates low-level specifications for the code before the loop (line 14); invokes the `Fixpoint` with the initial values of the ranking function, flags, and variables (line 16); skips the rest of the function if `rt` is true (line 18); and generates low-level specifications for the code after the loop if not returned (line 19). Spoq will syntactically analyze the IR code and produce `Vi`, `Vo`, and their initial values `i_Vi` and `i_Vo`. Note that Figure 3 shows a simplified low-level specification that omits the `bk` and `rt` flags and uses a tail recursion style.

**Identical refinement proofs for loops.** Spoq proves identical refinements for loops using induction. The base case is trivial because the input machine states are the same. Spoq only needs to prove that the initial ranking function is non-negative. This is automated using a tactic `xlia`, extended from Coq’s tactic `lia`, a decision procedure for arithmetic. The induction step is to show that when the input machine states for the low-level specification and Coq AST are the same after the  $i$ -th iteration and both `bk` and `rt` are false, the output machine states are still the same after the  $(i+1)$ -st iteration. The  $(i+1)$ -st iteration may have one of three outcomes: 1) continue to the next iteration, 2) break the loop due to a `break` statement or the loop condition becoming false), and 3) return from the function. For all three outcomes, Spoq first proves that the loop body and `Fixpoint` body have the same semantics by recursively invoking `lrefine`. Spoq then proves additional properties for each outcome. For the first outcome, Spoq proves that the ranking function decreases by at least one and is still greater than zero using `xlia`. This guarantees that the loop must terminate after at most the number of iterations indicated by the initial ranking function. For the second outcome, Spoq proves that `bk` is true after the iteration, and the ranking function is still non-negative when the loop condition becomes false using `xlia`. For the third

outcome, Spoq proves that `rt` is true after the iteration. Note that the `Fixpoint` function continues the iteration after `bk` or `rt` is true but will not make any changes to the state.

Spoq automatically generates the identical refinement proof for a loop if the loop is not contained within a conditional in the function. However, if the loop is contained within a conditional, or a series of conditionals, this results in the loop being used in multiple branches of execution, which Spoq currently does not automatically handle. In this case, the user will see that the loop termination proof failed in one or more branches, and needs to copy and paste the induction proof template into the other branches of execution with possible minor modifications; this is generally straightforward to do.

**Assembly code.** Spoq generates low-level specifications for assembly code by evaluating the assembly instruction list. The current implementation only supports automatic generation of low-level specifications for assembly code without jumps. Spoq simply evaluates instructions sequentially and outputs the machine state of the last instruction. If the destination of a call instruction is a C function, Spoq uses registers according to the Procedure Call Standard for the Arm 64-bit Architecture (AAPCS64) [5]. Spoq sets the arguments to the values in the argument registers according to AAPCS64. After the function call, Spoq checks the linker register of the machine state and evaluates the assembly instruction from where the linker register points. After returning from the function call to assembly code, Spoq sets the value of the caller-saved registers to `UNKNOWN` because the caller cannot assume any value in the caller-saved registers according to AAPCS64. Spoq disallows reads from any register with value `UNKNOWN`; assembly code must write to the caller-saved register first before it can be read. This helps prevent unexpected information leakage from registers.

By using the AAPCS64 calling conventions for assembly code functions so that arguments and return values are treated the same as C code functions, Spoq provides a unified approach to generating low-level specifications for assembly and C code. This includes using the same type `value` used in the IR semantics for assembly code. This unified approach makes it possible to link the proofs for assembly and C code.

Spoq generates low-level specifications for inline assembly in the same manner as other assembly code, since it already extracts the inline assembly into a separate assembly code procedure. However, Spoq requires that the operands used in inline assembly are C variables specified in the input or output operand list, system registers, and constants. Directly reading or writing general-purpose registers is disallowed to ensure proof correctness when linking inline assembly and C code, as the compiler may use them for temporary variables [40].

Spoq automatically generates identical refinement proofs for assembly code, which is straightforward without jumps as there are also no loops. The proof simply shows that the low-level specification and assembly instruction list transform the machine state in the same way.

## 6 Synthesizing Lifting Refinements

**High-level specifications.** Spoq generates high-level specifications by applying a set of transformation rules to low-level specifications to make them self-contained and simple. Spoq uses 12 transformation rules shown in Figure 7, though additional rules can easily be added. Spoq uses the Z3 SMT solver to apply rules involving symbolic execution or mathematical simplification. The goal of the transformation rules is to simplify the required control flow and eliminate as much as possible unnecessary operations.

$T_1$  unfolds a function's definition in an expression. Functions defined in lower layers that are called in the low-level specification are generally unfolded as part of the high-level specification to make it self-contained. Unfolding may also provide opportunities to apply other transformation rules to eliminate unnecessary operations to further simplify the specification.  $T_2$  eliminates a `let` assignment by substituting the variable with its value, which helps find opportunities for simplifying expressions.  $T_3$  eliminates an `if` branch if both branches are the same.  $T_4$  eliminates a `match` statement by syntactically determining which pattern matches the source value.  $T_5$  eliminates a `match` statement if both the source and return values are of `Option` type, and if the source value is `None`, the return value is `None`. It eliminates the `match` by making `body` the return value for all source values that are not `None`.  $T_6$  transforms a `match` statement in which the source value matches the pattern and is used in the return value by substituting the pattern in the return value. This can provide more opportunities for simplification since patterns are more specific.  $T_7$  moves the control flow of the source value to the outside of the `match` statement. Spoq tries to simplify the source value of `match` statements to make it easier to determine matching patterns.  $T_8$  moves the control flow within an expression to the outside of the expression to aggregate computations within the expression, which helps find opportunities for simplifying expressions.  $T_9$  does various simplifications for getter and setter methods. Here  $i$  and  $j$  indicate different fields. Whether  $i$  equals  $j$  can be determined syntactically (if they are structure names), or by Z3 (if they are integer indices).  $T_{10}$  performs symbolic execution using Z3 to identify whether the assertion of a `rely` is valid or invalid. If the assertion is always true, then `rely` is redundant and can be removed. If the assertion is always false, the statement can simply return `None`.  $T_{10}$  will do nothing if Z3 cannot decide if the assertion is true or false.  $T_{11}$  performs symbolic execution using Z3 to simplify `if` statements.  $T_{12}$  simplifies math expressions using Z3. For example, Spoq applies  $T_1$ ,  $T_2$ , and  $T_{11}$  to generate the high-level specification in Figure 4 from its low-level specification.

While the transformation rules can be applied in different orders to yield the same result, the order in which the rules are applied can have a significant impact on the execution time required. Spoq reduces execution time by applying the rules in stages. In the first stage, it applies rules  $T_2 - T_8$  and the  $T_9$

Figure 7: Transformation rules for high-level specifications.

syntactic transformations. In the second stage, it applies rule  $T_1$ , then repeats applying the rules from the first stage. Spoq unfolds only one function, and only when no other syntactic rules can apply, because unfolding multiple functions too early can cause extra work. In the extreme case, unfolding all functions first will cause the size of the specification to explode and result in many unnecessary tests on each expression in each unfolded function body. In the third stage, it applies rules that use Z3, specifically rules  $T_9 - T_{12}$ , then repeats applying the rules from the first and second stages. Spoq applies syntactic rules first to simplify the specification as much as possible before applying Z3 rules because Z3 rules take much longer to process. To avoid long Z3 processing times, Spoq enforces a short timeout on Z3 operations, which is set to half a second by default. Essentially, Spoq repeatedly applies all rules until the high-level specification converges, meaning the rules no longer change the specification.

Using transformation rules to make the high-level specification of each layer self-contained generally results in the high-level specification being of larger size than its corresponding low-level specification. However, this size increase is outweighed by the ability to use the self-contained specification to simplify reasoning for higher layers, especially with regard to reasoning about higher-level properties based on the top layer high-level specification.

**Lifting refinement proofs.** Spoq automatically generates lifting refinement proofs to prove that the low-level specification refines the high-level specification generated by the transformation rules. This will necessarily be the case for transformation rules done in Coq, so the task reduces to reconstructing the proofs in Coq for all transformations done by Z3; there is no need to trust any results from Z3. Spoq uses a Coq tactic library to enable the proof automation.

Spoq simplifies the construction of refinement proofs by introducing annotated high-level specifications, which are the same as high-level specifications except that they have additional annotations that encapsulate the results of all of the Z3 transformations applied. For example, if  $T_{11}$  is applied, there will be an annotation showing that  $A + 2 * 3 + 4 = A + 10$ , which serves as a hint for constructing proofs. Spoq generates the annotations as it is generating the high-level specification. Spoq then uses the annotations to tell Coq what step-by-step syntactic substitutions it should perform to prove the low-level specification refines the annotated high-level specification. Because the annotations tell Spoq what transformations to do, it only has to validate them in Coq, which is much easier than automatically discovering the transformations in Coq; that would be difficult without Z3. Spoq finally trivially proves that the annotated high-level specification refines the high-level specification by showing that removing the annotations does not change the machine behavior. The two-part refinement proof shows that the low-level specification refines the high-level specification.

Spoq introduces a Coq tactic `hrefine` to automate the core part of the proof, namely proving that the low-level specification is equivalent to the annotated high-level specification. The strategy of `hrefine` is similar to the one for `lrefine` used for the identical refinement proof discussed in Section 5. The `hrefine` tactic analyzes the structure of the annotated high-level specification, decomposes it into all possible branches of state transitions, and conducts the proof for each branch. For each branch, all `match`, `if`, and `rely` are eliminated because the branch corresponds to a specific set of values for their conditions. Each branch therefore has a list of conditions and annotations. Spoq uses those conditions and annotations to simplify the low-level specification and prove that the low-level specification has the same behavior as the high-level one for that branch. It then repeats this process to prove the refinement for each branch.

Section 7 shows that Spoq was able to automatically generate all lifting refinement proofs involving Z3 transformations in verifying a multiprocessor KVM hypervisor. However, it is theoretically possible for there to be Z3 transformations for which Spoq is not able to generate lifting refinement proofs, in which case the user needs to manually complete those proofs.

Spoq also uses Coq tactics to automatically generate lifting refinement proofs for `Fixpoint` constructions, which are used in high-level and low-level specifications for functions with loops. The proofs use induction and are straightforward to generate because they only involve `Fixpoint` constructions, which are guaranteed to terminate. The hard part of refining loops to `Fixpoint` constructions and completing termination proofs has already been done in the low-level specifications.

Using Spoq provides significant advantages in terms of proof modularity over previous approaches that required users to manually write high-level specifications and proofs [20, 38, 40]. Because creating a self-contained

high-level specification often involves unfolding function definitions from lower layers, any change to an implementation at a lower layer can require rewriting the high-level specifications for all higher layers, which also requires rewriting their refinement proofs. This makes it difficult to port specifications and proofs as a software implementation evolves over time if high-level specifications and refinement proofs are manually written, as many of them may have to be manually rewritten. With Spoq, the impact of an implementation change can be localized to its respective layer, even if that layer requires writing high-level specifications or proofs manually, since high-level specifications and proofs for higher layers can be automatically generated. This makes it much easier to port specifications and proofs across software updates.

**Assembly code.** Spoq generates high-level specifications and lifting refinement proofs for assembly code without jumps in the same manner as for C code. The current implementation leaves it to the user to write specifications and refinement proofs for assembly code with jumps.

## 7 Evaluation

We have implemented a Spoq prototype, which consists of three components: the translator from systems code into Coq, the specification and proof generator, and the Coq libraries for LLVM IR and assembly semantics and tactics. The three components are implemented using 4K lines of code (LoC) in C++ and Python, 6K LoC in Python, and 5K LoC in Coq, respectively. We evaluated Spoq’s effectiveness in translating C systems code into Coq for various widely used open-source software, and verifying a KVM hypervisor implementation.

### 7.1 Translating system software into Coq

Since the first step in verification is to translate systems code into Coq, we evaluated Spoq’s ability to do so for the applications, libraries, and Linux kernel version listed in Figure 8. We used the Makefile for the source code tree of each application, library, and kernel to build the source code using the default configuration, but output LLVM IR (.ll) files, in some cases by modifying the Makefiles by replacing the `-o` compilation option to output an executable with the `-S -emit-llvm` option to output LLVM IR files, which are then read by Spoq to translate them into Coq. The Linux kernel uses a more complex KBuild system [29], but no modifications were needed since it already accepts the `-S -emit-llvm` option to output LLVM IR files.

For comparison, we also tried to use ClightGen to translate the systems code into Coq. This required much more effort to the build source code trees because many of the compiler flags are not accepted by ClightGen. Instead, for most cases, we ran the existing Makefiles to get the compilation commands executed and saved them to a file, then used a

**Figure 8:** Translating C code into Coq. Each bar shows how many of the total number of C functions are successfully translated.

script to filter options not supported by ClightGen, then reran the filtered compilation commands using ClightGen instead.

Figure 8 shows the results for translating C systems code into Coq using Spoq versus CompCert’s ClightGen. Across all of the applications, libraries, and the Linux kernel, Spoq successfully translates over 99% of the functions in the source code into their Coq representations. The failures were caused by currently unsupported LLVM instructions, mainly advanced branching instructions (e.g. `callbr`, `invoke`, `resume`). Support for them is left for future work.

Spoq performs significantly better than ClightGen, which fails almost entirely on the Linux kernel and only translates roughly 50% of the functions in the source code into their Coq representations for most cases. Its best performance is on OpenSSL, for which it is still able to only translate less than 80% of the functions in the source code into Coq representations. ClightGen fails due to numerous unsupported C features, including variable-sized arrays, function parameters or return values with `union/struct`, additional keywords, C statements, and other unsupported inline assembly features. Furthermore, for the Linux kernel, GNU C directives are ubiquitous in almost all header files included by source code files and prevent ClightGen from translating the kernel source code into Coq.

Not only does Spoq perform far better than ClightGen in translating systems code into Coq representation, but it has a much smaller implementation. The module in Spoq responsible for translating systems code into Coq consists of 2.7K LoC in Python and 1.3K LoC in C++, the latter to make use of the official LLVM library to parse LLVM IR files. Its minimal implementation avoids bloating the TCB. In contrast, ClightGen is enormous, consisting of at least tens of thousands of lines of unverified OCaml code. ClightGen performs worse than Spoq and increases the TCB size much more significantly than Spoq as well.

### 7.2 Verifying a KVM hypervisor

We evaluated Spoq’s ability to reduce proof costs by verifying SeKVM, a retrofitted version of the KVM/Arm

```
#define __hyp_text __section(.hyp.text) notrace
u32 __hyp_text mem_region_search(u64 addr)
```

(a) Unsupported compiler directive.

```
/* Original source code:
 * inline assembly and macro of a C statement */
u32 __raw_readl(const volatile void __iomem *addr){
  u32 val;
  asm volatile("ldr %w0, [%1]\r\nldar %w0, [%1]",)
  : "=r" (val) : "r" (addr));
  return val;}
#define readl_relaxed(c) \
({ u32 __r = \
  le32_to_cpu((__force __le32)__raw_readl(c)); \
  __r;})

/* Verified source code:
 * original source code replaced with only C function
 * declaration so it can be parsed by ClightGen. */
u32 readl_relaxed(u64 addr);

(* Specification modeling the behavior of
 * readl_relaxed; implementation unverified. *)
Definition readl_relaxed_spec (addr: Z) (st: ST) :=
  (ZMap.get st.(mem) addr, st).
```

(b) Unsupported GNU Inline Assembly and C statement.

**Figure 9:** Example SeKVM changes required to use ClightGen.

hypervisor [13–15, 37] that was previously verified in Coq [38, 39, 54]; only its trusted core needed to be verified to guarantee the security properties of the entire multiprocessor hypervisor. We updated SeKVM to run on additional hardware, specifically the Raspberry Pi 4, which involved modest changes to its previously verified codebase. However, this required updating the proofs, so we used Spoq to verify the updated version, and compare the proof effort to the manually written Coq proofs for the earlier version of SeKVM.

**Generating Coq representations.** We first used Spoq to automatically translate the source code of the trusted core of the updated hypervisor version into Coq. Spoq successfully translated all of the 3.8K LoC of C and Arm assembly code into Coq. The same code that is compiled to execute is used for verification; there is no difference, ensuring that the proofs hold at the source code level for the code that is executed. This is in contrast to the previous work to verify SeKVM, which used ClightGen to translate its implementation into Coq. This required further retrofitting of the source code because of its use of many features unsupported by ClightGen, including removing all header files with versions that were amenable to translation by ClightGen.

Figure 9 shows examples of the retrofitting required to use ClightGen. Figure 9a shows a GNU C compiler directive `__section` which tells the linker to link the function into a special text section that SeKVM later isolates and protects from the rest of the kernel. ClightGen does not support such GNU C compiler directives, which are heavily used in systems code to control compilation and linking behavior. To use ClightGen, we first need to remove those GNU C compiler directives from all functions. Figure 9b shows a C macro `readl_relaxed` with inline assembly. ClightGen does not support such C macros or inline assembly. To use ClightGen, we need to either rewrite

all such macros into standard C functions, or model them as abstract functions whose implementations are not verified and must be included in the TCB. Figure 9b shows the latter approach. The macro is replaced with just a function declaration so it can be translated by ClightGen, and a specification is written for the function, but the function implementation cannot be verified. There are over a hundred such functions in the original source code. These required changes result in a gap between the code that is verified versus the code that is compiled and executed. Unfortunately, without supporting features such as GNU C compiler directives, the verified code cannot be directly compiled and executed.

**Generating specifications and proofs.** We then used Spoq to generate the top-level specification for SeKVM, including all layer specifications and refinement proofs. Table 1 shows the manual proof effort required to verify SeKVM’s functional correctness using Spoq, as measured by the LoC in Coq that still needed to be manually written to complete the verification. We also propagated the proofs to Arm’s relaxed memory hardware, but omit details as it is similar to VRM’s proof [54].

We wrote less than 100 LoC to provide the layer structure in a layer configuration file consisting of the same 34 layers as the original proofs for SeKVM; the changes in the updated version of SeKVM were minor enough that no changes in the layer structure were needed. We wrote 0.5K LoC for the bottom layer machine model for concurrency-related structures.

For C code without loops and Arm assembly code without jumps, Spoq automatically generated all low-level specifications and identical refinement proofs. For C code with loops, Spoq automatically generated all low-level specifications given a ranking function for each loop, each requiring 2 LoC. For C code with loops within conditionals, we wrote 0.8K LoC for identical refinement proofs that could not be automated by the current Spoq prototype, much of which involved copying and pasting of Coq code for termination proofs when multiple conditional branches used the same loop.

For C code and Arm assembly code without jumps, Spoq automatically generated all high-level specifications and lifting refinement proofs that do not use data abstractions. No manual proofs were required to verify Z3 transformations. For assembly code with jumps, we wrote 0.3K LoC for specifications and 0.1K LoC for refinement proofs, without decomposing specifications and proofs into low-level and high-level ones. For layers using data abstractions, one for locks and three for page tables, we manually wrote high-level specifications and lifting refinement proofs. For high-level specifications, we wrote 1.0K LoC for layers using data abstractions. For lifting refinement proofs, we wrote 0.8K LoC for locks, 2.5K LoC to show multi-level page tables refine a single-level page mapping, and 0.9K LoC to show data structures tracking ownership of physical pages refine an abstract map.

**Reducing manual proof effort.** Table 1 compares the proof effort to verify SeKVM using Spoq versus the manually writ-

LoC in Coq	Original	Spoq	Reduction
Layer configuration	—	0.1K	—
Machine model	1.8K	0.5K	72%
Low-level specifications for C	5.6K	0	100%
Ranking function	—	26	—
High-level specifications for C	5.5K	1.0K	82%
Specifications for Asm	0.5K	0.3K	40%
Identical refinement proofs for C	3.6K	0.8K	78%
Lifting refinement proofs for C	14.7K	4.2K	71%
Refinement proofs for Asm	1.8K	0.1K	94%
Security proof	4.8K	3.0K	38%
<b>Total for functional correctness</b>	<b>33.5K</b>	<b>7.0K</b>	<b>79%</b>
<b>Total w/security</b>	<b>38.3K</b>	<b>10.0K</b>	<b>74%</b>

**Table 1:** Manual proof effort to verify SeKVM.

ten proofs for the original version of SeKVM. The original manual proof effort required writing more than 3 times as many lines of specification and 5 times as many lines of proof as verified source code. Spoq only required writing a third as many lines of specification and roughly 1.4 times as many lines of proof as verified source code. In terms of LoC, Spoq reduced the overall manual proof effort by more than 70% compared to the original manually written proofs. The largest reductions in proof effort were for writing the specifications themselves. Spoq reduced manual effort for writing specifications by more than 90% overall, including eliminating the cost for specifications without data abstractions. Spoq reduced manual effort for refinement proofs by more than 70% overall, including eliminating the cost for C code without loops or data abstractions. Spoq reduced manual effort for refinement proofs for assembly code by more than 90% and linked them together with the proofs for C code, in contrast to the original assembly code proofs for SeKVM. Spoq largely eliminated the cost of using intermediate layers to modularize proofs, a substantial cost in the original manually written proofs, as the vast majority of those layer specifications and refinement proofs were automatically generated by Spoq.

Spoq also reduced the manual effort in defining the bottom layer machine model by roughly 70% due to three reasons. First, Spoq automatically derived many aspects of the abstract machine model from the source code. In contrast, the machine model for the original manually written proofs did not have such a correspondence with the source code and had to be manually written. Second, Spoq can use a simpler machine model because it does not need data oracles [38], which were introduced in the original manually written proofs to verify security properties. We discuss below how we verify security properties in a different manner, making data oracles unnecessary. Finally, Spoq does not need to include various getter and setter functions in the bottom layer, which were required in the original manually written proofs. These getters and setters, written using various Linux macros, previously had to be manually specified as part of the bottom layer specification because they could not be translated by ClightGen into Coq and hence could not be verified. In contrast, Spoq automati-

cally translated these getters and setters into Coq and verified them, eliminating them from the bottom layer specification.

We compared the Coq code generated by Spoq versus the original manually written proofs for SeKVM to provide a measure of the quality of the generated specifications and proofs versus what would be produced by humans. Spoq generated 2.5K, 6.6K, 4.2K, 6.9K, and 17.5K LoC in Coq for the machine model, low-level specifications for C code, high-level specifications for C code, identical refinement proofs for C code, and lifting refinement proofs for C code, respectively. In most cases, the generated Coq code was only modestly larger than what was produced by a human writing hand-tuned Coq specifications and proofs. In fact, Spoq generated tighter high-level intermediate layer specifications than the original manually written specifications. The top-level specification generated by Spoq was 1.6K LoC in Coq. This is essentially the same size as the original manually written top-level specification, though it is quite different as it is based on a different machine model derived from the source code for the bottom layer. The quality and complexity of the top-level specification is especially important since it should be simple enough that it can be used to prove higher-level properties of the system.

**Proving security properties.** To demonstrate the usefulness and correctness of the top-level specification generated by Spoq, we used it to verify the security properties of SeKVM, specifically that it protects the confidentiality and integrity of virtual machine (VM) data. The original manually written proofs used noninterference to prove the security properties along with data oracles for declassification. We instead leverage the ideal/real paradigm to prove security properties, introduced in our recent work on verifying the firmware for the Arm Confidential Compute Architecture [40]. We define an ideal machine model that guarantees the security of each VM’s private data regardless of the behavior of the hypervisor. The ideal machine defines for each VM a logically isolated memory space and register set, and directs all memory and register accesses from VMs to the logical state unless data declassification is defined. To account for data declassification in SeKVM in which a VM can make requests to dynamically start and stop sharing a piece of memory with the hypervisor, the ideal machine moves data from the VM’s logical memory to shared memory and vice versa. The VM accesses its private data from its logical memory space, and accesses the shared data from the shared physical memory. By definition, the per-VM isolated state is only accessible by the VM itself, so the confidentiality and integrity of VM data is naturally guaranteed in the ideal machine. We then prove the top-level specification refines the ideal machine, which verifies that SeKVM indeed protects the confidentiality and integrity of VM data.

The security proof provides three key advantages compared to the original security proofs based on noninterference. First, it does not require incorporating data oracles in the machine model and in various layer specifications, decoupling the security proof from verifying functional correctness. Second,

Name	Description
Apache	Apache server v2.4.41 handling 100 concurrent requests via TLS/SSL from remote ApacheBench [2] v2.3 client, serving index.html of the GCC 7.5 manual.
Kernbench	Compilation of the Linux kernel v4.18 using allnoconfig for Arm with GCC 9.3.0.
Memcached	Memcached v1.5.22 handling requests from a remote memtier [49] v1.2.11 client with default parameters.
MongoDB	MongoDB server v3.6.8 handling requests from a remote YCSB [10] v0.17.0 client running workload A with 16 concurrent threads and operationcount=500000.
MySQL	MySQL v8.0.31 running sysbench v1.0.11 with 32 concurrent threads and TLS encryption.

**Table 2:** Application benchmarks.

the proof itself is simpler, reducing manual proof effort. Table 1 shows the manual proof effort for the security proof using this approach is 38% less than the original security proof using noninterference, though this reduction in proof effort is unrelated to using Spoq. Finally, and most importantly, the security proof only needs to trust the specification of a small idealized secure machine model, which is roughly 200 LoC; the much larger specification of the real system does not need to be trusted. The trusted specification defines how VMs load and store private data to their logical isolated space and specifies the data declassification policy for moving data between the logical isolated and shared machine states.

**Performance of verified implementation.** We directly compiled the Spoq-verified SeKVM source code into a binary image, and executed it on a Raspberry Pi 4B with 8 GB RAM, 64 GB SanDisk SD card, and a built-in 1 Gbps NIC. We measured its performance by running the application workloads listed in Table 2 in a VM using SeKVM. For comparison, we also ran the workloads in a VM using vanilla KVM and natively on the hardware. Each VM was configured with 2 vCPUs and 4 GB RAM. vCPUs were pinned to individual physical cores, VHOST networking was used, and virtual block storage devices were configured with `cache=none` [12, 24, 33, 52]. When running natively, we restricted the workloads to use 2 CPUs and 4 GB RAM to provide a fair comparison. VMs used a vanilla Linux v5.4 kernel as their guest OS. The VM on SeKVM included modified virtio drivers in its guest OS to support SeKVM. The Raspberry Pi ran a proprietary Linux v5.4.55 kernel [45]. It lacks support for virtio front-end drivers so could not be used as a guest OS. For client-server applications, clients ran on an x86 machine with 10-core Intel Xeon CPU E5-2640 2.4 Ghz CPU, 48 GB RAM and a NetXtreme BCM5719 1 Gbps NIC, connected to the Raspberry Pi via a Netgear GS308 1 Gbps switch.

Figure 10 shows application workload performance when using VMs with vanilla KVM and SeKVM. Performance was normalized to native execution; lower is better. The performance results are consistent with those previously reported for SeKVM [54], with worst case overhead being

**Figure 10:** Application benchmark performance.

less than 15% compared to vanilla KVM. I/O intensive application workloads incurred higher overhead because the hypervisor cannot access VM memory unless the virtio front-end driver makes explicit hypercalls to request memory pages used for I/O be temporarily accessible to the hypervisor to pass the I/O data to the back-end driver in the host.

## 8 Limitations

Spoq’s TCB includes the Clang and LLVM toolchains, Spoq’s translator, and Spoq’s semantic definitions for LLVM IR and assembly. The translator is currently unverified and supports a subset of LLVR IR and Arm assembly, so it may fail to translate some source code into Coq. Spoq’s specification and proof generator are not part of its TCB. Enhancing their support for assembly code with jumps is an area of future work.

The Z3 solver is currently the bottleneck in Spoq’s runtime performance. Synthesizing high-level specifications for relatively large functions can take over 30 minutes because it may involve thousands of Z3 queries. Nevertheless, automatically generating specifications and proofs for SeKVM only takes two hours on an AWS machine with an 8-core 2.3 GHz Intel Xeon CPU E5-2686 v4 and 32 GB RAM, an insignificant amount of time compared to the time it takes to manually write specifications and proofs.

Spoq currently relies on users to complete all data abstraction proofs. Developing a library of commonly used data abstraction proofs for proof automation is an area of future work.

## 9 Related Work

**Verified systems in C.** seL4 [31] presents the first machine-checked functional correctness proof of an OS kernel. It used an unverified parser to translate C into Isabelle/HOL, and is manually proved with simplified C semantics. For example, pointers to local variables are disallowed by the simplified C semantics. Assembly code is also unverified. AtomFS [61] used a verification framework [56] that does not support assembly code or full C semantics. Many verified systems [3, 8, 11, 20, 30, 32, 38–41, 54] used ClightGen. For code that can be parsed by ClightGen and compiled by CompCert, the CompCert toolchain can guarantee proofs hold at the assembly level. However, CompCert cannot make

any guarantees regarding concurrent code even if it can compile, and our results show that ClightGen cannot support verification of most real-world unmodified systems code.

**Modeling and verifying LLVM IR.** VeLLVM [59] includes formal semantics and tools to verify LLVM IR code in Coq. VeLLVM adopts CompCert’s sequential machine memory model, so it cannot verify concurrent systems. It directly models small-step semantics of IR instructions in CFGs, making it problematic to use for systems with complex control flows. CreLLVM [28] extends VeLLVM to verify compiler optimization passes, but shares the same limitations of VeLLVM. VIR [48] also models small-step semantics of IR instructions in CFGs, suffering the same problems as VeLLVM. K-LLVM [36] defines LLVM IR operational semantics in the K framework, but cannot be used for deductive reasoning. SeaHorn [22] statically checks assertions in C programs by translating them to LLVM IR, then using the IR with an SMT solver and abstraction interpretation. Such automated verification tools cannot verify the functional correctness of a complex system. It is difficult to define program specifications using just assertions, and SMT solvers and abstract interpretation cannot prove complex proof goals.

**Automating systems verification.** AutoCorres [17] synthesizes specifications from C programs based on a fixed and simplistic machine model, which cannot be used to verify concurrent systems. It only supports an even more limited subset of C than ClightGen and does not support assembly code. The specifications generated are low level yet machine dependent, making them difficult to use to verify higher-level properties.

Push-button verification is a fully automated verification technique that has been used to verifying a file system [50], compiler [53], and OS kernel [43, 44, 51]. Users only need to write specifications in addition to the system implementation, and the verification framework automatically completes the proofs. However, implementations have restrictive constraints, such as uniprocessor only and constant bounds for loops so SMT solvers can be used. Unlike Spoq, verification requires manually defined specifications, does not hold for concurrent systems, and lacks machine-checkable proofs, as the unverified SMT solver provides no proof of its answer or any way to express a proof that can be machine checked.

Verification-aware programming languages such as Dafny [34] and F\* [47] have been used to implement verified storage systems [25, 26] and crypto libraries [46, 60]. Developers write code, specifications, and proofs all together in the same language. A compiler validates users’ proofs, in part using an SMT solver, and generates source code in familiar programming languages, which can in turn be further compiled and executed. Building on Dafny, Armada [42] uses a set of pre-built proof strategies to generate refinement proofs between levels of intermediate specifications, which users are expected to write to bridge the semantic gap between an implementation and its high-level specification. Unlike

Spoq, layers are not supported and systems written in C and assembly code cannot be verified without being rewritten.

**Decompilation.** Decompilation techniques recover a program’s source code given only its binary [1, 6, 9, 23, 27, 57, 58], though the recovered and original source code generally do not match. Some techniques do not reconstruct program structure [1, 58], some do so with goto statements [6], and some only do so with various restrictions on program CFGs [57]. More recent work can reconstruct program structure for arbitrary CFGs [23] without using goto statements, but requires a much more complex algorithm than used by Spoq. In contrast, Spoq employs a simpler algorithm to reconstruct program structure for arbitrary CFGs, and keeps the original LLVM IR instructions, which are much simpler and more rigorously defined than C, instead of trying to recover source code. To support proof decomposition and simplify specification synthesis, Spoq intentionally does not employ a richer variety of source code primitives such as goto or switch statements. Its resulting representation is more amenable to verification. Its design and implementation is far simpler than previous approaches to keep its TCB small, which is important for verification.

## 10 Conclusions

Spoq is the first system that can automate the generation of Coq representations, specifications, and proofs for C systems code to enable machine-checkable verification of concurrent system software. Spoq translates C systems code compiled into LLVM IR directly into Coq, converting IR control flow graphs into structured program functions to simplify verification while supporting full C semantics, including GNU C extensions and inline assembly. Using a layering proof strategy, Spoq introduces novel Coq tactics and transformation rules to automatically synthesize layer specifications and refinement proofs, even for functions with loops. Users can interact with Spoq to further refine the generated specifications and proofs at any layer. We used Spoq on commodity system software, such as the Linux kernel, to translate over 99% of their source code directly into Coq for verification. We also used Spoq to verify a multiprocessor KVM hypervisor implementation, showing that it reduces manual proof effort by over 70% while ensuring that the proofs hold for the unmodified implementation that is compiled and executed.

## Abstract

Multi-version concurrency control (MVCC) is a widely used, sophisticated approach for handling concurrent transactions. vMVCC is the first MVCC-based transaction library that comes with a machine-checked proof of correctness, providing clients with a guarantee that it will correctly handle all transactions despite a complicated design and implementation that might otherwise be error-prone. vMVCC is implemented in Go, stores data in memory, and uses several optimizations, such as RDTSC-based timestamps, to achieve high performance (25–96% the throughput of Silo, a state-of-the-art in-memory database, for YCSB and TPC-C workloads). Formally specifying and verifying vMVCC required adopting advanced proof techniques, such as logical atomicity and prophecy variables, owing to the fact that MVCC transactions can linearize at timestamp generation prior to transaction execution.

## 1 Introduction

Applications routinely rely on databases not just for storing data durably on disk, but also for ensuring that transactions execute atomically despite concurrency and crashes. This simplifies application development, because the application developer no longer has to worry about concurrency bugs or partial state left over after a crash. Indeed, this pattern is so ubiquitous that it is common for cloud providers to offer databases as a black-box service to application developers. In this model, application correctness and performance crucially hinges on the database system correctly handling all possible corner cases and doing so efficiently.

Achieving both correctness and high performance in a database system for many concurrent transactions is challenging. In particular, when transactions read and write an overlapping set of data items, the database system must ensure the transactions appear to execute in a serial order. A widely used technique for improving performance in this setting is *multi-version concurrency control*, or MVCC [8, 30, 35, 36], in which the database stores not just the latest version of a data item, but also past versions. Storing past versions allows the database system to execute writes that add a new version, while also being able to use the older versions to execute reads from transactions that appear to execute earlier in the serial order.

Multi-version concurrency control requires a sophisticated implementation of its data structures, in order to efficiently track multiple versions of each tuple, implement garbage collection (GC), etc. The implementation must also employ low-level optimizations to get high performance. For instance, using a mutex on a shared counter to get a unique ID for each transaction is too costly, and highly scalable implementations must use contention-free approaches such as relying on the CPU timestamp counter. The end result, therefore, is a complex implementation that can have bugs leading to incorrect or non-serializable executions. These bugs can be costly: they can cause data to be lost or corrupted; they can lead to many applications being affected; and tracking down bugs in the database system can be difficult for application developers.

This paper presents vMVCC, a high-performance MVCC-based transaction library with a formal specification and a machine-checked proof of correctness. vMVCC addresses the core technical challenges faced by the transaction layer in a database, and can be used to build transactional applications. Verifying vMVCC requires addressing several challenges. First, we must formalize a specification that captures the guarantees provided by MVCC transactions in a concise manner. Second, we must develop proof techniques to show that MVCC achieves a serializable execution order in the presence of concurrency. Finally, we must be able to formally reason about high-performance implementations that use low-level programming techniques such as sharded data structures, accessing the CPU timestamp counter with an RDTSC-like instruction, etc.

The key technical challenge addressed in vMVCC lies in dealing with the fact that MVCC’s linearization point happens before the transaction body runs—the linearization point is when the timestamp is obtained in `Begin()`. This makes it challenging to verify MVCC-based transactions because, at the linearization point, the transaction has not executed yet, and the proof does not know what data the transaction is going to write or whether it is going to commit or abort. However, it is important for the specification and proof to update the abstract state of the system at the linearization point, because subsequent transactions must observe these changes. In contrast, under two-phase locking, a transaction linearizes at the point when it commits, where it is well known what state the transaction modified and that it is about to commit.

**Figure 1:** Overview of the main vMVCC data structures. Implementation details are not shown on the figure (e.g., the index and the active transaction IDs are partitioned into multiple shards for scalability).

vMVCC addresses this challenge by adopting *prophecy variables* [1, 18]. Our use of prophecy variables allows the proof to speculatively predict what state the transaction is going to modify and whether it will commit. This translates into the proof considering every possible prediction, allowing vMVCC to update the abstract state accordingly at the linearization point. As the transaction is about to commit, the proof can check whether the prediction was correct or not, and either stop considering further an incorrect prediction, or continue with a correct prediction. vMVCC is not the first to develop or use prophecy variables—many earlier frameworks developed support for them and proved that they are a sound proof technique—but it is the first to prove the correctness of MVCC-based transactions.

We implemented vMVCC in Go, and verified it using the Goose and Perennial frameworks. vMVCC implements sophisticated optimizations such as the use of RDTSC to generate strictly increasing timestamps, on-the-fly GC of past versions, and efficient data structures for storing multiple versions. vMVCC provides a transactional key-value store interface, similar to Silo [35]. For the YCSB benchmark with 32 worker threads, vMVCC achieves an aggregated throughput of 18.6M–52M transactions per second, which is 38–96% of that achieved by the unverified Silo database. For TPC-C, vMVCC achieves a throughput of 10.7K–33K transactions per second per warehouse, which is 25–43% of Silo’s throughput.

The key technical contribution of vMVCC lies in demonstrating how to formally reason about transactions whose linearization point precedes the execution of their transaction body, using prophecy variables. This verification technique would be applicable to any system that uses MVCC [8, 10–12, 14, 19, 27, 30, 32, 35–37]. The second contribution is vMVCC itself, the first verified MVCC transaction library. The vMVCC artifact is interesting in its own right, providing a high-assurance and high-performance implementation, and can be used as a Go package independent of verification. vMVCC includes several other technical contributions, including a verified algorithm for computing strictly increasing transaction IDs using RDTSC, and a precise specification of a transaction library interface using logical atomicity [16].

One of the limitations of vMVCC is that it does not implement durability. In-memory databases are widely used in practice, but we do plan to extend vMVCC to store data durably on disk so that it persists across crashes, and to for-

mally verify it using techniques from Perennial [3]. Another limitation of vMVCC is that it provides a simple key-value data model, as opposed to SQL’s relational data, and does not support range scans.

## 2 Design and interface of vMVCC

vMVCC is a transaction library, and applications interact with it through a standard interface for transactions, as follows (in Go syntax):

```
func (db *DB) Begin() *Txn
func (txn *Txn) Write(key K, value V)
func (txn *Txn) Delete(key K)
func (txn *Txn) Read(key K) (V, bool)
func (txn *Txn) Commit() bool
func (txn *Txn) Abort()
```

vMVCC uses an MVCC design closest to the original protocol as proposed by Reed [30] (also known as multi-version timestamp ordering [36]). The design is based around assigning a strictly increasing timestamp in `Begin()` to every transaction, and storing multiple versions for each key, corresponding to a range of timestamps for which that version is valid. When an application modifies a key, using `Write(k, v)` or `Delete(k)`, the vMVCC transaction keeps track of the modification in a per-transaction write buffer. When an application invokes `Read(k)`, the transaction first checks its local write buffer for pending writes to `k`; if there are no pending writes, it then searches from the global state the version of key `k` whose timestamp immediately precedes the transaction’s timestamp. On successfully calling `Commit()`, the transaction creates a new version for each key in the write buffer with the transaction’s timestamp as well. On calling `Abort()`, or a failed `Commit()`, the transaction drops its write buffer.

Read-only transactions always succeed in vMVCC because vMVCC retains all past versions required by active transactions (i.e., those that have begun but not yet committed or aborted). A transaction involving updates, however, might fail to commit if another transaction with a higher timestamp has read or updated the modified key in the meantime. The reason this requires aborting the first transaction is that, to achieve linearizability, the second transaction should have seen the update made by the first one, but it did not.

**Data structures.** Figure 1 shows the data structures that vMVCC uses to implement its design. The crux of multi-versioning lies in the data structure *tuple*, consisting of a list of versions, a `tslast` field to detect conflicts, and a mutex (not shown) used for synchronizing access to this data structure. Each version corresponds to a range of timestamps for which it is valid, represented by the `ts` field, which marks the start of the validity region. The version is valid until the next version’s `ts` field, or, if this is the last version in the tuple, then it is the latest version. Each version also contains the value (`val`) and whether this key is deleted or not (`del`). The `tslast` field of each tuple represents the highest timestamp of any transaction that has read or written this tuple. It is

Figure 2: Two example executions of concurrent transactions in vMVCC.

used to detect conflicts if a Write or a Delete with an earlier timestamp tries to commit later on. On top of tuples, vMVCC maintains its *index*, a hash map from keys to tuple pointers. Keys not present in the index are assumed to be not present (deleted) at every timestamp.

Every active transaction in vMVCC is represented using a *transaction object*, which consists of a unique timestamp *ts*, as well as a local write buffer keeping track of the modifications made by this transaction so far. When the transaction commits, it tries to acquire the mutexes of the tuples to be modified, and if successful, atomically applies the modification in its local writer buffer. Transaction IDs are generated by the *transaction manager*. For the purposes of GC, it also keeps track of the IDs of active transactions.

**Execution examples.** Figure 2(a) illustrates an example of two concurrent transactions accessing the same key *k*. The tuple in the example corresponds to key *k*. ① Txn 4 reads the value *u* from the tuple, as the timestamp of the corresponding version (i.e., 2) immediately precedes that of Txn 4. ② Txn 15 writes *v* to *k* by appending a new version tagged with its timestamp at commit time, and ③ increases *tslast* to  $15 + 1$ , preventing transactions with timestamp below 16 from modifying this tuple.

This example also shows the concurrency advantages of MVCC over conventional concurrency control approaches such as two-phase locking (2PL) and optimistic concurrency control (OCC). With 2PL, Txn 15 cannot commit until Txn 4 commits, at which point the lock on *k* is released. With OCC, Txn 4 would have to abort as the value of *k* changes during the execution of Txn 4.

Figure 2(b) shows an example of how vMVCC detects and aborts conflicting writes. ① Txn 12 reads the second

version of the tuple, and ② increases the *tslast* field to its timestamp. ③ Txn 10 attempts to commit and update the tuple, but fails because the timestamp of Txn 10 is less than *tslast* of the tuple (i.e., 12). Thus, Txn 10 aborts.

**Garbage collection.** To reclaim space occupied by unusable versions, vMVCC employs a garbage collector that runs in the background to remove those versions. The garbage collector must ensure that the versions it removes cannot be accessed by any transactions, including those that have not even begun. Concretely, the garbage collector first determines a lower bound on the transaction IDs of all active and future transactions. This lower bound can be computed by finding the minimal transaction ID among the active ones; if there are no active transactions, the current timestamp is used. Because timestamps are strictly increasing (as described below), the garbage collector can safely remove versions whose lifetime ends before that lower bound.

**Generating timestamps with CPU timestamp counter.**

A key requirement for vMVCC is that every transaction is assigned a strictly increasing timestamp. However, assigning these timestamps by modifying a shared in-memory counter leads to contention on that counter. Instead, vMVCC uses the CPU timestamp counter (e.g., RDTSC on x86 machines) to generate timestamps in a scalable way. Modern hardware ensures that timestamps are monotonically increasing and consistent across cores and sockets [2].

One complication is that two threads running on different cores may obtain the same timestamp. vMVCC addresses this problem by using *transaction sites* to make transaction IDs unique. Each site has its own ID, which is a short integer value (e.g., from 0 to 63). When the transaction manager wants to assign a timestamp, it replaces the low bits of the timestamp counter with the site ID value. To ensure that the transaction manager does not use the same site for two transactions at the same time, vMVCC maintains an array of mutexes, one per site, and the transaction manager holds the site's mutex while computing the timestamp. The transaction manager can pick any site ID, such as the one associated with the local core. vMVCC takes a more flexible approach by assigning each thread a site ID in a round-robin manner. Having per-site mutexes ensures that the transaction manager does not contend when assigning timestamps on different sites.

Naïvely replacing the low bits of the timestamp counter with the site ID leads to subtle correctness issues. For example, Txn A may choose the highest possible site ID (all ones), quickly execute, and commit. Txn B, runs after Txn A but chooses the lowest possible site ID (all zeroes). The processor ensures that the RDTSC value seen by Txn B is higher than that seen by Txn A, but once the low bits are replaced with all-ones and all-zeroes, it may be that Txn B's transaction ID is lower than that of Txn A. One possible fix would be to represent the transaction ID as a tuple of the complete

64-bit RDTSC value and the site ID. However, since transaction IDs are used throughout vMVCC, this leads to a noticeable performance overhead.

Instead, vMVCC modifies the timestamp algorithm to ensure that timestamps are strictly increasing. To obtain a timestamp, the transaction manager first obtains  $t$ , the current RDTSC value, and then computes the next highest value  $t' \geq t$  such that  $t'$  has the desired site ID in the low bits. The transaction manager then spins in a loop calling RDTSC until it returns a timestamp  $t'' > t'$ . The transaction manager then uses  $t''$  as the transaction's ID. The reason this loop-based design achieves strictly increasing transaction IDs is that the transaction manager is holding the site's mutex while the CPU timestamp counter passed through  $t'$ . This means no other thread could have generated the same transaction ID. In practice, of course, the loop runs for a few cycles at most, since the RDTSC value will quickly exceed the loop threshold.

**Whole-transaction execution.** For developer convenience, vMVCC provides an interface that wraps up the details of beginning, committing, and aborting a transaction, in `db.Run`, a higher-order function whose implementation is as follows:

```
func (db *DB) Run(body func(txn *Txn) bool) bool {
    t := db.Begin()
    commit := body(t)
    if commit {
        return t.Commit()
    } else {
        t.Abort()
        return false
    }
}
```

The developer provides the body of the transaction, which can use `Read`, `Write`, and `Delete` to access the system state. The transaction body returns a boolean to indicate whether it wants to commit or abort.

### 3 Using and specifying vMVCC

vMVCC is a transaction library that facilitates building and verifying applications by providing an atomic transaction abstraction. We begin with constructing on top of vMVCC an example application that atomically transfers some amount from one account to another, along the lines of what a bank application might do (§3.1). We then describe the formal specification of vMVCC and how to build arbitrary applications on top of it (§3.2).

#### 3.1 Example: AtomicXfer

Figure 3 shows the implementation of `AtomicXfer` (ignore the inline proof for now). This code is implementing a simple bank, transferring `amt` from the `src` account to `dst`. If not enough funds are available in `src`, the transaction aborts. vMVCC ensures that the logical effect of the transaction body, `xfer`, appears to apply atomically. This frees the developer from worrying about other concurrent transactions that

```
// { src ↦ v_s * dst ↦ v_d }
func xfer(txn *Txn, src, dst, amt uint64) bool {
    // { src ↦ v_s * dst ↦ v_d }
    sbal, _ := txn.Read(src)
    // { src ↦ v_s * dst ↦ v_d ∧ sbal = v_s }
    if sbal < amt {
        // { src ↦ v_s * dst ↦ v_d ∧ sbal < amt ∧ ... }
        return false
    }
    // { src ↦ v_s * dst ↦ v_d ∧ sbal = v_s ∧ sbal ≥ amt }
    txn.Write(src, sbal - amt)
    // { src ↦ v_s - amt * dst ↦ v_d ∧ ... }
    dbal, _ := txn.Read(dst)
    // { src ↦ v_s - amt * dst ↦ v_d ∧ dbal = v_d ∧ ... }
    txn.Write(dst, dbal + amt)
    // { src ↦ v_s - amt * dst ↦ v_d + amt ∧ ... }
    return true
}
// If returning false, then { T }
// Else { src ↦ v_s - amt * dst ↦ v_d + amt }

// ⟨ src ↦ v_s * dst ↦ v_d ⟩
func AtomicXfer(db *DB, src, dst, amt uint64) bool {
    body := func(t *Txn) bool {
        return xfer(t, src, dst, amt)
    }
    return db.Run(body)
}
// If returning false, then ⟨ src ↦ v_s * dst ↦ v_d ⟩
// Else ⟨ src ↦ v_s - amt * dst ↦ v_d + amt ⟩
```

Figure 3: Implementation and proof of `AtomicXfer` using vMVCC library.

may affect the balance in `src` or `dst`, or about the versioning going on inside of vMVCC. vMVCC also ensures the transactions execute in a linearizable order, so that once `AtomicXfer` returns, any subsequent transactions will observe the effects of this `AtomicXfer`.

**Sequential reasoning in `xfer`.** vMVCC formalizes the fact that the developer need not consider other concurrent transactions by allowing the developer to use sequential reasoning for the body of the transaction. To achieve this, vMVCC uses Iris [17], a modern concurrent separation logic (CSL) [29], to specify its interface. In Iris/CSL, threads can own logical *resources*, and resource ownership can be exclusive, meaning that if one thread owns a resource, no other thread can own the same resource. For example, the resource  $k \mapsto v$  says that the value of  $k$  is  $v$ , and also says that the current thread *owns*  $k$ —that is, no other thread can own  $k \mapsto v$  in the meantime (and thus no other thread can read or write  $k$ ).

In our example, the proof of the transaction body, `xfer`, assumes ownership of  $src \mapsto v_s * dst \mapsto v_d$ ; the  $*$  operator (“separating conjunction”) says the thread owns both resources and they are disjoint. Having ownership of these resources allows the proof to assume that it is the only one accessing `src` and `dst`. This, in turn, allows the developer to prove `xfer` as if it was running in isolation, with no other concurrent transactions. The overall specification for `xfer` is that, starting with  $\{src \mapsto v_s * dst \mapsto v_d\}$ , if `xfer` runs and terminates, then it either returns false to abort the transaction, or it returns true to commit, and the resources are

**Figure 4:** Figurative specifications of `xfer` and `AtomicXfer`. We highlight the duration of owning the resources with red.

now  $\{src \mapsto v_s - amt * dst \mapsto v_d + amt\}$ . To prove this, the developer considers each line of code, and how that code affects the resources owned by the thread, as shown in the proof state comments between lines of code.

**Concurrent specification for `AtomicXfer`.** Specifying a function with exclusive resource ownership (like we did with `xfer`) simplifies the reasoning for that function, but at the cost of limiting its implementations to sequential ones—only the thread owning the required resources would be allowed to execute the function.

To specify the behavior of `AtomicXfer` in Iris/CSL without requiring ownership of `src` and `dst` for the entire duration of `AtomicXfer`, vMVCC uses the notion of *logical atomicity* [16]. Figure 4 shows the flow of resources in a logically atomic specification of `AtomicXfer` as compared to that of sequential `xfer`. The `xfer` specification says that the thread owns the resources throughout the entire execution of `xfer`, whereas in `AtomicXfer`, the specification says that there will be some point in time at which `AtomicXfer` appears to run atomically. One notable difference here is the kinds of resources appearing in the two specifications. Intuitively, the  $k \mapsto v$  used by `xfer` says that “this transaction believes the value of  $k$  is  $v$ ”, whereas the  $k \mapsto v$  used by `AtomicXfer` reflects “the actual value of  $k$  is  $v$ ”. We will explain the meaning of these resources in more depth in §3.2.

The resulting logically-atomic specification for `AtomicXfer` captures that any number of threads are allowed to concurrently invoke `AtomicXfer`, possibly with overlapping `src` and `dst` values. For each thread’s invocation of `AtomicXfer`, the specification says that the transfer will execute correctly and atomically. The application can, in turn, prove that this maintains some application-level invariant, such as the sum of the balances of all accounts remains fixed.

**Proving `AtomicXfer`.** Proving `AtomicXfer` involves two parts. First, the developer proves that `xfer` meets its specification, as described above. Second, the developer uses the vMVCC library to obtain a proof that `AtomicXfer`’s specification is the logically-atomic equivalent of `xfer`’s sequential specification, as shown in Figure 3. The next subsection describes how vMVCC formally specifies `db.Run` in the general case to enable this second step.

**Figure 5:** Specification of `db.Run`. The angle brackets indicate a logically atomic specification [16]. The vertical arrow indicates that, as a precondition for invoking `db.Run`, the developer must prove the standard Hoare-logic specification shown above the arrow for `body`. Not shown is the part of the specification that describes the representation predicates. We color the resources established for commit with green, and for abort with red.

### 3.2 Specifying the transaction interface

Transactions give users an illusion that they are “isolated” from each other. To capture this intuition, we define the resource  $k \mapsto v$  (which already showed up in the above example) as the *transaction-local view* of the system state. We can then specify operations that manipulate the transaction-local view in terms of  $k \mapsto v$ :

$$\begin{aligned} & \left\{ k \mapsto v \right\} \text{txn.Read}(k) \left\{ RET\ v.\ k \mapsto v \right\} \\ & \left\{ k \mapsto v \right\} \text{txn.Write}(k, u) \left\{ k \mapsto u \right\} \\ & \left\{ k \mapsto v \right\} \text{txn.Delete}(k) \left\{ k \mapsto \perp \right\} \end{aligned}$$

These specifications use standard Hoare-logic syntax, where  $\{P\} op \{Q\}$  means that, if `op` runs starting with the resources specified in precondition  $P$ , it will return with the resources as specified in the postcondition  $Q$ .

Next, we define the resource  $k \mapsto v$  as the *logical view* of the system state, representing the linearizable state. The fact that only a single value of each key is exposed to users might seem counter-intuitive in the case of MVCC, given that the system physically stores multiple values for each key. However, from the application’s point of view, it suffices to view the abstract state of the system as having a single value for each key at any given point in time, and updating that value at the transaction’s linearization point. (We discuss this in more detail in §4.2.)

The specification of `db.Run` shown in Figure 5 connects these two kinds of resources. This is also the top-level theorem of vMVCC as a transaction library. The specification requires the developer to prove a sequential specification for `body` with a precondition that takes the transaction-local view of some set of key-value pairs,  $m$ , along with some

**Figure 6:** An example of two concurrently running vMVCC transactions. Both transactions appear to execute their reads and writes at their linearization points (marked as red). The reason linearization points appear at timestamp generation is that if Txn A linearizes (i.e., runs across its linearization point) before Txn B, then all reads and writes of A should appear to happen before that of B. This is precisely what timestamps are intended to do.

constraints on those values, represented by the predicate  $P(m)$ . The postcondition of body says that, if it chooses to commit, then it should return the transaction-local view of  $m'$  with some constraints  $Q(m, m')$  on how these key-value pairs relate to the starting state.

Given such a specification for body, the specification of `db.Run` says that `db.Run(body)` will be the logically atomic equivalent: at some instant during its execution, it will swap the logical view of  $m$  satisfying  $P(m)$  for that of  $m'$  satisfying  $Q(m, m')$ . Further, if this transaction aborts (either at its own will or because of conflicts with another transaction), then `db.Run(body)` keeps the logical view of  $m$  intact.

As an example, we can instantiate  $P$  and  $Q$  for `AtomicXfer` from §3.1 as follows:

$$P(m) \triangleq \text{dom}(m) = \{\text{src}, \text{dst}\}$$

$$Q(m, m') \triangleq m'[\text{src}] = m[\text{src}] - \text{amt} \wedge m'[\text{dst}] = m[\text{dst}] + \text{amt}$$

The use of  $P$  and  $Q$  as arbitrary predicates allows the `db.Run` specification to capture the behavior of body and transfer it to the logically atomic specification of `db.Run(body)`. One technicality here is that  $P$  and  $Q$  are both *pure* predicates, meaning they cannot encode ownership of other resources, but merely restrict the values of  $m$  and  $m'$ .

The specification of `db.Run` can be regarded as a program-logic formalization of strict serializability [15] in the database literature. Serializability comes from the part of the specification that says transactions appear to observe and modify the system state one at a time (at their linearization point), with strictness owing to the fact that they do so during the course of their respective execution (and hence the serial order respects the transaction precedence order).

## 4 Proving vMVCC

This section describes the important aspects of our proof for vMVCC. We start with a key verification challenge and how we solve it with prophecy variables (§4.1). We describe how

**Figure 7:** Transaction futures, showing several example futures speculated through prophecy variables and their interaction with prophecy resolution.

we abstract a tuple from its physical representation containing multiple versions to its logical view with a single value, which potentially reflects some update that happens only in the future (§4.2). We present a key invariant about the prophecy variable used in vMVCC, and how the invariant helps maintain other system-wide invariants under correct and incorrect predictions (§4.3). We discuss how we define the transaction-local view of the system state, and its connection to the logical view (§4.4). We finally conclude this section with the challenges and the approach regarding proving strict monotonicity of transaction IDs (§4.5).

### 4.1 Speculation using prophecy variables

We introduce the verification challenge with an example shown in Figure 6. Observe that in the example, the value of  $k$  to be read by Txn 10 is determined up front by  $k \mapsto v$  at its linearization point, despite the fact that by the second read of Txn 10, Txn 15 has already committed and updated the physical state of  $k$ . Similarly, the write of Txn 15 updates the logical state to  $k \mapsto v + 1$  before it physically executes. This kind of “speculative” behavior of MVCC turns out to be tricky to reason about in a Hoare-logic reasoning style where the proof considers each line of code in turn and reasons about how that code updates the abstract and physical states.

The challenge arises from the fact that MVCC transactions linearize when their timestamp is generated. In the proof, the logical state must be updated at the transaction’s linearization point, which happens before the transaction body runs. The changes to the logical state depend both on the transaction itself (i.e., what data the transaction decides to write), as well as conflicts with other transactions (i.e., whether another transaction reads or writes the same keys as this transaction in a way that will force this transaction to abort, as discussed in §2). This poses the question: how do we know, at the transaction’s linearization point, what values will a transaction write, and whether a transaction will encounter a conflict and thus be forced to abort? To tackle this issue, we use prophecy variables.

Intuitively, prophecy variables allow the proof to speculate about future execution. In the case of vMVCC, the prophecy variable is a list of transaction actions, which describes what actions each transaction will perform, and in what order.

**Figure 8:** Overview of vMVCC’s key physical states (in blue regions), logical states (in red regions), intermediate states, and the system-wide invariants relating them (the dotted lines). We introduce the tuple abstraction relation, the prefix invariant and the last-value invariant in §4.2, the conflict-free invariant in §4.3, and the transaction-local invariant in §4.4. Here  $u_4$  is the value of the speculative view of  $k_2$  at timestamp 5.

We refer to the list as the *future-action list*. There are two kinds of actions in vMVCC’s proof:  $C_t^m$  (“Txn  $t$  commits and applies updates  $m$  to the system state”) and  $R_t^k$  (“Txn  $t$  reads key  $k$ ”). Transaction aborts are represented by a commit with an empty write-set.

At transaction begin time, vMVCC’s proof uses the prophecy variable to speculatively predict the execution of the transaction, which allows the proof to update the logical state as if it knew what the transaction is going to do. The main challenge of using the prophecy variable, however, is that some of the predictions could be *incorrect*—it predicts something that does not match what happens later. As an example, Figure 7 shows five concrete predictions for Txn 15 that increases the value of  $k$  by 1. Only the bottom prediction turns out to be correct when the transaction actually commits. The incorrect predictions eventually diverge from the actual changes made by the transaction, and will make the logical state inconsistent with the physical state.

To deal with the divergence, the proof performs *prophecy resolution* at the point where the transaction actually commits and updates the physical state. Prophecy resolution allows the proof to stop considering cases corresponding to predictions that did not match reality, and continue only with the cases that did. We will elaborate more on correct/incorrect predictions and prophecy resolution with a concrete example in §4.3.

This description may make it sound like there are a large number of cases to consider in the proof, greatly increasing the proof burden. In practice, the predictions are symbolic, rather than concrete timestamps, keys, and values; for instance, the prophecy variable speculates the updates made by a transaction as a symbolic partial map. Furthermore, the proof can group together many speculative executions (e.g., those in which the transaction of interest is speculated to commit without encountering a conflict), and consider the entire family of executions just once.

## 4.2 Incorporating speculation in abstract state

vMVCC exposes a single linearizable copy of the system state, thereby freeing the users from explicitly reasoning about the timestamps. Thus, the logical view (shown in the “logical” row of Figure 8) of vMVCC is a single value for every key, and the proof must connect this logical view to the physical state (shown in the “physical” row of Figure 8), consisting of the Go struct representing each tuple.

This connection is challenging for several reasons, including the fact that the Go data structure contains multiple versions, and the fact that the value in the logical view may not even be present in the Go data structure, if it is made by a write speculated by the prophecy variable for an active transaction. Moreover, reasoning about the physical layout of the tuple in all intermediate proofs is cumbersome.

To address these challenges, we introduce two intermediate layers modeled with *monotonic lists* (i.e., lists that only grow). The first is the *linear view* of the tuple, shown in the “linear” row of Figure 8. The linear view is a contiguous list of values, indexed by timestamps. The linear view gives us an elegant way to specify operations on tuples: reading a tuple with a given timestamp  $t$  just returns its value at index  $t$ . If the transaction needs to extend `tslast`, doing so extends the linear view up to the new `tslast` timestamp, filling in new entries with the last value in the list. Writing a tuple with a given timestamp  $t$  extends the tuple up to index  $t$ , and appends the new value to the end.

To capture the speculative behavior of MVCC as described in §4.1, we add the “speculative” layer, as shown in Figure 8 as well. The *speculative view* is yet another contiguous timestamp-indexed list, much like the linear view, but includes the writes from transactions that have linearized but have not yet finished executing and updating the physical state. The proof looks up and extends the speculative view at the linearization point (the ability for such extension is guaranteed by strict monotonicity of vMVCC’s timestamps),

The second challenge stems from the fact that an inconsistent prediction, such as the example above, involves multiple transactions, and therefore relies on prophecy resolution in multiple threads. The prediction about each individual transaction and thread could be correct in its own right, but it is the combination of them that leads to a contradiction. How should the proof be structured to establish the contradiction despite only doing one prophecy resolution at a time? vMVCC's proof addresses this challenge by maintaining a sufficiently strong invariant that carries along facts from each prediction to derive contradictions against later predictions as needed, as we describe below.

To illustrate this point, we first sketch out the proof for a correct prediction, where a transaction commits and there are no conflicts that would have forced it to abort, and then show how vMVCC's proof handles incorrect predictions.

**Predicted commit without conflicts.** In Figure 9(a), Txn 5 is speculated to commit without encountering any conflict. The reason is that at its linearization point, the commit action of Txn 5 in the future-action list,  $C_5^{(k,v_5)}$  (there might be multiple of them in the list, but the proof cares only about the first one), is *conflict-free* against all the actions prior to it. We define  $C_t^m$  to be conflict-free against an action  $a$  if (1)  $a = \mathcal{R}_{t'}^k$ , where  $t' \leq t \vee k \notin \text{dom}(m)$ , or (2)  $a = C_{t'}^{m'}$ , where  $t' < t \vee \text{dom}(m') \cap \text{dom}(m) = \emptyset$ . Knowing that Txn 5 will commit without conflicts, the proof safely extends the speculative view up to timestamp 5 using the old value  $v_2$ , and appends the new value  $v_5$  to it (which updates the logical view to  $v_5$  as well) without violating the *conflict-free invariant*, as described below.

Intuitively, the conflict-free invariant requires that a transaction reflects its update to the speculative view only if the first commit action of the transaction is conflict-free against all the actions prior to it in the future-action list. As we will see below, this invariant is crucial to prove invariance of the prefix property between the linear and speculative views.

On reading key  $k$ , the proof resolves the head of the future-action list to  $\mathcal{R}_5^k$ . Then, it uses the conflict-free invariant to deduce that transactions which contain updates to the speculative view, but not to the linear view, must have timestamps greater than or equal to the timestamp of this read. This implies that the speculative view can differ from the linear view only after a timestamp  $t > 5$ , allowing the proof to re-establish the prefix invariant after extending the linear view. A similar reasoning goes for commit, except the proof additionally uses the promise that Txn 5 will commit to know the value at timestamp 5 of the speculative view is  $v_5$ .

**Predicted commit despite conflicts.** In Figure 9(b), Txn 5 is speculated to commit despite the presence of conflicts because its first commit action,  $C_5^{(k,v_5)}$ , conflicts with an earlier action  $C_6^{(k,v_6)}$ . The proof, as in the previous case, extends the speculative view up to timestamp 5 using the old value  $v_2$ ; however, it does not append the new value  $v_5$  as doing so

would violate the conflict-free invariant, and proceeds as if the transaction will abort, which makes the invariant true.

For read, the proof of the prefix property is similar to the previous case. For commit, however, the proof cannot re-establish the prefix property after extending the linear view, because it indeed did not apply the new value  $v_5$  at the linearization point. Fortunately, at this point the proof knows two facts that contradict each other: (1) reaching the prophecy resolution point for commit, the execution must have passed the conflict detection as illustrated in Figure 2(b), implying the length of the linear view  $l \leq 5 + 1$  (the +1 part is due to our lists being zero-indexed); (2) some conflicting action (in this case  $C_6^{(k,v_6)}$ ), which extends the linear view to at least timestamp  $t > 5$ , must have happened *before* Txn 5 commits, implying  $l > 5 + 1$ . The proof closes this case with the derived contradiction.

#### 4.4 Abstract state of a transaction

As mentioned in §4.1 (and illustrated in Figure 6), the value of key  $k$  to be read by a transaction is determined up front by  $k \mapsto v$  at the transaction's linearization point. Reading from the physical state, however, happens only at some later point in time, and the value is based on  $k \mapsto v'$ , as specified in §3.2. This means the proof has to somehow connect  $k \mapsto v$ ,  $k \mapsto v'$ , and  $v''$ , the result of physically reading the tuple of  $k$ . This section describes how the system-wide invariants shown in Figure 8 establish that connection.

Let us first consider the case where the transaction has not written key  $k$ . Our first step then is to show  $v = v'$ . Recall that at the linearization point of Txn  $t$  that reads or writes  $k$ , we extend the speculative view of  $k$  up to  $t$  using its last value. Doing so, along with the last-value invariant, allows us to deduce that the value of the speculative view at index  $t$  is  $v$  (and will remain so since the speculative view is monotonic). The proof then follows from the definition of the *transaction-local invariant*, which says that if Txn  $t$  has not written  $k$ , then  $v'$ , the transaction-local value, is equal to the value of the speculative view at index  $t$ .

Our next step is to show  $v' = v''$ . Again recall that physically reading the tuple of  $k$  at timestamp  $t$  means extending the linear view of  $k$  up to  $t$  (if the value at  $t$  is still absent), and looking up its value at index  $t$ . The proof of  $v' = v''$  then follows immediately from the prefix invariant that requires the linear view to remain a prefix of the speculative one.

Now consider the case where the transaction has last written  $k$  with value  $u$ . As specified in §3.2, the logical effect of the write is  $k \mapsto u$ . We thus define the remaining case for the transaction-local invariant: if the transaction has written  $k$ , then the transaction-local value is equal to the value in its local write buffer.

The contents of the write buffer are also what the speculated updates in a commit action (i.e.,  $m$  in  $C_t^m$ ) resolve to. This allows us to obtain the equality between the speculated updates with the actual updates at the prophecy resolution

point, which is crucial when re-establishing the prefix invariant as discussed in §4.3.

#### 4.5 Strict monotonicity of transaction ID

Another challenge in vMVCC’s proof is establishing strict monotonicity of transaction IDs, for vMVCC’s RDTSC-based algorithm described in §2. The challenge lies not only in proving that the algorithm generates strictly increasing transaction IDs, but also in being able to logically execute the transaction (i.e., update the logical state) at the linearization point corresponding to that transaction ID. The reason this is challenging is that the linearization point for some transaction ID  $t'$  might not correspond to any line of code that was executed for this transaction—the algorithm simply spins in a loop waiting for RDTSC to advance past  $t'$ , and linearization occurs when *any* transaction observes that  $t'$  has passed.

To formally reason about this algorithm, vMVCC’s proof maintains a logical table of slots, one per timestamp. The slot contains the logical set of changes that a transaction with that timestamp wants to perform, represented as a ghost function. The actual state changes performed by this ghost function are determined by prophecy variables, as described above. The proof uses the slots to invoke the ghost functions for each timestamp in order, as the RDTSC clock advances; the proof maintains a “latest-slot” timestamp corresponding to the last table slot that has been invoked. The invariant associated with this proof states that this latest timestamp is always below (or equal to) the real RDTSC clock. Furthermore each future slot is protected by the site’s mutex that corresponds to this timestamp.

When the transaction manager first computes  $t'$ , it registers the  $t'$  slot in the table, putting in a ghost function that will perform its transaction’s changes. Since  $t' > t$ , the proof has not yet invoked the ghost function for this slot, and the current thread also holds the site’s mutex needed to fill this slot (which proves that no concurrent thread could fill the same slot). As the transaction manager runs the loop waiting for RDTSC to move past  $t'$ , it updates the latest-slot with each iteration, executing all of the ghost functions in the slots that have been advanced over. The proof takes advantage of *later credits* [31] in Iris that enable verification of this “unsolicited helping” pattern.

The invariant for the slot table says that, for every slot with a timestamp below the latest-slot, its ghost function callback has been invoked. As a result, when the transaction manager’s loop exits, it knows that the latest-slot is at least as high as  $t'$ , and therefore its ghost callback must have been invoked (either by this same thread or by some other thread running the same loop).

## 5 Implementation and proof details

We implemented vMVCC in Go, and verified its implementation using the Perennial framework [3] (based on Iris [21–23] and Coq [33]), using Goose [4] to lift vMVCC’s Go code into

Component	Lines of code (Go) / proof (Coq)
Tuple	260 / 1947
Transaction	419 / 4489
Index	85 / 496
Timestamp	24 / 311
Misc	39 / 361
Ghost state	- / 947
Global invariants	- / 2566
Total	827 / 11117

Figure 10: Lines of code and proof for each component of vMVCC.

Perennial. To enable vMVCC’s proofs of MVCC transaction linearizability, we incorporated prophecy variable support from Iris [18] into Perennial.

Figure 10 summarizes the implementation and proof effort, not including changes to Perennial that were necessary for the verification. The lines of proof include the specifications for each function in vMVCC’s implementation. The proof effort for vMVCC required about 13× as many lines of proof as lines of code, which is in the same ballpark as other verified systems that handle concurrency [3, 6, 13].

The implementation contains several low-level optimizations that improve performance. We used RDTSC to generate transaction IDs. We also padded data structures to avoid false cache-line sharing that limits multi-core scalability, and sharded the index and the set of active transaction IDs to reduce contention from concurrent accesses.

### 5.1 Bugs found during verification

When we were first designing and implementing vMVCC, we were careful to structure the code in a way that makes it clear why the code is correct, what the invariants are, how they are maintained, and what guarantees each interface or function provides. Nevertheless, during the actual verification, we ran into several bugs in corner cases that we missed or did not correctly handle in the implementation, highlighting the importance of formal reasoning. In this subsection, we give several examples of such bugs.

One interesting bug we found when verifying vMVCC is related to garbage collection. The buggy code is:

```
func (site *TxnSite) getSafeTS() uint64 {
    site.mutex.Lock()
    var tidmin uint64 = MAX_U64 /* buggy */
    // var tidmin uint64 = site.getCurrentTS()
    for _, tid := range site.tidsActive {
        if tid < tidmin {
            tidmin = tid
        }
    }
    site.mutex.Unlock()
    return tidmin
}
```

When the garbage collector starts a new round of GC, it first calls `getSafeTS` on each site to collect the per-site minimal transaction ID, and then computes a globally minimal one

**Figure 11:** Comparison of Silo and vMVCC. For YCSB, each transaction reads or writes a key sampled from a uniform distribution with a certain R/W ratio. For TPC-C, the number of warehouses is same as the number of worker threads.

among them. If every transaction site is empty (i.e., if every site returned `MAX_U64`), the garbage collector generates a timestamp using an arbitrary site. (Recall that vMVCC always places a site ID in the low bits of the timestamp, and the choice of site ID does not matter, as it is purely there to ensure uniqueness.) The bug arises when a transaction enters the system right after `getSafeTS` returns, and then the garbage collector computes a timestamp larger than the ID of that transaction. Our fix to this bug is to generate a timestamp within each site, as shown in the commented-out code. Doing so ensures that future transaction IDs generated by this site will be larger than the one `getSafeTS` returns.

Another subtle bug we discovered is missing the wait loop when generating transaction IDs, violating the strict monotonicity of our timestamp generation scheme. The fix was the looping `RDTSC` algorithm described in §2. Finally, since our protocol is centered around timestamps, we also discovered several off-by-one errors in the implementation when conducting the verification of vMVCC (e.g., where greater-than comparisons should have been greater-than-or-equal-to comparisons).

## 6 Evaluation

We experimentally answer the following questions:

- Is vMVCC competitive with state-of-the-art unverified systems? (§6.2)
- Does the use of MVCC in vMVCC help with long-running read-only transactions? (§6.3)
- Are the low-level optimizations in vMVCC important for performance? (§6.4)
- Does vMVCC scale under high-contention workloads? (§6.5)

### 6.1 Experimental setup

All experiments were done on an AWS EC2 `c5.9xlarge` instance with 36 vCPUs (18 physical CPUs, each shared by 2 hardware threads via hyper-threading) and 72 GB of main memory, running Linux 5.15.0 and Go 1.20.3.

**Figure 12:** Comparison of 2PL and vMVCC under YCSB (4 keys accessed per transaction,  $\theta = 0.85$ , 24 threads), with and without 8 long-running reader threads that repeatedly read 1% of the entire key space.

We used the YCSB benchmark [7] to understand the performance characteristics of vMVCC under various workloads. Unless otherwise specified, we execute each YCSB put or get in a separate transaction. The data set contains 1M key-value pairs with each key being an 8-byte integer and value an 100-byte string. The access pattern follows the uniform distribution, or the Zipfian distribution, with a parameter  $\theta$  controlling the skewness of the distribution. We vary the read-write ratio and the number of keys accessed in each transaction.

We also used the TPC-C benchmark, which involves more sophisticated transactions. TPC-C models the operation of a wholesale supplier, a common online-transaction processing (OLTP) workload. It contains 9 tables and 5 kinds of transactions, each with various workload characteristics. In particular, most transactions can be processed in a single warehouse, so it is natural and efficient to map each warehouse to one thread. Our current implementation of vMVCC requires the key to be an 8-byte integer, and every tuple needs a key. Because of these limitations we made two modifications to TPC-C. First, we do not support “get customers by their last name” appearing in the `OrderStatus` and `NewOrder` transactions; they are replaced with just “get customers by customer ID”. Second, the `History` table does not have a primary key, so we randomly generate one for it.

We employ a background GC thread for vMVCC in every experiment. We repeat each experiment 10 times, each for 30 seconds. We report the mean, minimum, and maximum (the last two as error bars) among the 10 runs.

### 6.2 Comparison with Silo

To evaluate whether vMVCC achieves competitive performance with state-of-the-art systems, we compare vMVCC to Silo [35], a high-performance transactional database system. Because vMVCC does not store data durably, we compare with MemSilo, a variant of Silo that does not persist its data. Silo is an OCC/MVCC based system, using OCC to provide serializability, and using MVCC to access a consistent snapshot of old versions. Unlike vMVCC, Silo does not generate a new version for every write, but only once per *snapshot epoch* (on the order of 1 second), which reduces memory management costs. Silo’s OCC/MVCC design has the ad-

**Figure 13:** Comparison of 2PL and vMVCC under TPC-C (32 warehouses), with a thread periodically invoking the read-only transaction StockScan.

vantage of lower memory usage and allocation overhead over vMVCC’s pure MVCC design. On the other hand, Silo only ensures its snapshot transactions (those that access past versions) always read a consistent snapshot, without imposing ordering constraints on them with respect to normal linearizable transactions, whereas in vMVCC, a “snapshot transaction” is simply a linearizable transaction that does not perform writes.

Figure 11 shows the results of the comparison for several configurations of YCSB and TPC-C, normalizing to the throughput achieved by Silo. Similarly to Silo, each worker thread in vMVCC generates the workload parameters and then immediately processes the transaction. We used a YCSB profile where each transaction accesses a single key sampled from a uniform distribution. vMVCC achieves 96.6% the throughput of Silo for a read-only workload in YCSB, and 38.8% for a write-only workload. For TPC-C, vMVCC achieves 43% the throughput of Silo for 1 warehouse and 25.7% for 32 warehouses. We hypothesize that the performance difference between Silo and vMVCC is largely due to (1) vMVCC’s higher memory allocation overhead for storing past versions, and (2) its inefficient way of executing range scans—lacking a tree-like index structure, vMVCC relies on the continuity invariant of TPC-C [34], and expands a range query into multiple point queries. To test these hypotheses, we conducted the following two experiments.

First, we ran the same write-only YCSB workload, except that we fixed the write value to some statically allocated string, and modified vMVCC to perform in-place update on its tuples, without changing any other parts of the code (hence the resulting system is not even correct, but it is merely for us to understand more about vMVCC’s performance characteristics). Applying these changes increases the relative performance from 38.8% to 87.3%.

Second, we ran an additional range scan workload where each transaction first randomly picks a starting key, and then reads the next 100 keys. Silo executes each transaction with a single scan, whereas vMVCC issues 100 reads. Figure 11 shows the results in the “scan” column. vMVCC achieves 48.1% of Silo’s throughput; the difference mostly attributes to more cache misses in vMVCC.

Based on these experiments, we conclude that the gap between vMVCC’s performance and that of Silo is indeed

**Figure 14:** Throughput of vMVCC with different optimizations enabled. The benchmark is YCSB (1 key read per transaction,  $\theta = 0.2$ ).

largely due to memory allocation and vMVCC’s lack of support for range scans. For benchmarks that do not stress these two aspects, vMVCC achieves performance competitive with Silo.

### 6.3 Robustness to long-running readers

One main advantage of MVCC over traditional concurrency control protocols is that its performance should remain stable even in the presence of long-running readers. To confirm that vMVCC’s design indeed achieves these performance benefits, we implemented a variant of vMVCC that uses two-phase locking for concurrency control instead of MVCC, and compared the performance of vMVCC with this 2PL variant.

**YCSB.** We first compare vMVCC and 2PL under the YCSB workload, using a YCSB profile where each transaction reads or writes 4 keys. We fixed the number of threads to 24,  $\theta$  to 0.85, and varied the read-write ratio from 0% to 100%. We then ran one experiment without long-running readers, and another one where the workload includes 8 transactions repeatedly reading 10K keys (1% of the entire key space).

Figure 12 shows the results. In the absence of long-running readers, 2PL performs better than vMVCC for all read-write ratios except for the read-only workload (comparing the solid lines). The difference stems from MVCC’s overhead of (1) generating timestamps and (2) keeping past versions and the associated memory allocation costs.

In the presence of long-running readers (comparing the solid and dashed lines of each system), vMVCC’s throughput drops slightly between the range of 11.5%–22.2%, whereas 2PL’s throughput drops significantly as the write ratio increases (e.g., 72.6% and 84.9% for write ratio 80% and 100%, respectively). As a result, the performance of 2PL with long-running readers is worse than that of vMVCC for workloads with 40% or more writes; for instance, under write ratios 80% and 100%, vMVCC performs 2.2 $\times$  and 4 $\times$  better than 2PL, respectively. The reason is that, in 2PL, the long-running readers hold read locks on keys for a long duration, preventing other transactions from writing to those keys.

**TPC-C.** We also compare vMVCC and 2PL under the TPC-C workload. Similarly to prior work [36], we add a read-only transaction StockScan that counts the number of each item in

(a) Read scalability of vMVCC under high-contention workloads.

(b) Write scalability of vMVCC under high-contention workloads.

Figure 15: Scalability analysis under high contention. The benchmark is YCSB (4 keys accessed per transaction).

all warehouses. We parametrize the workload by the interval of invoking StockScan. Figure 13 shows the results.

When no StockScan is invoked (represented by the  $\infty$  interval on the x-axis), 2PL performs better than vMVCC by around 14%. However, when there are StockScan transactions running, NewOrder transactions that update the stock table will conflict with StockScan, and block under 2PL concurrency control. As the interval between StockScan transactions decreases, 2PL’s performance drops significantly, whereas vMVCC throughput remains more-or-less the same, since StockScan accesses old versions of tuples and does not impact other transactions. For StockScan intervals 500 and 100 ms, the throughput of vMVCC is 11 $\times$  and 54.4 $\times$  that of 2PL. In terms of latency, vMVCC maintains its 99.9% latency around 3.4 ms across all StockScan intervals, whereas the 99.9% latency of 2PL increases from 3.2 ms in the absence of StockScan transactions, to a few tens and occasionally hundreds of ms when StockScan is invoked every 100 ms.

## 6.4 Low-level optimizations

vMVCC implements (and verifies) two low-level optimizations to achieve high performance on many cores: (1) padding and sharding data structures and mutexes, to avoid cache-line contention, and (2) using RDTSC to generate transaction IDs without shared-memory contention. To understand whether they are important for performance, we enable each optimization in turn and measure the resulting performance. To stress the implementation, we chose a lightweight YCSB profile where each transaction accesses a single key. We chose a low-contention setting ( $\theta = 0.2$ ) so that transactions largely access different portions of the key space; we will evaluate scalability under high contention in the next subsection.

To evaluate the benefit of the RDTSC-based transaction ID generation, we compare with two alternatives. The first is a lock-based design where the transaction manager acquires a mutex to get (and increment) the next transaction ID counter. The second is a lock-free implementation that uses the fetch-and-increment (FAI) instruction to atomically obtain the next transaction ID.

Figure 14 shows the results. The optimizations have little effect on a single core, but significantly improve vMVCC’s performance on 32 cores. Partitioning and padding index and transaction sites improves vMVCC’s performance by 2.8 $\times$  at 32 cores. Using FAI increases throughput by a further 3 $\times$  over the lock-based design at 32 cores. Finally, RDTSC-based transaction IDs achieve yet another 3.7 $\times$  improvement in throughput compared to FAI at 32 cores. In summary, the results show that all of these optimizations are important for scaling vMVCC’s performance with many cores.

Enabling all the optimizations, vMVCC’s throughput scales by 15.6 $\times$  using 16 threads. The result suggests that vMVCC eliminates almost all contention on its internal data structures (when the keys themselves do not contend). The throughput scales further by 1.66 $\times$  when doubling the number of threads to 32, implying that vMVCC can benefit from hyper-threading even though not as much as from having more physical cores.

## 6.5 Scalability under contention

The previous section showed that vMVCC scales nearly linearly for a low-contention workload, with its low-level optimizations. In this section, we evaluate vMVCC’s scalability under high-contention workloads, using a YCSB profile where each transaction issues 4 reads/writes, with the skewness parameter  $\theta$  ranging from 0.8 to 0.95.

Figure 15 shows the results. For reads (Figure 15(a)), before reaching the hyper-threading threshold (i.e., 18 cores), the throughput scales almost linearly with respect to the number of threads, except for extremely contended workloads (e.g.,  $\theta = 0.95$ ): the aggregated throughput of 16 threads is 14.9 $\times$  that of a single thread for  $\theta = 0.8$ , and 12.6 $\times$  for  $\theta = 0.95$ . Scalability drops after reaching the hyper-threading threshold because of interference, especially for higher skewness: using 32 threads achieves 22.8 $\times$  better performance for  $\theta = 0.8$ , and 16.9 $\times$  for  $\theta = 0.95$ .

For writes (Figure 15(b)), besides from hyper-threading interference, having more contention also causes more conflicts between transactions, and hence higher abort rates. For instance, the abort rate at 32 threads for  $\theta = 0.8$  is 4.8%, whereas for  $\theta = 0.95$  is 27.6%. The result is that vMVCC’s

throughput with 32 threads is 11.7× that of a single thread for  $\theta = 0.8$  and 9.9× for  $\theta = 0.95$ .

The results show that vMVCC’s performance scales with the number of cores even for workloads of high contention.

## 7 Related work

vMVCC is the first formally verified MVCC-based system, but builds on prior work on formal verification and specification of transactions, as we now discuss.

**Verified systems.** The closest related work to vMVCC is GoTxn [6], a verified transaction library that uses 2PL for concurrency control. GoTxn stores data durably to disk and uses the verified GoJournal [5] journaling system to provide crash atomicity. vMVCC uses a more sophisticated concurrency control plan (MVCC), which allows it to achieve high performance for long-running read-only transactions, while GoTxn uses standard 2PL which does not perform well with long-running readers. vMVCC also implements and verifies sophisticated optimizations, such as strictly increasing RDTSC-based timestamps, which are not present in GoTxn.

Malecha et al. [28] verified a simple relational database, focusing on SQL queries, the relational data model, and the use of B+-trees on disk. These issues are complementary to the focus of vMVCC, which targets handling concurrent transactions using sophisticated concurrency control protocols and low-level optimizations.

**Prophecy variables.** Abadi and Lamport [1] first proposed prophecy variables as a proof technique to establish refinement mappings between state machines. Jung et al. [18] later integrated it in a Hoare-style program logic. Prior work using prophecy variables is mostly focused on verification of protocols and small examples of data structures and algorithms, such as RDCSS, the Herlihy-Wing queue [18], and the atomic snapshot algorithm [24].

In this paper, we apply prophecy variables in a sophisticated transaction library. We use prophecy variables to make more elaborate predictions about the behavior of transactions, including what data they read and write, and we demonstrate that prophecy variables are useful for reasoning about transactions.

### Framework for specifying and verifying transactions.

Lesani et al. [25] develop a framework for verifying software transactional memory systems and apply it to the NOrec transactional memory algorithm [9]. NOrec uses a form of OCC, in which transactions check whether they have been invalidated by conflicting writes during commit time. As with 2PL, NOrec transaction’s linearization point occurs during commit, and hence does not appear to require prophecy variables in its proof.

vMVCC uses logically atomic triples to specify transactions, instead of classical serializability and linearizability definitions [15] that are based on trace equivalence (e.g., as

used by GoTxn). This makes it easier to verify clients of a transaction library by proving Hoare triples about code running inside of the transaction library. Prior work has similarly found it useful to introduce alternate specifications for transactions and serializability in the context of formal verification. The Push/Pull model [20] provides a set of primitive operations which can be used to describe a variety of transactions. Any system that can be decomposed into these operations is guaranteed to be serializable. C4 [26] is a framework that supports verifying transactional objects, that is, concurrent data structures that allow chaining multiple operations together in an atomic transaction. The framework supports composing transactional objects as components of a higher-level transactional object.

## 8 Conclusion

This paper presented vMVCC, the first MVCC-based transaction library with a machine-checked proof of correctness. A key challenge in verifying vMVCC lies in reasoning about the linearization of transactions under MVCC, where the linearization point occurs before the transaction body actually runs. vMVCC addressed this challenge by using prophecy variables to speculate whether upcoming transactions are going to commit, and what values they are going to write, thereby allowing vMVCC to state and prove a simple yet general specification for its top-level transaction interface using logical atomicity. vMVCC incorporates further low-level optimizations, such as using RDTSC to generate strictly increasing transaction IDs, with corresponding proofs of correctness, to achieve high performance. An evaluation demonstrated that, for a range of YCSB and TPC-C workloads, vMVCC’s throughput is 25–96% of the throughput of Silo, a state-of-the-art unverified system; that vMVCC benefits from MVCC to achieve good performance for long-running read-only transactions compared to two-phase locking; and that vMVCC’s low-level optimizations are important for achieving high performance. At the same time, vMVCC’s proof effort—13× as many lines of proof as lines of code—is on par with other verified concurrent systems.

## Acknowledgments

We are grateful to Anish Athalye, Sanjit Bhat, Alexandra Henzinger, Jon Howell, Derek Leung, the anonymous reviewers, and our shepherd, Adriana Szekeres, for their valuable feedback that improved this paper. We thank Tej Chajed for discussions on transactions and the Perennial framework. ## Abstract

Serverless computing has become a popular cloud computing paradigm. By default, when a serverless function fails, the serverless platform re-executes the function to tolerate the failure. However, such a retry-based approach requires functions to be idempotent, which means that functions should expose the same behavior regardless of retries. This requirement is challenging for developers, especially when functions are stateful. Failures may cause functions to repeatedly read and update shared states, potentially corrupting data consistency.

This paper presents Flux, the first toolkit that automatically verifies the idempotence of serverless applications. It proposes a new correctness definition, *idempotence consistency*, which stipulates that a serverless function's retry is transparent to users. To verify idempotence consistency, Flux defines a novel property, *idempotence simulation*, which decomposes the proof for a concurrent serverless application into the reasoning of individual functions. Furthermore, Flux extends existing verification techniques to realize automated reasoning, enabling Flux to identify idempotence-violating operations and fix them with existing log-based methods.

We demonstrate the efficacy of Flux with 27 representative serverless applications. Flux has successfully identified previously unknown issues in 12 applications. Developers have confirmed 8 issues. Compared to state-of-the-art systems (namely Beldi and Boki) that log every operation, Flux achieves up to 6× lower latency and 10× higher peak throughput, as it logs only the identified idempotence-violating ones.

## 1 Introduction

A serverless application typically comprises a collection of functions, which may be stateful. For example, they may communicate with each other through a shared database. Major serverless platforms generally support the stateful model, such as AWS [17], Microsoft [59], and Google [36]. Platforms generally employ a retry-based fault tolerance mechanism for stateful applications — they automatically retry a function in case of an unexpected error [18, 35, 57].

However, this mechanism mandates developers to write

*idempotent* applications that produce consistent results irrespective of the number of retries. In a sequential system that invokes functions sequentially, developers can reason about each function independently. However, a concurrent system can invoke functions simultaneously. Therefore, developers must consider all possible interleavings of concurrent functions, making it challenging to write idempotent applications.

This paper presents Flux, the first toolkit that automatically verifies the idempotence of concurrent serverless applications. Building such a toolkit posed several challenges. First, a formal idempotence definition for concurrent systems is desired but currently missing. Second, automated verification requires examining all possible interleavings of concurrent serverless functions with arbitrary failures, which is prohibitively expensive. Third, for non-idempotent applications, the toolkit should accurately identify the code that corrupts idempotence, enabling developers to fix the issues.

To overcome the first challenge, we propose a novel idempotence definition for concurrent systems — *idempotence consistency*. A serverless application is idempotence-consistent if, for any observable behavior of an execution with retries, there exists another execution without retries that can produce the same behavior. Achieving idempotence consistency makes clients unaware of retries during execution (Section 3). Unlike alternative idempotence conditions, such as exactly-once execution [45, 73], idempotence consistency offers greater flexibility. An idempotence-consistent application does not necessarily ensure exactly-once execution of *all* database operations.

To tackle the second challenge, we propose *idempotence simulation* to realize compositional proof, which enables proving the idempotence consistency of an application by verifying each function individually. For each function, Flux verifies that every possible execution with retries has a corresponding retry-free execution that can simulate it (Section 4). Existing work [66] can realize automated verification in a sequential system by comparing the execution results when retries happen with the results without retries. However, in a concurrent system, verification requires modeling the con-

current environment to account for the side effects of running multiple functions concurrently. Unfortunately, existing modeling approaches are not fully automated as they ask developers for hints, such as invariants [40, 60] and rely conditions [47, 53]. In contrast, Flux automates the generation of rely conditions and other hints. Additionally, Flux proposes *failure reduction* to avoid enumerating all failure cases.

To help fix idempotence issues, Flux can identify idempotence-violating operations whose re-execution corrupts idempotence consistency. Developers can use logs to ensure exactly-once execution semantics for these operations rather than all operations via existing mechanisms [45, 73].

We evaluate Flux on 27 representative serverless applications with 79 functions. These applications are from various sources, such as the AWS serverless application repository [3], a GitHub repository (10.9k stars) [9], popular serverless benchmarks [8, 10], and applications commonly used in papers about serverless computing [5, 6]. Flux successfully identifies previously unknown idempotence issues in 12 applications. Compared to state-of-the-art systems (namely Beldi [73] and Boki [45]) that log all operations, Flux achieves up to 6× lower latency and 10× higher peak throughput, as it logs only identified idempotence-violating operations.

Nevertheless, Flux still has several limitations. First, although we design it for stateful serverless functions, its assumption that states only include data in NoSQL databases restricts its applicability to storage systems of other types. We need to model the semantics of other storage systems carefully. Second, our verification method is sound but incomplete since Flux cannot handle certain serverless functions, such as functions having certain types of unbounded loops. Last, Flux currently supports only Java applications since we build Flux based on a symbolic execution engine for Java applications [61]. Despite these limitations, we believe that Flux takes an important step towards enabling verification for idempotence consistency of serverless functions.

## 2 Motivation and Our Approach

**Why Need Idempotence?** The concept of idempotence is crucial for applications that rely on retry-based methods to tolerate failures. Without idempotence, re-executing failed computations may result in unexpected side effects, causing severe correctness issues [42, 48, 64, 67]. With the emergence of serverless computing, idempotence has become a significant requirement for serverless applications. However, this requirement poses a challenge when serverless functions run concurrently and are stateful, placing a substantial burden on using serverless platforms [44, 69, 73].

We use an example in Figure 1 to illustrate why re-executing a non-idempotent application can cause issues. This is an example derived from a real-world e-commerce web application, Spree [68]. The *payment* function atomically checks the customer’s balance and deducts the price with a discount rate using a conditional update API (line 4). This

```

1 void payment(productId, userId, price) {
2   discount := get("Discount", productId);
3   total := price * discount;
4   success := cond_update("Balance", userId,
5                       inc(-total), gte(total));
6   receiptId := generateId(userId, productId,
7                       localtime());
8   if(success)
9     put("Receipt", receiptId, total);
10 }
11
12 void adaptDiscount(productId, percent) {
13   if(!isValid(percent))
14     return;
15   discount := 1.0 - percent/100.0;
16   put("Discount", productId, discount);
17 }

```

**Figure 1:** A simplified e-commerce serverless application with two functions. When *balance* in the database is greater than or equal to *total* (*gte(total)* is true), *cond\_update* (line 4) decreases *balance* by *total* (*inc(-total)*) and returns true. Otherwise, it returns false. The *generateId* function (line 6) returns a receipt identifier. The *isValid* function (line 13) returns true iff *percent* is between 0 and 100.

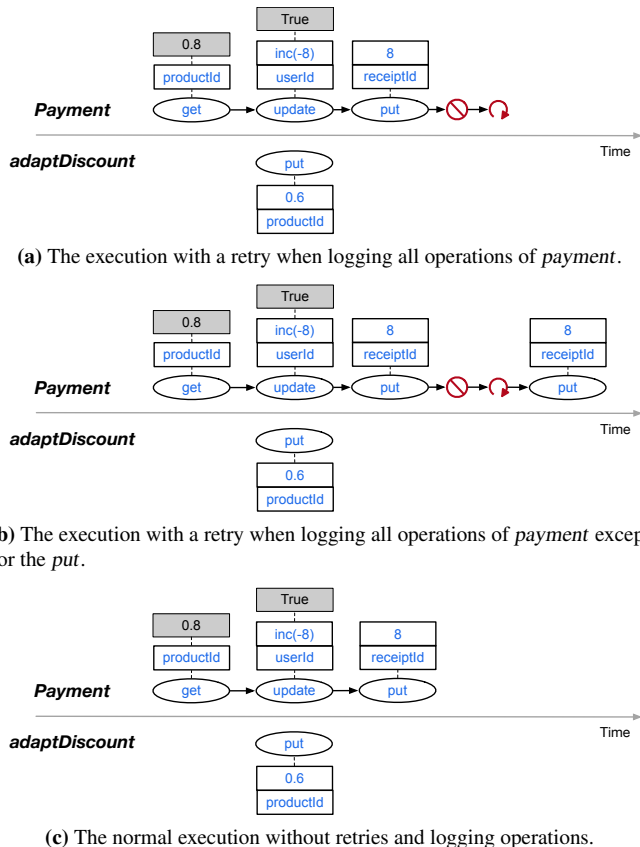

**Figure 2:** The concurrent execution of *payment* and *adaptDiscount* in Figure 1.

method needs to create a receipt accordingly (line 9). Meanwhile, the *adaptDiscount* function changes the discount for a specific product, which the seller typically invokes.

Suppose a failure occurs after *payment* deducts the price from the customer’s balance at line 4 but before it creates a new receipt at line 9. Consider the sequential execution of *payment* without concurrency. If the platform re-executes this function after the failure, the function will deduct the price twice from the customer’s balance. One possible solution to ensure idempotence is to log the conditional update operation. Additionally, it is necessary to log the execution of *generateId*, as *localTime* returns different values on retry. These logs can ensure that the function will not re-execute *update* (line 4) and *generateId* (line 6) on retry, which will always return the same value as the first execution. The solution is enough to provide idempotence under the sequential scenario.

However, the above solution does not work when *payment* runs concurrently with *adaptDiscount*. For example, suppose *adaptDiscount* changes the discount after *payment* fails at line 4 but before its re-execution. Then, *payment* would have deducted the price with the old discount but created a new receipt with the new discount, which poses an inconsistency between the customer’s balance and the corresponding receipt. Figure 2 shows the specific interleaving. Flux aims to automatically find the correct logging strategy under both

**Figure 3:** Three different concurrent executions of the functions in Figure 1. The legend is the same as that in Figure 2.

sequential and concurrent scenarios via verification.

**Idempotence Condition.** Some recent efforts have focused on the retry-based fault tolerance mechanism for serverless applications [44, 45, 69, 73]. Although they optimize runtimes or libraries of serverless computing, they overlook the definition of idempotence. For example, Beldi [73] and Boki [45], which contribute novel distributed logging mechanisms, equate idempotence with executing each database operation exactly once. They achieve this by logging every operation to ensure that functions execute each operation only once. However, repeating some operations does not compromise idempotence. For instance, as shown in Figure 3b, logging all operations except for *put* on *receipt* can still ensure idempotence, as *payment* will always write the same value into the receipt on retry as it did in its first execution. However, as illustrated in Figure 3a, Beldi and Boki need to log every operation, which is over-restricted and incurs unnecessary performance costs. This logging strategy misses the opportunity to maximize performance while ensuring idempotence.

When defining idempotence for serverless applications, we should consider what kind of execution with retries is acceptable. The intuitive requirement is that clients should be unaware of retries. This requirement enables us to define acceptable execution with retries in terms of normal execution

without retries. For instance, the executions with a retry in Figure 3b and Figure 3a are both acceptable because they are equivalent to the normal execution in Figure 3c. However, the execution in Figure 2 is unacceptable because we cannot find an equivalent normal execution for it. The normal concurrent execution of *payment* with *adaptDiscount* will never deduct “8” from the balance but record “6” in the receipt. Therefore, determining whether an application is idempotent requires checking whether any possible execution with retries is acceptable.

**Verification of Idempotence.** Several frameworks for verifying storage systems also prove the idempotence of recovery functions [23, 24, 27, 28, 66]. Specifically, the resulting state of the recovery should be consistent even if the system fails during recovery and retries the recovery function many times. The work based on Crash Hoare Logic [23, 24, 27, 28] verifies idempotence by proving that the crash condition of the recovery function always implies its precondition. Developers need to specify both pre and crash conditions manually. The push-button verification approach [66] frees developers from such a proof burden by automatically verifying recovery functions with SMT solvers. However, all such methods assume that the recovery procedure is sequential. Verifying the idempotence of concurrent functions is still missing.

To prove the idempotence of concurrent functions, we use compositional proof techniques. The fundamental idea is to break down the verification of an application’s idempotence into verifying each function individually. However, the main challenge is defining the property that needs verification for each function, which can facilitate compositional proof. Besides, modeling the behavior of other concurrent function instances also poses a challenge. Existing methods typically use invariants [60] or rely conditions [47, 53] to model the concurrent environment. Invariants describe the properties of the system state that persist during concurrent execution, while rely conditions depict how other concurrent functions can change the system state. Unfortunately, developers must explicitly specify all of them. We need to infer invariants or rely conditions automatically for automated verification.

**Our Approach.** To define idempotence, we propose a new consistency model called *idempotence consistency* (Section 3). An execution with retries is acceptable if there exists another normal execution without retries that can exhibit the same observable behavior (e.g., Figure 3b). An application is idempotence-consistent if all possible executions with retries are acceptable. To verify idempotence consistency, we propose idempotence simulation (Section 4), which extends traditional forward simulation [55] and enables compositional proof for idempotence consistency. Specifically, the verification process tries to find a mapping from each step during the execution with retries to  $n$  steps during the execution without retries such that the single step and the  $n$  steps exhibit the same observable behavior.

Figure 4: The architecture of Flux.

```

1 bool retry := random();
2 if(retry)
3 {
4   reset_local_state();
5   goto BEGIN;
6 }

```

Figure 5: The pseudocode simulating random failures and retries of a function  $f$ . BEGIN is a label at the beginning of  $f$ .

Figure 4 shows the components of Flux. First, developers provide the source code of a serverless application for Flux. Then, Flux checks each function individually to reason about idempotence simulation (Section 5). If all functions pass verification, the application is idempotence-consistent. If not, advisor identifies operations that corrupt idempotence consistency based on the results of the verifier (Section 6). Developers can use existing logging mechanisms to ensure exactly-once semantics of such operations. Compared with logging all operations pessimistically, Flux guarantees idempotence while reducing unnecessary protection overhead.

### 3 Idempotence Consistency

Idempotence consistency requires that each execution with retries should have the same observable behavior as another execution without retries. To formally define idempotence consistency, Flux uses an automaton to model the concurrent execution of functions. An automaton includes system states and a set of steps. Each step  $(S, e, S')$  represents a state transition from state  $S$  to  $S'$ , which triggers an event  $e$  observable to clients (e.g., a function invocation). Note that some steps may not produce events because they are not observable to clients.

**System State.** The system state consists of the shared state and the local state of each function instance. In scenarios where functions use a NoSQL database, the shared state  $D$  constitutes a collection of key-value pairs stored persistently in databases. Given an instance executing a function, its local state includes the invocation arguments, the local variables, the return value, and the next program statement to execute. The start system state only contains the shared state because the platform has not invoked any functions at the beginning.

**Event.** An automaton may produce an event during each state transition, which is observable to clients. In the context of serverless functions, Flux considers three types of events: function invocation events, function response events, and third-party service events. When creating a new instance  $f_{id}(args)$  to run the serverless function  $f$ , the automaton pro-

duces an invocation event  $(f_{id}, inv(args))$ . When the instance  $f_{id}$  finishes its execution and successfully responds to clients with the value  $v$ , it produces a response event  $(f_{id}, resp(), v)$ . When the serverless function requests a third-party service  $s$ , it produces a third-party service event  $(id_s, args, ret)$ . The  $args$  and  $ret$  represent parameters and return values, respectively. An automaton produces such events when a service has side effects, which developers must explicitly specify.

**Client-Observable Behavior.** The client-observable behavior of an execution includes all events generated during the execution and the final shared state observable by clients. The events include function invocation, response, and third-party service events. We use  $\langle H, D \rangle$  to denote the client-observable behavior, where  $H$  represents the event sequence generated by the automaton throughout the execution, and  $D$  is the shared state reached after the execution.

Given a function set  $F$ , to model the execution of functions in  $F$  under failure, we rely on the following failure model and star operator.

**Failure Model.** Flux assumes that failure can occur at any time during the execution of an instance. The failure of individual instances does not affect the persistent shared state or individual local states of other instances. Furthermore, when the platform retries an instance, it retains the same identifier and arguments, generating no invocation events.

**Star Operator.** Given a function  $f$ ,  $f^*$  denotes a function synthesized by inserting a code fragment after every statement. When random failures and retries occur during a function's execution, the platform will re-initialize the local state and re-execute the function from the first statement (without retry events). The code fragment (Figure 5) simulates random failures by resetting the local state and simulates retries by jumping to the beginning of  $f$ .  $F^*$  is a function set synthesized by applying the star operator to each function in  $F$ .

Based on the above concepts, Flux is able to define idempotence consistency as the relationship between two automata. It means that  $F$  allows all possible client-observable behaviors for the automaton of  $F^*$ .

**Definition 1 (Idempotence Consistency)** For any start system state  $S$  and any step sequence of the automaton executing  $F^*$  from  $S$ , if the step sequence results in the client-observable behavior  $\langle H, D \rangle$ , then there always exists another step sequence of the automaton executing  $F$  from  $S$  such that it also results in  $\langle H, D \rangle$ .

### 4 Proof Strategy

Using compositional proof techniques [52–54, 76], Flux automatically verifies the idempotence consistency of serverless applications. The fundamental idea is to simplify the proof of a concurrent program by reasoning about each of its components separately. Several existing approaches utilize compositional proof to verify the correctness of concurrent programs, such as RGSim [53], AtomFS [76], and Armada [54].

However, the primary difference between Flux and existing approaches is that existing approaches require human experts to aid the proof, such as manually specifying the correctness definition or modeling program behavior under concurrency. Flux, on the other hand, performs entirely automated verification without human intervention.

**Preliminary.** Flux adopts compositional proof techniques, verifying a concurrent program by checking each component individually rather than enumerating all possible interleavings. For instance, when verifying a concurrent stack implementation [52], programmers only need to separately consider the correctness of *push* and *pop* functions under concurrency. To perform compositional proof, programmers first need to manually specify each component’s expected behavior (e.g., specifications for *push* and *pop* functions). Second, programmers should carefully craft the pre- and post-conditions of each statement, which are propositions describing the system state before and after executing the statement. The verification goal is that when the start system state satisfies the pre-condition of the first statement, the system state after executing the component must satisfy the post-condition of the last statement under concurrency. Note that other concurrent threads can simultaneously modify the system state. Therefore, to consider all possible execution results, pre- and post-conditions must cover all possible system states before and after executing a statement. Developers need to prove that the pre- and post-conditions are stable under concurrency, which means they always hold irrespective of how other concurrent functions simultaneously modify the system state. Finally, to verify the stability of pre- and post-conditions, programmers must manually define a rely condition  $R$ , which describes the state transition made by other concurrent threads.  $R$  is a relation of system states. Each  $(S, S')$  in  $R$  indicates that other concurrent threads might change the current state  $S$  to  $S'$ . In the example of the stack, the rely condition specifies the impact of concurrent *push* and *pop* operations on the global linked list that represents the stack. We can define it as  $\{(\ell, \ell') \mid ((\exists v. \ell' = PUSH(\ell, v)) \vee (\ell' = POP(\ell)))\}$ .  $\ell$  represents the state of the linked list, while  $\ell'$  is the new state after applying the operations of  $PUSH(\ell, v)$  or  $POP(\ell)$ .

## 4.1 Idempotence Simulation

Instead of manually crafting the specification, Flux introduces a new correctness definition — *idempotence simulation*. A serverless function  $f$  satisfies idempotence simulation if there exists a forward simulation [55] between  $f^*$  and  $f$  under the same rely condition  $R$ . The forward simulation means that from the same start shared state with the same invocation argument, each step of executing  $f^*$  has zero or multiple corresponding steps of executing  $f$  that can simulate it. If a step  $s$  of  $f^*$  changes the shared state  $D$  to  $D'$  and produces an event  $e$ , a step sequence  $s_1 \dots s_i$  of  $f$  can simulate it if and only if carrying out these steps sequentially from  $D$  also reaches  $D'$  and produces  $e$ . Note that idempotence simulation

does not only consider the shared state reached by executing the current instance but also  $D$  reached by executing other concurrent instances according to  $R$ . Flux differs from previous verification frameworks [23, 24, 27, 28, 66] that focus on the idempotence of sequential functions by considering intermediate states. This difference is significant because, in a concurrent setting, these intermediate states may be externally observable.

Given a function set  $F$ , Flux decomposes the proof of idempotence consistency into reasoning about the idempotence simulation of every function  $f$  in  $F$  based on the following theorem.  $f^* \sqsubseteq_R f$  means that for any start shared state and invocation argument, there exists a forward simulation between  $f^*$  and  $f$  under the same rely condition  $R$ .

**Theorem 1** Given a function set  $F$ , if each function  $f$  in  $F$  satisfies idempotence simulation, then  $F$  satisfies idempotence consistency, denoted as the predicate  $idem(F)$ .

$$(\forall f \in F. \exists R. f^* \sqsubseteq_R f) \rightarrow idem(F).$$

Appendix A presents the formal proof of Theorem 1. We only illustrate its intuition as follows. Existing work [53] based on rely conditions has proposed methods to prove that the specification can exhibit all possible observable behaviors of the implementation. When proving idempotence consistency, we observe that we can treat  $F^*$  as the implementation and  $F$  as its specification. Then we can utilize the compositional proof technique in the existing work to verify idempotence consistency. An important fact is that the steps of implementation consist of the steps from each component, while the specification of the implementation consists of the specification of each component. Therefore, the existing work first proves that for each component and its specification, each step of the component has zero or multiple steps of the specification that can simulate it under the rely condition  $R$ . Then the verifier can compose the proof for each component to imply that each step of the implementation always exhibits the observable behavior allowed by its specification. In the scenario of idempotence consistency, we treat each serverless function  $f^*$  as the component. Then we can treat  $f$  as the specification for  $f^*$ . Based on the observation, Flux defines idempotence simulation as the forward simulation between  $f^*$  and  $f$ , which can imply idempotence consistency.

## 4.2 Automated Concurrency Reasoning

To verify the program with compositional proof, existing approaches [52–54, 76] require programmers to manually define the pre- and post-condition of each statement, as well as the rely condition for concurrent state transitions. The cause of the need for manual effort is that different definitions of correctness usually require different pre-, post-, and rely conditions. Programmers need to deeply understand the definition of correctness to find and specify the appropriate conditions.

However, idempotence consistency presents a unified correctness definition for stateful serverless functions, establish-

ing an opportunity to generate pre-, post- and rely conditions automatically. These conditions capture the potential concurrent accesses to the shared database state and describe the state transition on each access. Flux accomplishes this with symbolic execution. To reduce the complexity of analysis, Flux models the semantics of each API as a sequence of atomic read operations or atomic write operations on a set of key-value pairs, as most serverless platforms use NoSQL databases with key-value interfaces [16, 34, 58]. Then, it can symbolically execute all functions and check the parameters of issued database operations to analyze the data in the shared state that functions can access. Section 5 will depict more details.

Flux identifies three types of rely conditions.

- **Read-only:** all concurrent accesses to a specific key-value pair are read operations. Flux formalizes this type of rely condition as  $(D[k] = v, D[k] = v)$ , which means before and after the access, the value ( $v$ ) indexed by  $k$  in the database keeps unchanged.
- **Arbitrary update:** functions could update the data in the database to arbitrary values. Flux formalizes this type of rely condition as  $(\exists v_1. D[k] = v_1, \exists v_2. D[k] = v_2)$ .
- **Constant update:** functions will update the specific key-value pair to only a constant value. Flux formalizes this type of rely condition as  $(\exists v_1. D[k] = v_1, D[k] = c)$ , where  $c$  is the constant value.

Flux constructs pre- and post-conditions in the Floyd-Hoare style (“ $\{P\}C\{Q\}$ ”).  $C$  is the next program statement to execute.  $P$  is the pre-condition before executing  $C$ , while  $Q$  is the post-condition after the execution. If  $C$  is the first statement of the function, then  $P$  is *true*. Flux adopts the following rules to automatically generate the pre- and post-conditions according to the semantics of  $C$  and different rely conditions:

- $\{P\}put(k,c)\{P \wedge (D[k]=c)\}$ : if the rely condition specifies that all concurrent updates are constant updates with a constant value of  $c$ , then  $D[k]$  will always be  $c$  after executing  $put(k,c)$ .
- $\{P\}v := get(k)\{P \wedge (D[k]=v)\}$ : if the rely condition specifies that all concurrent accesses to  $k$  are read operations, then the value of  $D[k]$  should be exactly  $v$  which is the return value of the  $get$  operation in  $C$ .
- $\{P\}if(P_1(v))\{P \wedge P_1(D[k])\}$ : suppose  $C$  is a branch statement based on  $P_1(v)$ , and  $v$  is the value read from the database, indexed by  $k$ . The post-condition is  $P \wedge P_1(D[k])$  if  $D[k]$  satisfies one of the following requirements according to rely condition: 1)  $D[k]$  is read-only; 2) functions can update  $D[k]$  to a constant value  $c$  such that  $P_1(c)$  is true.
- $\{P\}C\{P\}$ : in the other cases, the post-condition is the same as the pre-condition, which is stable.

### 4.3 Unbounded Loop

Another challenge in automated verification involves dealing with functions that contain unbounded loops. A loop is unbounded when its maximum number of iterations is not constant. Existing approaches require that programmers manually specify loop invariants to handle unbounded loops. However, previous works have shown that finding a proper loop invariant is challenging [19, 33]. Flux reasons about unbounded loops without requiring loop invariants. The following paragraphs provide the details in two cases:

Case 1. The operations in the unbounded loop do not modify the shared state in the database. For this case, Flux treats the entire unbounded loop as an uninterpreted function [12], which is a symbolic function and may return arbitrary values. Specifically, Flux derives a new function  $g$  from the original function  $f$  by replacing the unbounded loop with an uninterpreted function. Then, Flux directly reasons the idempotence simulation for  $g$  instead of  $f$ .

Case 2. The operations in the unbounded loop may modify the shared state. Flux addresses this type of unbounded loop with Theorem 2, which requires that the parameters of the write operations in such unbounded loops must remain the same between normal execution and retry. For convenience, Flux represents a function with an unbounded loop as  $\{C_1; L; C_2\}$ , where  $L$  is the unbounded loop,  $C_1$  denotes all code before the loop, and  $C_2$  denotes all code after the loop.  $B_L$  denotes the loop body of  $L$ . We present the theorem as follows. Appendix C provides the formal proof and an example of applying the theorem.

**Theorem 2** Given a function  $f$  with the unbounded loop in case 2,  $f$  satisfies idempotence simulation if the number of iterations of the loop  $L$  remains unchanged on retry, and  $C_1$ ,  $C_2$  and  $B_L$  can satisfy the following requirements: 1) They all satisfy idempotence simulation; 2) Their inputs do not change on retry; 3) They will not affect the shared state on retry once the function has successfully executed them.

### 4.4 Failure Reduction

The platform may re-execute a function an arbitrary number of times. It is impossible to verify idempotence simulation if we enumerate all possible failure cases, which yields infinite possible executions. Instead, we prove that it is sufficient to verify a function only by examining the executions satisfying two conditions, as stated in the following theorem.

**Theorem 3** For any function set  $F$ , if each function  $f \in F$  satisfies idempotence simulation under the following two conditions: 1) failure happens only after statements modifying the shared state, and 2) failure occurs at most once, then each function  $f \in F$  also satisfies idempotence simulation under arbitrary failure and retries.

This result (i.e., failure reduction) mitigates the challenge of proving idempotence simulation with infinite failure. It

```

1 bool retry := random();
2 if(retry && hasretried < LIMIT)
3 {
4   reset_local_state();
5   hasretried++;
6   goto BEGIN;
7 }

```

**Figure 6:** The pseudocode simulating random failures and retries of  $f^n$ .

transforms the problem of examining executions with infinite failure into the problem of reasoning about executions with finite failure. Moreover, it maintains the soundness of the verification, signifying that Flux does not overlook any idempotence issues.

The intuition behind the first condition is that a statement that does not modify the shared state lacks side effects if a failure occurs after it. Because the failure effectively renders the result of the statement invisible to clients and the following code. Therefore, when the failure occurs, it appears as if the function instance never executed the statement.

The second condition is correct and ensures soundness. We formalize its correctness based on the following concepts. Given a function  $f$ ,  $f^n$  denotes the function whose number of re-execution is not more than  $n$  times ( $n \geq 0$ ). We can construct  $f^n$  by inserting the code fragment in Figure 6 after every statement of  $f$ . The global variable *hasretried* is initially zero, which indicates the number of retries that have occurred. We can simulate  $n$  retries for  $f^n$  by setting the constant *LIMIT* to  $n$ . The correctness of the second condition follows from the following theorem. Appendix B presents the formal proof.

**Theorem 4** Given a function  $f$  in  $F$ , if the execution of  $f$  can simulate  $f^1$  under concurrency, then for any  $n \geq 1$ , the execution of  $f$  can simulate  $f^n$  under concurrency.

$$(\exists R. f^1 \sqsubseteq_R f) \rightarrow (\forall n \geq 1. \exists R. f^n \sqsubseteq_R f).$$

Compared to Yggdrasil [66], which assumes that failure happens only once when verifying the idempotence of sequential recovery procedures, Flux targets a different setting — concurrent vs. sequential. Yggdrasil proves that if the execution with one retry produces the same system state and return value as the retry-free execution, then the execution with arbitrary times of retries also produces the same system state and return value. This approach ignores intermediate system states. It only considers the system state and return value when the function finishes because intermediate system states for sequential functions are not observable to clients. However, under concurrency, we should consider intermediate system states. We need to define and prove failure reduction based on simulation relation  $\sqsubseteq_R$ .

## 5 Implementation

Flux builds a verifier to automatically verify idempotence simulation for each function based on failure reduction. It models the execution of a function with symbolic traces generated by

symbolic execution. Each trace represents a feasible execution path and records the path condition, events, and database operations. The verifier can only handle Java applications because Flux builds the verifier by extending a symbolic execution engine for Java [61]. However, our definition and verification method for idempotence consistency is not specific to any particular programming language.

When functions invoke third-party services, Flux mandates that developers explicitly indicate whether these services have side effects. In particular, developers provide a vector of service names and a corresponding bit vector, where each bit indicates whether the corresponding service has side effects. For instance, developers should annotate the *random* function with a “0” since it has no side effects, whereas developers should annotate the *print* function with a “1”.

Next, Flux handles unbounded loops by first converting functions into abstract syntax trees (ASTs) and identifying unbounded loops within them. Then, Flux replaces each unbounded loop that does not modify the shared state with an uninterpreted function. It further identifies all variables modified within the loop and assigns the return value of the uninterpreted function to these variables. For each unbounded loop that modifies the shared state, Flux partitions the code into three parts via ASTs and checks them (Section 4.3).

---

### Algorithm 1: Workflow of the Verifier

---

```

1 Input: A function set  $F$ , a function  $f \in F$ , a string vector
   services of the names of services, and a bit vector bv
   indicating whether each service has side effects.
2 Output: The verification result of  $f$ .
3 Verify( $F$ ,  $f$ , services, bv):
4    $R := \text{GenRelyCond}(F)$ 
5    $T := \text{TracesNoRetry}(f, R, \textit{services}, \textit{bv})$ 
6    $T_r := \text{TracesWithRetry}(f, R, \textit{services}, \textit{bv})$ 
7   foreach  $\langle t_r, pc_r \rangle \in T_r$ :
8     if  $\neg \text{HasSimulatedTrace}(\langle t_r, pc_r \rangle, T)$  then
9       return false
10  return true
11  $\text{HasSimulatedTrace}(\langle t_r, pc_r \rangle, \textit{Traces})$ :
12  foreach  $\langle t, pc \rangle \in \textit{Traces}$ :
13    if  $\text{CheckSimulation}(t_r, pc_r, t, pc)$  then
14      return true
15  return false

```

---

Algorithm 1 shows the verification algorithm. The goal is to prove the simulation relation between  $f^1$  defined in Section 4.4 and  $f$ . First, *GenRelyCond* generates the rely condition  $R$  by symbolically executing all functions in  $F$ . Based on  $R$ , *TracesNoRetry* generates all possible symbolic traces  $T$  for  $f$  via another symbolic execution. *TracesWithRetry* returns all possible symbolic traces  $T_r$  for  $f^1$ . Then, for every trace  $t_r \in T_r$ , *HasSimulatedTrace* checks whether there exists a trace in  $T$  that can simulate  $t_r$ . The initial path condition of symbolic execution is true, which does not contain any constraints on database states and function arguments. Therefore, if Flux can find a retry-free trace for each trace  $t_r$ , the retry-free trace is feasible, and the idempotence simulation holds for any possible database states and arguments.

## 5.1 Generating Symbolic Traces

Each trace is an ordered list with a path condition. Every list element includes the following fields: step id, event, database operation, and the post-condition after the step. The step id identifies the atomic step causing state transition. The event produced by the step has a type, some arguments, and a return value, which are symbolic expressions or constants. Flux considers three types of events for the execution of a serverless function: function invocation, function response, and third-party services with side effects. Developers specify whether a third-party service has side effects via the bit vector  $bv$  in Algorithm 1 (line 3). The fields of the operation include the type ( $optype$ ), the argument ( $oparg$ ), and the result of the operation ( $opret$ ), where  $oparg$  and  $opret$  are symbolic expressions or constants. As described in Section 4.2, Flux models the semantics of each API as a sequence of read or write operations. Post-conditions can help model the return value of read operations. For example,  $D[k]=c$  implies that the results of the subsequent read operations on  $k$  must be  $c$ . Flux adds these propositions about return values of read operations to the path condition.

$GenRelyCond(F)$  symbolically executes all functions in  $F$  and returns the rely condition  $R$ . As illustrated in Section 4.2, Flux identifies three kinds of data. If an operation modifies the data indexed by a symbolic key, Flux assumes that the operation can change arbitrary data in the database. If an operation writes a symbolic value into the data, Flux uses the path condition to infer whether it is a constant or an arbitrary value. Users can also annotate that some variables in a serverless function are unique. That means other concurrent instances cannot access the data indexed by these unique variables. For example, developers can annotate  $receiptId$  in Figure 1 to be unique to indicate that other concurrent instances cannot write the receipt created by the current instance.

## 5.2 Checking Idempotence Simulation

---

### Algorithm 2: Checking Idempotence Simulation

---

```

1  $CheckSimulation(t_r, pc_r, t, pc)$ :
2    $premise := pc_r \wedge pc$ 
3    $pass := CheckWithPremise(t_r, t, premise)$ 
4   return  $pass$ 
5
6  $CheckWithPremise(t_r, t, premise)$ :
7   if  $t_r.empty()$  then
8     return true
9    $step := t_r.subtrace(0, 1)$ 
10  foreach  $n$  from 0 to  $t.size() - 1$ :
11     $nsteps := t.subtrace(0, n)$ 
12     $pass := CheckStep(step, nsteps, premise)$ 
13    if  $!pass$  then
14      continue
15     $next\_premise := UpdatePremise(step, nsteps, premise)$ 
16     $next\_t_r := t_r.subtrace(1, t_r.size())$ 
17     $next\_t := t.subtrace(n, t.size())$ 
18     $pass := CheckWithPremise(next\_t_r, next\_t, next\_premise)$ 
19    if  $pass$  then
20      return true
21  return false

```

---

$CheckSimulation$  in Algorithm 2 determines if two traces,

$t_r$  from  $f^1$  and  $t$  from  $f$ , satisfy the idempotence simulation. Their associated path conditions are  $pc_r$  and  $pc$ . Specifically,  $CheckSimulation$  tries to construct a mapping from every step in  $t_r$  to  $n$  ( $n \geq 0$ ) steps in  $t$  such that the  $n$  steps can simulate the single step. The existence of such a step mapping can imply idempotence simulation.

$CheckWithPremise$  recursively checks all possible step mappings. It first uses  $CheckStep$  (Line 12) to check if the  $n$  steps in  $t$  ( $nsteps$ ) can simulate the first step in  $t_r$  ( $step$ ). If the check fails, it increases  $n$  to enumerate other possible mappings. Otherwise, it continues to check the subsequent steps in  $t_r$  in a recursive way (Line 18). To reason the simulation between  $step$  and  $nsteps$ ,  $CheckStep$  requires that the write operations in  $step$  and  $nsteps$  result in the same database state. It means that every write operation in  $nsteps$  should have the same parameters as the write operation in  $step$  under the proposition of  $premise$ , where  $premise$  is the conjunction of the path conditions associated with  $t$  and  $t_r$ . Specifically, two symbolic parameters,  $p_1$  and  $p_2$ , are equivalent under  $premise$  if  $premise \rightarrow (p_1 = p_2)$  is true. Flux leverages an SMT solver to check this first-order logic formula. If  $step$  does not record any write operations,  $nsteps$  should also contain no write operations. Besides, when  $step$  has an event, such as invoking a third-party service with side effects and function response, Flux requires that  $nsteps$  contains the same event. After the check succeeds, Flux updates  $premise$  with  $UpdatePremise$ , which maintains the relations among symbolic variables.  $UpdatePremise$  has three parameters, including  $step$ ,  $nsteps$ , and  $premise$ . If operations in  $step$  and  $nsteps$  read the data indexed by the same key in databases,  $UpdatePremise$  adds a proposition to  $premise$  that these operations return the same value. Otherwise, it does nothing.

Algorithm 2 enumerates all possible mappings, which introduces heavy verification burdens. Flux proposes a heuristic algorithm based on the observation that  $f^1$  and  $f$  are almost the same, except that the platform may re-execute  $f^1$ . Thus, for each step  $s_i^1$  of  $f^1$  before the retry, Flux tries to map it to the  $i$ th step  $s_i$  of  $f$ . For each step  $s_j^1$  of  $f^1$  after the retry, if  $f^1$  has executed  $s_j^1$  before the retry, then Flux maps it to a nop step, a step that does nothing. Otherwise, it maps  $s_j^1$  to a step  $s_k$  in  $f$  such that  $s_k$  can simulate  $s_j^1$ . This only constructs and checks one mapping instead of enumerating all possible mappings, which may miss the correct mapping. If the constructed mapping does not work, Flux will randomly sample other mappings to reduce false positives. However, the method causes no false positives in the evaluation.

**Example.** After logging all operations except for the  $put$  operation, the  $payment$  function will have no idempotence issues. We also need to log  $generateId$ , which always returns the same value on retry. First,  $GenRelyCond(F)$  returns a rely condition that other concurrent function instances can arbitrarily change  $balance$  and  $discount$  in the database because

**Figure 7:** The example of verifying *payment* in Figure 1 when logging all database operations except for *put* (line 9). Variables, such as *discount1*, have symbolic values.  $PC(t)$  is the path condition of the trace  $t$ .

the function writes them by symbolic values. Second, Figure 7 shows that  $t_r$  is a symbolic trace produced by retrying *payment*<sup>1</sup> after it generates *receiptId*, while  $t$  is a symbolic trace produced without retries. Since Flux models *update* (line 4) as a read and a write operation executed atomically, there is no arrow between them. The post-conditions in traces are true. Third, Algorithm 2 finds a proper mapping from every step in  $t_r$  to  $n$  steps in  $t$  and returns true. According to the heuristic algorithm in the previous paragraph, there are three steps in  $t_r$  before the retry. Flux maps each of them to one step in  $t$ , accordingly. For instance, the first step in  $t_r$  corresponds in  $t$ , accordingly. The last step in  $t_r$  corresponds to the *put* (line 9) executed in the first execution of *payment*<sup>1</sup>. Thus, Flux maps this step to a nop step. The first step in  $t$  can simulate the first step in  $t_r$  because they do not modify the database state and produce no events. Since the start database states of the two steps are the same, the return values of their read operations are the same, which means  $discount1 = discount2$ . The second step in  $t$  can simulate the second step in  $t_r$  because they change *balance* to the same value with no events. Due to a similar reason, the third step in  $t$  can simulate the third step in  $t_r$ . Because of logging, *get* on retry in  $t_r$  still returns *discount2* in the first execution, while *update* on retry in  $t_r$  does nothing and returns true. The *generateId* function also returns the same identifier. Flux can use a nop step to simulate the last step in  $t_r$  because it is a useless write that does not change the data in the receipt. Since the function has no return value, we omit the function response event. Other traces of *payment* under retry can also pass the verification. Therefore, *payment* with these logs has no idempotence issues.

**Soundness and Completeness.** The verifier is sound and incomplete. Soundness means the verifier will not overlook any idempotence issues, which the theorems in Section 4 can imply. Incompleteness means some idempotence-consistent

```

1 void unsupportedLoop(key, n) {
2   value := get("Data", key);
3   while(value % n != 0) {
4     put("Data", key, value + 1);
5     value := get("Data", key);
6   }
7 }

```

**Figure 8:** An example of an unbounded loop unsupported by Flux.

applications cannot pass the verification. Note that although the verifier is incomplete, it can still ensure idempotence consistency and reduce the performance overhead of logging. The verifier is incomplete and will introduce false positives in the following cases. First, an application is idempotence-consistent, but individual functions do not satisfy idempotence simulation. For example, an application incorporates two functions,  $f_1$  and  $f_2$ . They blindly write different values to the same record  $R_a$ , while no functions will read it. Consider the interleaving of  $f_1.write(R_a, 1) \rightarrow f_2.write(R_a, 0) \rightarrow f_1.retry() \rightarrow f_1.write(R_a, 1)$ . In this example, functions flip  $R_a$ 's value twice due to the retry. Nevertheless, since no functions read the record  $R_a$ , clients will not observe that two flips occur. Idempotence consistency still holds. However, Flux will consider these two writes as non-idempotent because they fail to follow idempotence simulation and will log each of them; Second, an application contains unbounded loops with write operations such that the parameters of issued write operations can be different between normal execution and retry. For example, the unbounded loop in Figure 8 uses the data read from the database to be the parameters of write operations and the loop condition. As a result, the parameters of write operations and the number of loop iterations may change on retry, which does not satisfy the requirements of Theorem 2. Section 4.3 depicts two specific types of unbounded loops that can be handled by Flux. Third, when examining the idempotence simulation of a function  $f$ , Flux constructs a step mapping using a heuristic approach instead of enumerating all potential mappings. The heuristic runs under the assumption that if  $f$  fails before a specific operation  $op$ ,  $f$  will execute  $op$  on retry. When the assumption does not hold, the heuristic may not work, and Flux may miss correct mappings. Last, Flux does not generate all possible rely, pre- and post-conditions, which may impede the verification capability of idempotence simulation.

## 6 Advisor

Advisor identifies idempotence-violating operations based on a brute-force algorithm and a heuristic algorithm. The brute-force algorithm first enumerates all possible operation sets. Second, for every set, it invokes the verifier to prove the function after ensuring exactly-once execution of each operation in the set via logs. Flux models the exactly-once execution of an operation by adjusting the generated traces rather than modifying functions. Specifically, it deletes each trace element that records a retried write operation in the set.

**Table 1:** An example of executing the heuristic algorithm of advisor.

get	0	1	1
update	1	0	1
put	1	1	0
Verify( $F, f$ )	False	False	True

Furthermore, it appends a formula to the path condition for each retried read operation in the set, indicating that the retried operation returns the same result as the initial execution. Third, among all operation sets that enable the function to pass the verification, Flux selects the set that incurs the least performance cost. Flux estimates the performance cost via the evaluation results derived from the adopted logging mechanism. This algorithm enumerates  $O(2^n)$  possible operation sets, where  $n$  is the number of operations.

To reduce the complexity, we propose a heuristic algorithm checking only  $O(n)$  sets. Initially, Flux logs all operations in the function. Then Flux gradually removes the logs of operations one by one. If the function can pass the verification after removing a log, advisor will permanently remove the log. Otherwise, the operation is idempotence-violating, and advisor preserves the log. Table 1 shows how to apply the heuristic to *payment* in Figure 1. Assume that advisor has logged *generateId*. “0” denotes that advisor logs the operation. “1” denotes that advisor does not log the operation. Advisor first removes the log of *get* ( $get=0$ ) but  $Verify(F, f)$  returns *false*. Therefore, advisor preserves the log for idempotence. Due to the same reason, advisor does not remove the log of *update*. Last,  $Verify(F, f)$  indicates removing the log of *put* does not break the idempotence. Therefore, advisor does not log it.

The incompleteness of the verifier may result in advisor being unable to detect certain redundant logs. Nonetheless, Flux can still diminish logging overhead for functions while ensuring idempotence consistency. Specifically, for an unbounded loop that the verifier cannot handle, advisor logs all operations before and within the loop except for read operations on read-only data. Then advisor directly addresses the code after the unbounded loop.

## 7 Evaluation

We aim to answer the following questions: 1) How effective is the verifier? 2) How long does it take for advisor to identify idempotence-violating operations? 3) How much performance benefit does Flux bring?

### 7.1 Experimental Setup

We evaluate the execution time of the verifier and advisor on a desktop running Ubuntu 18.04, which has an Intel Core i7-8700 processor and 15GB DRAM. Additionally, we evaluate the performance of serverless applications on multiple AWS servers.

We compare our system with Beldi [73] and Boki [45],

which logs all operations. Although some other systems [44, 69] also guarantee idempotence for serverless applications, we focus on comparing with Beldi and Boki because they are state-of-the-art. It is worth noting that while Flux aims to provide idempotence consistency, Beldi and Boki go further by ensuring transactional properties as well. To ensure fairness in our comparison, we do not utilize the transaction mechanisms provided by Beldi and Boki, as our focus is on idempotence assurance alone. Therefore, the advantage that Flux may have over Beldi and Boki in terms of performance does not result from its lack of guarantee for transactional properties.

We store the data of applications in DynamoDB [15]. We run Beldi on AWS Lambda [16] with 1GB DRAM for each instance and collect performance results via AWS CloudWatch. Boki provides its own serverless platform. We deploy Boki according to the evaluation environment in its paper [45]. Boki’s serverless platform can report the latencies of functions but cannot report their throughputs precisely.

We use wrk2 [1] as the load generator, which runs on an m5.2xlarge instance for Beldi and a c5d.xlarge instance for Boki. We adapt representative applications from the AWS serverless applications repository [3], a GitHub repository (10.9k stars) [9], popular benchmarks [8, 10, 29], and applications commonly used in papers about serverless computing [5, 6]. They have covered diverse real-world scenarios of serverless computing, such as image processing and web applications. We choose the applications with at least 1,000 deployments in AWS serverless application repository [3]. We skip some applications since they are micro-benchmarks or stateless (no database operations). Table 2 summarizes the characteristics of these applications. **Type-I** applications satisfy idempotence consistency, while **Type-II** applications do not. Although most applications in Table 2 have fewer than a thousand lines of code, they remain representative because serverless platforms typically impose restrictions on code size and running time [2, 4, 7]. For instance, existing work [75] that adapts web applications to serverless platforms needs to largely reduce the application’s code size.

Flux’s approach is orthogonal to specific programming languages. However, its implementation depends on a Java symbolic execution engine [61] for program analysis. We manually port applications to Go with the same semantics for a fair performance comparison with Beldi and Boki, which target Go applications. We choose to implement a verifier for applications in Java rather than Go because Java is a more frequently utilized language in developing serverless applications than Go [11].

### 7.2 Verification Efficacy

Table 2 shows that the verifier identifies all 12 applications with idempotence issues. All issues are previously unknown. Developers have confirmed 8 issues among them. The verifier works for all applications except SPECjbb, which has

**Table 2:** The characteristics of 27 serverless applications. The applications with † have unbounded loops. **LoC** indicates lines of Java code. **C/S** indicates whether functions run sequentially (S) or concurrently (C). **#F**, **#I**, and **#N** indicate the number of functions, functions without idempotence issues, and functions with issues. **#R/#W** and **#S** indicate the number of read/write operations and idempotence-violating operations. **VTime**, **ATime(H)**, and **ATime(B)** indicate the execution time (in seconds) of the verifier, advisor using the heuristic algorithm, and advisor using the brute-force algorithm.

unbounded loops unsupported by the verifier. However, all functions in SPECjbb that cannot be verified have idempotence issues. Thus, the verifier does not introduce false positives for SPESjbb. Nonetheless, it is worth noting that false positives are still possible for other applications.

The 21 non-idempotent functions detected by Flux in 12 applications result in various bug patterns and outcomes due to incorrectly repeated write operations on retry. First, the database state is inconsistent with user expectations. For instance, the idempotence violation in SPECjbb causes duplicate balance deductions. Second, the value responded to clients is inconsistent with the database state. An example is an IoT application called Alexa, where a function successfully modifies device configuration but returns “failed” instead of “success” to clients. Third, a single write operation may update multiple records on retry, resulting in duplicated records with identical content. For example, the *PlaceOrder* function in the Hotel benchmark always places a new order with a random identifier on each retry, resulting in duplicate records. Last, concurrent functions may observe the inconsistent shared state. An example is the Media benchmark, which relies on a counter in the database to perform synchronization among concurrent functions. However, the *ComposeReview* function will falsely increase the counter due to retry, leading to false synchronization among concurrent instances.

To test the scalability of the verifier, we run micro-benchmarks with increasing verification complexity. When the number of branches in a single function increases, the verification time increases exponentially, as the number of traces also increases exponentially. Verifying a function with 16 branches takes 1441.48 seconds. When we increase the number of database operations, functions, or LoC, the verification time increases linearly because the number of generated traces increases linearly. Figure 15 in Appendix D presents more details. Note that the verification time does not affect the execution time of applications.

### 7.3 Performance of Advisor

For the second question, Table 2 shows the execution time of advisor with two different algorithms. Compared to the brute-force algorithm, the heuristic algorithm achieves up to 4× smaller search space, which cuts down 80.39% of the execution time of advisor. Although the heuristic algorithm does not guarantee finding the minimum operation set, the evaluation shows that it finds the same set as the brute-force algorithm in practice. Although SPECjbb2015 has unbounded loops unsupported by the verifier, advisor can still handle it with the method described in Section 6.

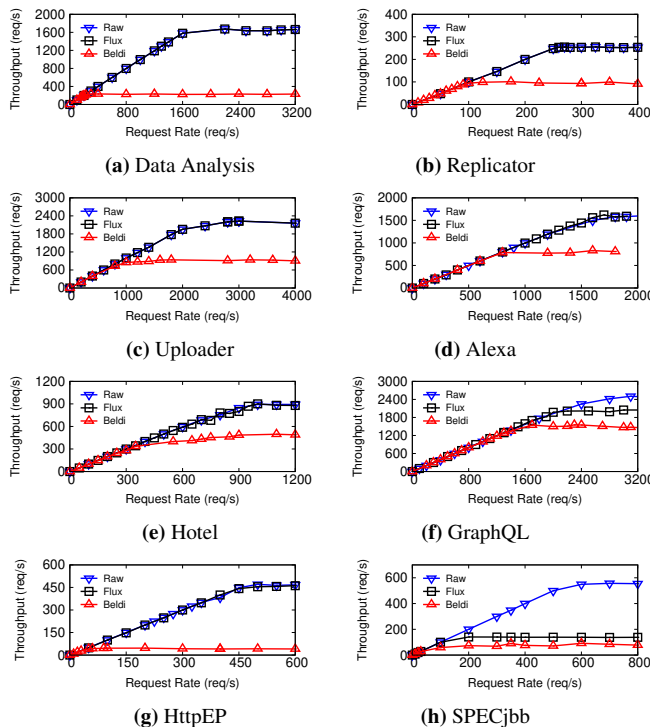

**Figure 9:** The median (box) and 99% tail latency (whisker) of Raw, Flux, and Beldi for eight applications. The y-axis is in the log scale.

**Figure 11:** The median (box) and 99% tail latency (whisker) of Flux and Boki for six applications at 1 RPS.

**Figure 10:** The throughput of each serverless application under different configurations with increasing request rates.

## 7.4 Performance of the Applications

To answer the third question, we run applications under four configurations: Raw, Flux, Boki, and Beldi. Raw means running applications without any logs, which may be non-idempotent. Flux uses existing mechanisms to log operations identified by advisor. Wrk2 runs for 7 minutes to generate random requests. We will show the results of 8 representative applications marked by ✓ in Table 2. Since Type-I applications are idempotence-consistent, Flux removes all logging operations. For Type-II applications, Flux reduces up to 99.47% of logging operations during execution compared to Beldi and Boki.

### 7.4.1 Flux vs. Beldi

**Latency.** Figure 9 shows the results on AWS Lambda. Flux poses no logging overhead over Raw for Type-I applications. Compared with Beldi, which logs all operations, Flux brings 2.5× ~ 6× performance improvement. For Type-II applications, Flux can avoid logging some operations. As a result, it

achieves up to 5.5× performance improvement over Beldi.

**Throughput.** Figure 10 shows that Flux achieves the same peak throughput on Type-I applications as Raw and up to 7.36× higher peak throughput than Beldi. For Type-II applications, Flux can avoid part of logging operations. Therefore, it has up to 80% higher peak throughput than Beldi, except for HttpEP. For HttpEP, Flux has 10× higher peak throughput than Beldi because Flux avoids logging a scan operation that can return massive data, which reduces much overhead under concurrency.

### 7.4.2 Flux vs. Boki

Boki [45] is another system to provide idempotence for serverless applications. The comparison can also demonstrate that Flux is general enough to be independent on a specific serverless platform. Because of Boki’s limitations, it does not guarantee idempotence for read-modify-write database operations [13]. Thus, we do not evaluate Alexa and SPECjbb on Boki.

Figure 11 shows that at 1 RPS, Flux reduces the median latency by up to 62.6% compared to Boki. The performance of Boki is better than Beldi because Boki designs a more efficient logging mechanism. Under high concurrency, the logging mechanism of Boki introduces more overhead. We further evaluate the latency at 800 RPS. Flux reduces the median latency by up to 82.5% and the p99 latency by up to 69.0% for Type-I applications compared to Boki because Flux introduces no logs. For Type-II applications, Flux reduces the median latency by up to 88.4% and the p99 latency by up to 72.4%. Flux achieves 8.7× lower median latency than Boki on HttpEP because Flux avoids logging an expensive “scan”.

### 7.4.3 Performance of the Java Applications

Since Beldi and Boki only support Go applications, we compare the performance of Java applications on AWS Lambda under the configurations of Flux and Raw. We implement the logging mechanism via transactions [73]. At 1 RPS, Flux achieves a tail latency up to 22.6% higher than Raw due to the additional logging overhead. However, despite better performance, Raw cannot guarantee idempotence consistency and may cause incorrect execution results.

## 8 Related Work

**Verification of Idempotence.** Table 3 summarizes the major differences between Flux and prior works that can verify

**Table 3:** Main differences between Flux and prior works. FSCQ-based works use a method akin to FSCQ [28] to prove the idempotence. Partial protection means ensuring idempotence consistency while reducing unnecessary logs.

	Definition of Idempotence		Verification Method of Idempotence				Protection

idempotence. Jangda et al. [44] formalizes the semantics of serverless computing and ensures idempotence with transactions. There are two main differences between Jangda et al. and Flux. For the idempotence definition, idempotence consistency is more relaxed than the idempotence provided by Jangda et al., as it allows more concurrent schedulings. Jangda et al. tries to model serverless computing with naive semantics to conceal the low-level details of serverless function execution, such as concurrency and warm-start. It requires the platform to process concurrent requests in the same way as processing a single request at a time without concurrency or retries. Consequently, it necessitates atomicity, serializability, and exactly-once execution. Besides, Jangda et al. focuses on verifying protocols instead of source code. To ensure idempotence, it protects the entire function with serializable transactions and uses logs to ensure that the transaction only commits once. However, using transactions is not optimal since some applications may not require transaction semantics, resulting in redundant protection and performance cost.

FSCQ [28] and DFSCQ [27] verify the crash safety of file systems via Crash Hoare Logic (CHL). CHL requires developers to manually write pre-conditions, post-conditions, and crash conditions to specify crash safety. Under crash, CHL proves that the program state always satisfies crash conditions after a crash happens at any time. It defines the idempotence of a recovery program to be that crash conditions imply pre-conditions. Perennial [23], GoJournal [24], and DaisyNFS [25] achieve significant progress in the verification of concurrent crash-safe systems. They adopt a similar approach as FSCQ to verify the idempotence of a recovery program. Thus, they cannot realize automated verification. Different from them, Flux focuses on automated verification without human effort.

Recent SMT-based verification approaches [26,39,66] have solved many issues of the automated verification of storage systems. Yggdrasil proposes a new correctness definition for sequential file systems — *crash refinement*. It means that for any disk state produced by the implementation with crash recovery, the specification can also produce the same disk state. The definition is amenable to automated verification. Yggdrasil also verifies the idempotence of recovery functions.

Unfortunately, it verifies sequential functions rather than concurrent functions. Others [26,39] also verify sequential functions.

Ramalingam et al. [62] formally defines idempotence in the general distributed setting, proving that logging each operation can guarantee this property. It has two main differences from Flux. First, for the definition of idempotence, both Ramalingam et al. and Flux require that any execution with retries has the same observable behavior as another normal execution. However, Ramalingam et al. targets a general distributed setting. The observable behavior only includes function invocation and response. In contrast, Flux also considers database states. As a result, for stateful serverless applications, Ramalingam et al.’s definition may allow inconsistent database states on retry as long as functions do not return database states to clients. This anomaly is critical if clients directly access database states for analysis or other purposes. In contrast, Flux’s definition prohibits inconsistent database states and can prevent such anomalies. Second, for verification and protection, Ramalingam et al. manually proves the protocol of logging each operation and presents a compiler that automatically logs each operation. Flux focuses on verifying the implementation of applications and its advisor only logs necessary operations.

**Crash-Only Software.** Previous work [20] comprehensively analyzes the requirements for crash-only software, a program that can crash safely and recover quickly via retries. Our work can assist in revising these requirements. Specifically, serverless applications fulfill most of these requirements, such as explicit boundaries around what is retried and dedicated storage for non-volatile data. However, our work only mandates that all functions satisfy idempotence consistency instead of necessitating that every request is idempotent, as stated in previous work [20]. This distinction results in fundamental differences in several aspects. First, idempotence pertains to a single component, while idempotence consistency pertains to the entire application comprised of multiple components. Second, while idempotence requires a function’s execution result to remain the same despite retries, idempotence consistency only requires the existence of an execution without retries for each execution with retries such that they produce the same result. For example, a read-only function

may not satisfy idempotence because concurrent modifications to the database state can result in different return values with and without retries. However, read-only functions do not violate idempotence consistency. In addition to serverless functions, other applications with “imperfectly crash-only” code can also refer to the requirements revised based on Flux.

**Research on Serverless Computing.** Some systems [44, 45, 62, 69, 73] focus on ensuring idempotence via runtime mechanisms. Different from them, Flux focuses on verifying idempotence consistency. Furthermore, combining them with Flux can ensure idempotence efficiently. Some other systems [21, 30–32, 46, 49, 51, 56, 63, 65, 71, 72, 74] target other things, such as startup time.

**Consistency Model.** There are many consistency models [14], which define the permitted execution order under concurrency. Idempotence consistency specifies the expected behavior of concurrent systems when failure happens, which is the main difference from existing consistency models.

## 9 Discussion

**Serverless Applications vs. Other Applications.** *Idempotence* [43] is a property that is important not only for serverless applications but also for programs that use retry-based fault tolerance approaches, such as RPC-based distributed systems [41, 50], AI systems [38], and even some intermittent systems [70]. Thus, it is worth considering *whether we can apply Flux to programs beyond serverless applications*. The answer is *yes and no*.

One of the key contributions of Flux is formally defining idempotence consistency, which is general enough for various scenarios. For instance, different RPC handlers in distributed systems may concurrently manipulate shared states. Repeated state updates due to failures and retries could impair data consistency under concurrency. Specifically, we successfully detect an issue in HDFS according to the definition of idempotence consistency, which the community has confirmed [41]. When the system retries NameNode RPC of *ClientProtocol.truncate*, it may truncate a file multiple times, which will potentially cause data loss if another RPC simultaneously updates the same file. However, this issue will not happen under sequential execution.

However, using Flux’s method to verify other systems poses many challenges. First, the automated verification algorithm mainly focuses on serverless applications. We need to redesign it for other scenarios. For example, Flux presumes that shared states are solely key-value pairs stored in NoSQL databases. However, shared states could be file descriptors, shared variables, or global configurations in distributed systems. Programmers must reinterpret them across various scenarios. Additionally, Flux automatically constructs pre-, post-, and rely conditions based on the NoSQL interface assumption, necessitating a re-examination of the construction algorithm based on other modeling methods of states. Second, Flux’s

implementation targets serverless applications. For example, Flux currently only supports Java programs and DynamoDB, which are commonly used by serverless applications. Engineering effort is necessary to support other languages and storage services. Furthermore, advisor in Flux relies on existing logging mechanisms for serverless applications to fix idempotence issues. Therefore, the new scenario should also provide mechanisms to ensure exactly-once execution of operations on shared states. Failure to do so limits Flux’s potential to identify and fix idempotence issues via advisor.

**Idempotence Consistency vs. Atomicity.** Although atomicity is vital for fault tolerance, Flux does not guarantee it. Atomicity is not mandatory for some applications to sustain fault tolerance, as they may permit other functions to see partial updates. Furthermore, it is essential to emphasize that Flux is orthogonal to approaches that ensure atomicity. An application that necessitates atomicity can still utilize Flux to guarantee idempotence consistency and minimize logging overhead.

Although Flux does not verify atomicity and some other transactional properties, extending our approach to verify these properties is an intriguing research direction. Some verifiers [22–25, 37, 53, 54, 76] target transactional properties but may not consider retries. After ensuring idempotence consistency based on Flux, we can prove the transactional properties of functions without considering failures and retries. Therefore, we can combine Flux and these verifiers by ensuring idempotence consistency via Flux and then proving other properties with these verifiers.

**Automated Verification vs. Interactive Verification.** We adopt symbolic execution engines to develop Flux, which requires less manual effort than using interactive theorem provers. [37]. Additionally, although interactive theorem provers can handle unbounded loops by crafting loop invariants, finding proper loop invariants is notoriously difficult.

## 10 Conclusion

This paper presents Flux, the first toolkit that can automatically verify and help ensure the idempotence consistency of serverless applications. It guarantees idempotence consistency via logs while reducing unnecessary logging overhead.

## Appendix A Proof of Theorem 1

In this section, we prove that it is sufficient to verify the idempotence consistency of a function set  $F$  by proving that each function  $f \in F$  satisfies idempotence simulation, which is Theorem 1 in the paper. Since our verification approach adopts existing compositional proof techniques in RGSim [53], our formal proof is similar to the proof in that paper.

Let's start by introducing some important concepts. When we have two functions running concurrently, we can consider them as one unit and denote their local state using the symbol  $\sigma_1 \parallel \sigma_2$ , where  $\sigma_1$  represents the local state of the first function and  $\sigma_2$  represents the local state of the second function. Using this notation, we can represent the overall system state as  $\langle \sigma_1 \parallel \sigma_2, D \rangle$  when two functions run concurrently. We use  $\langle \sigma_1 \parallel \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_1 \parallel \sigma'_2, D' \rangle$  to denote that the system can take one step and change the system state from  $\langle \sigma_1 \parallel \sigma_2, D \rangle$  to  $\langle \sigma'_1 \parallel \sigma'_2, D' \rangle$ , producing an event  $\alpha$  (if any). During each execution cycle, the system can either advance the first function by one step or advance the second function by one step. It means that if there exists  $\sigma'_1$  and  $D'$  such that  $\langle \sigma_1, D \rangle \xrightarrow{\alpha} \langle \sigma'_1, D' \rangle$ , then we can imply that  $\langle \sigma_1 \parallel \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_1 \parallel \sigma_2, D' \rangle$ . Similarly, if there exists  $\sigma'_2$  and  $D'$  such that  $\langle \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_2, D' \rangle$ , then we can imply that  $\langle \sigma_1 \parallel \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma_1 \parallel \sigma'_2, D' \rangle$ .

$\langle \sigma_1 \parallel \sigma_2, D \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D \rangle$  denotes that the concurrent execution of two functions with the local state  $\Sigma_1$  and  $\Sigma_2$  can simulate the concurrent execution of another two functions with the local state  $\sigma_1$  and  $\sigma_2$  under the rely condition  $R$ . Here is the detailed definition of the simulation relation. We use  $\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle$  to denote that the system can take  $n$  ( $0 \leq n$ ) steps to change the system state from  $\langle \Sigma_1, D \rangle$  to  $\langle \Sigma'_1, D' \rangle$ , producing an event  $\alpha$  (if any).

- For any local state  $\sigma'_1$  and database state  $D'$ , if  $\langle \sigma_1, D \rangle \xrightarrow{\alpha} \langle \sigma'_1, D' \rangle$ , then there exists a local state  $\Sigma'_1$  such that  $\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle$ . If  $\alpha$  is a *response* event, then  $\langle \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma_2, D' \rangle$ . Otherwise,  $\langle \sigma_1 \parallel \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D' \rangle$ . This condition represents the requirement for the simulation relation when the system advances the first function by one step.
- For any local state  $\sigma'_2$  and database state  $D'$ , if  $\langle \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_2, D' \rangle$ , then there exists a local state  $\Sigma'_2$  such that  $\langle \Sigma_2, D \rangle \xrightarrow{\alpha} \langle \Sigma'_2, D' \rangle$ . If  $\alpha$  is a *response* event, then  $\langle \sigma_1, D' \rangle \sqsubseteq_R \langle \Sigma_1, D' \rangle$ . Otherwise,  $\langle \sigma_1 \parallel \sigma'_2, D' \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D' \rangle$ . This condition represents the requirement for the simulation relation when the system advances the first function by one step, which is similar to the first requirement.
- If  $(D, D') \in R$ , then  $\langle \sigma_1 \parallel \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D' \rangle$ .

We can extend the above definition to more than two functions.

To prove Theorem 1, we first prove the following two lemmas based on the above definitions.

**Lemma 1** Assume there are four functions  $f_1, f_2, g_1$ , and  $g_2$ . Suppose that the execution of  $g_1$  can simulate the execution of  $f_1$  under the rely condition  $R$ , while the execution of  $g_2$  can simulate the execution of  $f_2$  under the rely condition  $R$ . Then we can imply that the concurrent execution of  $g_1$  and  $g_2$  can simulate the concurrent execution of  $f_1$  and  $f_2$  under the rely condition  $R$ . We use  $\sigma_1, \sigma_2, \Sigma_1$ , and  $\Sigma_2$  to represent the local states of  $f_1, f_2, g_1$ , and  $g_2$ , respectively.

$$\begin{aligned} & \forall \sigma_1, \Sigma_1, \sigma_2, \Sigma_2, D. \\ & ((\langle \sigma_1, D \rangle \sqsubseteq_R \langle \Sigma_1, D \rangle) \wedge (\langle \sigma_2, D \rangle \sqsubseteq_R \langle \Sigma_2, D \rangle)) \rightarrow \\ & (\langle \sigma_1 \parallel \sigma_2, D \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D \rangle) \end{aligned}$$

### Proof

The premises include

$$\langle \sigma_1, D \rangle \sqsubseteq_R \langle \Sigma_1, D \rangle, \quad (1)$$

and

$$\langle \sigma_2, D \rangle \sqsubseteq_R \langle \Sigma_2, D \rangle. \quad (2)$$

The conclusion is

$$\langle \sigma_1 \parallel \sigma_2, D \rangle \sqsubseteq_R \langle \Sigma_1 \parallel \Sigma_2, D \rangle. \quad (3)$$

Below we prove the conclusion by *co-induction* on  $\sqsubseteq_R$ . According to the definition of  $\sqsubseteq_R$  described above, the execution of two functions belongs to one of the following five cases.

- $\langle \sigma_1, D \rangle \xrightarrow{\alpha} \langle \sigma'_1, D' \rangle$ , where  $\alpha$  is not a *response* event.

According to the definition of  $\sqsubseteq_R$ , we need to prove that there exists  $\Sigma'_1$  such that  $\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle$  and  $\langle \sigma'_1 \parallel \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma'_1 \parallel \Sigma_2, D' \rangle$ .

From Equation (1), there exists  $\Sigma'_1$  such that

$$\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle, \quad (4)$$

and

$$\langle \sigma'_1, D' \rangle \sqsubseteq_R \langle \Sigma'_1, D' \rangle. \quad (5)$$

Since  $(D, D') \in R$ , from Equation (2), we know

$$\langle \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma_2, D' \rangle. \quad (6)$$

From both Equation (5) and Equation (6) we know

$$\langle \sigma'_1 \parallel \sigma_2, D' \rangle \sqsubseteq_R \langle \Sigma'_1 \parallel \Sigma_2, D' \rangle. \quad (7)$$

- $\langle \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_2, D' \rangle$ , where  $\alpha$  is not a *response* event. The proof is similar to the first case.

- $\langle \sigma_1, D \rangle \xrightarrow{\alpha} \langle \sigma'_1, D' \rangle$ , where  $\alpha$  is a *response* event. According to the definition of  $\Xi_R$ , we need to prove that there exists  $\Sigma'_1$  such that  $\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle$ , and  $\langle \sigma_2, D' \rangle \Xi_R \langle \Sigma_2, D' \rangle$ .

From Equation (1), there exists  $\Sigma'_1$  such that

$$\langle \Sigma_1, D \rangle \xrightarrow{\alpha} \langle \Sigma'_1, D' \rangle. \quad (8)$$

Since  $(D, D') \in R$ , we know

$$\langle \sigma_2, D' \rangle \Xi_R \langle \Sigma_2, D' \rangle. \quad (9)$$

- $\langle \sigma_2, D \rangle \xrightarrow{\alpha} \langle \sigma'_2, D' \rangle$ , where  $\alpha$  is a *response* event. The proof is similar to the third case.
- $(D, D') \in R$ , which means that other concurrent functions change the database state from  $D$  to  $D'$ .

According to the definition of  $\Xi_R$ , we need to prove that  $\langle \sigma_1 \parallel \sigma_2, D' \rangle \Xi_R \langle \Sigma_1 \parallel \Sigma_2, D' \rangle$ .

From  $(D, D') \in R$  and Equation (1), we know

$$\langle \sigma_1, D' \rangle \Xi_R \langle \Sigma_1, D' \rangle. \quad (10)$$

From  $(D, D') \in R$  and Equation (2), we know

$$\langle \sigma_2, D' \rangle \Xi_R \langle \Sigma_2, D' \rangle. \quad (11)$$

From both Equation (10) and Equation (11), we know

$$\langle \sigma_1 \parallel \sigma_2, D' \rangle \Xi_R \langle \Sigma_1 \parallel \Sigma_2, D' \rangle. \quad (12)$$

Therefore, the conclusion Equation (3) is true.  $\square$

Then we prove the following lemma.

**Lemma 2** We use  $A_F$  to denote an automaton running functions in a function set  $F$ . For any function set  $F$  and automaton  $A_F$ , if every function in  $F$  satisfies idempotence simulation, then the following fact holds: from the same initial database state, every time the automaton  $A_{F^*}$  takes one step,  $A_F$  can take  $n$  steps ( $n \geq 0$ ) such that they reach the same database state and produce the same event (if any).

### Proof

The premise is that every function  $f \in F$  satisfies idempotence simulation:

$$\forall f \in F. \quad (\forall D, arg. \langle init(f^*, arg), D \rangle \Xi_R \langle init(f, arg), D \rangle), \quad (13)$$

where  $init(f, arg)$  denotes the initial local state of running the function  $f$  with the argument  $arg$ , and we omit the existential quantifier on  $R$ . The conclusion is that the execution of  $F$  can simulate the execution of  $F^*$ .

We prove the conclusion by classifying every step taken by  $A_{F^*}$  into three cases.

- $A_{F^*}$  creates a function instance to run a function  $f^*$ . Then,  $A_F$  can create an instance with the same identifier to run  $f$  with the same invocation arguments. Both of them do not change the database state and produce the same invocation event. Note that we treat  $f$  and  $f^*$  as the same in invocation events since their only difference is whether to be retried.

- A function instance takes one step. From Equation (13) and Lemma 1, we know that for any functions  $f_1, f_2, \dots \in F$ , function arguments  $arg_1, \dots$ , and shared state  $D$ ,

$$\langle init(f_1^*, arg_1) \parallel \dots, D \rangle \Xi_R \langle init(f_1, arg_1) \parallel \dots, D \rangle. \quad (14)$$

From Equation (14), we know that for any intermediate local states  $(\sigma_{f_1}, \dots)$  and database state  $D'$  during executing functions,

$$\langle \sigma_{f_1^*} \parallel \dots, D' \rangle \Xi_R \langle \sigma_{f_1} \parallel \dots, D' \rangle. \quad (15)$$

According to the definition of  $\Xi_R$ , Equation (15) implies that every time a function instance in  $A_{F^*}$  takes one step, another function instance in  $A_F$  can always take  $k$  ( $0 \leq k$ ) steps to result in the same database state and the same event (if any).

- $A_{F^*}$  retries an instance. Then  $A_F$  takes no steps such that it produces the same database state and no event. The proof is similar to the second case.

Then, the conclusion is true.  $\square$

Finally, we can prove Theorem 1 in the paper.

**Theorem 5** Given a function set  $F$ , if every function  $f \in F$  satisfies idempotence simulation, then  $F$  satisfies idempotence consistency.

### Proof

The premise is that every function  $f \in F$  satisfies idempotence simulation.

$$\forall f \in F. \quad (\forall D, arg. \langle init(f^*, arg), D \rangle \Xi_R \langle init(f, arg), D \rangle). \quad (16)$$

The conclusion is that  $F$  satisfies idempotence consistency (Definition 1).

From Lemma 2 and Equation (16), we imply that the execution of  $F$  can simulate the execution of  $F^*$ . That means every time  $A_{F^*}$  takes one step,  $A_F$  can take  $n$  ( $n \geq 0$ ) steps such that they reach the same database state and produce the same event (if any). Therefore, if some execution of  $A_{F^*}$  can result in the client-observable behavior  $\langle H, D \rangle$ , then there exists another execution of  $A_F$  that can also result in  $\langle H, D \rangle$ . The conclusion is proved.  $\square$

## Appendix B Proof of Failure Reduction

In this section, we prove Theorem 4 in the paper, which proves the second condition in Theorem 3. The first condition in Theorem 3 is intuitive. Thus, we omit its formal proof in this section. We first prove two lemmas and then prove Theorem 4 based on them.

**Lemma 3** If the execution of  $f$  can simulate  $f^1$ , then for any  $n \geq 1$ , the execution of  $f^{n-1}$  can simulate  $f^n$ . The definition of  $f^1$ ,  $f^n$ , and  $f^{n-1}$  are in Section 4.4.

$$\begin{aligned} & (\forall D, arg. \langle \text{init}(f^1, arg), D \rangle \sqsubseteq_R \langle \text{init}(f, arg), D \rangle) \rightarrow \\ & (\forall D, arg, n \geq 1. \langle \text{init}(f^n, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^{n-1}, arg), D \rangle). \end{aligned}$$

### Proof

The premise is

$$\forall D, arg. \langle \text{init}(f^1, arg), D \rangle \sqsubseteq_R \langle \text{init}(f, arg), D \rangle. \quad (17)$$

We want to prove for all  $n \geq 1$ ,

$$\forall D, arg. \langle \text{init}(f^n, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^{n-1}, arg), D \rangle. \quad (18)$$

We prove it by induction on  $n$ .

**Base case:** When  $n = 1$ , Equation (18) is true, because it is equivalent to the premise Equation (17).

**Inductive step:** Suppose Equation (18) is true when  $n = k$  ( $k \geq 1$ ).

$$\forall D, arg. \langle \text{init}(f^k, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^{k-1}, arg), D \rangle. \quad (19)$$

Then when  $n = k + 1$ , we want to prove

$$\forall D, arg. \langle \text{init}(f^{k+1}, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^k, arg), D \rangle. \quad (20)$$

According to the definition of  $\sqsubseteq_R$ , we need to map every single step during the execution of  $f^{k+1}$  to  $s$  ( $s \geq 0$ ) steps during the execution of  $f^k$ . We can construct the mapping in the following way.  $f^{k+1}$  and  $f^k$  are almost the same, except that the platform retries them for different times. Then before the first retry, we map every single step when executing  $f^{k+1}$  to a single step of  $f^k$ . That means  $f^{k+1}$  and  $f^k$  always execute the same statement. This mapping can satisfy the requirements of  $\sqsubseteq_R$ .

When the first retry of  $f^{k+1}$  happens, we ask  $f^k$  to be also retried. Assume the database state immediately before the retry is  $D_1$ . The executions of  $f^{k+1}$  and  $f^k$  from  $D_1$  after the first retry are equivalent to the executions of  $f^k$  and  $f^{k-1}$  from  $D_1$  before the first retry, respectively. This is because after the first retry, the platform will retry  $f^{k+1}$  for  $k$  times and retry  $f^k$  for  $k - 1$  times. From Equation (19), we know that

$$\forall arg. \langle \text{init}(f^k, arg), D_1 \rangle \sqsubseteq_R \langle \text{init}(f^{k-1}, arg), D_1 \rangle. \quad (21)$$

Then there exists a step mapping from every step of  $f^{k+1}$  to steps of  $f^k$  after the first retry, which satisfies the requirements of  $\sqsubseteq_R$ . Therefore, Equation (18) is true for  $n = k + 1$ .

**Conclusion:** By the principle of induction, Equation (18) is true for any  $n \geq 1$ .  $\square$

**Lemma 4** For any  $i, j, k \geq 0$ , if the execution of  $f^k$  can simulate  $f^j$  and the execution of  $f^j$  can simulate  $f^i$ , then the execution of  $f^k$  can simulate  $f^i$ .

$\forall i, j, k.$

$$\begin{aligned} & ((\forall D, arg. \langle \text{init}(f^i, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^j, arg), D \rangle) \wedge \\ & (\forall D, arg. \langle \text{init}(f^j, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^k, arg), D \rangle)) \\ & \rightarrow (\forall D, arg. \langle \text{init}(f^i, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^k, arg), D \rangle). \end{aligned}$$

### Proof

This lemma is similar to the transitivity of forward simulation. The premises include

$$\forall D, arg. \langle \text{init}(f^i, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^j, arg), D \rangle, \quad (22)$$

and

$$\forall D, arg. \langle \text{init}(f^j, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^k, arg), D \rangle. \quad (23)$$

The conclusion is

$$\forall D, arg. \langle \text{init}(f^i, arg), D \rangle \sqsubseteq_R \langle \text{init}(f^k, arg), D \rangle. \quad (24)$$

We use  $\sigma_i$ ,  $\sigma_j$ , and  $\sigma_k$  to denote the local state when executing  $f^i$ ,  $f^j$ , and  $f^k$ , respectively. We will prove the conclusion Equation (24) by *co-induction*. According to the definition of  $\sqsubseteq_R$ , every step taken during executing  $f^i$  belongs to one of the following three cases.

- $\langle \sigma_i, D \rangle \xrightarrow{\alpha} \langle \sigma'_i, D' \rangle$ , where  $\alpha$  is not a *response* event.

According to the definition of  $\sqsubseteq_R$ , we need to prove that there exists  $\sigma'_k$  such that  $\langle \sigma_k, D \rangle \xrightarrow{\alpha} \langle \sigma'_k, D' \rangle$  and  $\langle \sigma'_i, D' \rangle \sqsubseteq_R \langle \sigma'_k, D' \rangle$ .

From Equation (22), we know that there exists  $\sigma'_j$  such that

$$\langle \sigma_j, D \rangle \xrightarrow{\alpha} \langle \sigma'_j, D' \rangle, \quad (25)$$

and

$$\langle \sigma'_i, D' \rangle \sqsubseteq_R \langle \sigma'_j, D' \rangle. \quad (26)$$

From Equation (23) and Equation (25), we know there exists  $\sigma'_k$  such that

$$\langle \sigma_k, D \rangle \xrightarrow{\alpha} \langle \sigma'_k, D' \rangle, \quad (27)$$

and

$$\langle \sigma'_j, D' \rangle \sqsubseteq_R \langle \sigma'_k, D' \rangle. \quad (28)$$

From Equation (26) and Equation (28), we know that

$$\langle \sigma'_i, D' \rangle \sqsubseteq_R \langle \sigma'_k, D' \rangle. \quad (29)$$

- $\langle \sigma_i, D \rangle \xrightarrow{\alpha} \langle \sigma'_i, D' \rangle$ , where  $\alpha$  is a *response* event.

According to the definition of  $\Xi_R$ , we need to prove that there exists  $\sigma'_k$  such that  $\langle \sigma_k, D \rangle \xrightarrow{\alpha} \langle \sigma'_k, D' \rangle$ .

From Equation (22), we know that there exists  $\sigma'_j$  such that

$$\langle \sigma_j, D \rangle \xrightarrow{\alpha} \langle \sigma'_j, D' \rangle. \quad (30)$$

From Equation (23) and Equation (30), we know there exists  $\sigma'_k$  such that

$$\langle \sigma_k, D \rangle \xrightarrow{\alpha} \langle \sigma'_k, D' \rangle. \quad (31)$$

- $\langle D, D' \rangle \in R$ , which means that other concurrent functions change the database state from  $D$  to  $D'$ .

According to the definition of  $\Xi_R$ , we need to prove that  $\langle \sigma_i, D' \rangle \Xi_R \langle \sigma_k, D' \rangle$ .

From Equation (22), we know

$$\langle \sigma_i, D' \rangle \Xi_R \langle \sigma_j, D' \rangle. \quad (32)$$

From Equation (23), we know

$$\langle \sigma_j, D' \rangle \Xi_R \langle \sigma_k, D' \rangle. \quad (33)$$

From Equation (32) and Equation (33), we know

$$\langle \sigma_i, D' \rangle \Xi_R \langle \sigma_k, D' \rangle. \quad (34)$$

Thus, we have proved the conclusion Equation (24).  $\square$

Finally, we can prove Theorem 4 in the paper based on the above two lemmas.

**Theorem 6** Given a function  $f$ , if each execution with one retry under concurrency has a corresponding retry-free execution that can simulate it, then each execution with arbitrary times of retries also has a corresponding retry-free execution that can simulate it.

$$\begin{aligned} & (\forall D, arg. \langle \text{init}(f^1, arg), D \rangle \Xi_R \langle \text{init}(f, arg), D \rangle) \rightarrow \\ & (\forall D, arg, n \geq 1. \langle \text{init}(f^n, arg), D \rangle \Xi_R \langle \text{init}(f, arg), D \rangle). \end{aligned}$$

### Proof

The premise is

$$\forall D, arg. \langle \text{init}(f^1, arg), D \rangle \Xi_R \langle \text{init}(f, arg), D \rangle. \quad (35)$$

The conclusion is

$$\forall D, arg, n \geq 1. \langle \text{init}(f^n, arg), D \rangle \Xi_R \langle \text{init}(f, arg), D \rangle. \quad (36)$$

From Lemma 3 and the premise Equation (35), we know

$$\forall D, arg, n \geq 1. \langle \text{init}(f^n, arg), D \rangle \Xi_R \langle \text{init}(f^{n-1}, arg), D \rangle. \quad (37)$$

From Lemma 4 and Equation (37), we know

$$\forall D, arg, n \geq 1. \langle \text{init}(f^n, arg), D \rangle \Xi_R \langle \text{init}(f^0, arg), D \rangle. \quad (38)$$

Since  $f^0$  is equivalent to  $f$ , Equation (38) is equivalent to the conclusion Equation (36). The conclusion is true.  $\square$

```

1 int f(input)
2 {
3   output = f1(input);
4   return f2(output);
5 }

```

**Figure 12:** A function composed of two sub-functions called  $f_1$  and  $f_2$ .

## Appendix C Proof of Theorem 2

This section proves Theorem 2 in Section 4.3 of the paper. We first define and prove sequential compositionality of idempotence simulation.

**Definition 2** Given a function  $f$  and the rely condition  $R$ ,  $f$  satisfies strong idempotence simulation means that: 1)  $f$  satisfies idempotence simulation under  $R$ ; and 2) after the platform successfully executes  $f$  without retries for one time, retrying  $f$  again will not modify the shared state.

Particularly, the second condition is equivalent to the third requirement in Theorem 2 of paper: it will not affect the shared state on retry once it has been successfully executed.

**Lemma 5** Given any two functions  $f_1$  and  $f_2$ , if  $f_1$  satisfies strong idempotence simulation,  $f_2$  satisfies idempotence simulation, and the input of  $f_2$  remains unchanged on retry, then the function  $f$  in Figure 12 composed of  $f_1$  and  $f_2$  also satisfies idempotence simulation.

**Proof** According to Theorem 3, we prove the simulation relation between  $f^1$  and  $f$ . Note that  $f^1$  is defined in Section 4.4, which is different from  $f_1$ . Then we classify the location where retry occurs during the execution of  $f^1$  into three cases and prove that under all these cases, executing  $f$  without retries could exhibit all possible client-observable behaviors produced by executing  $f^1$ . Then we can prove that  $f$  satisfies idempotence simulation.

- Retry happens during the execution of  $f_1$ . Then the execution of  $f^1$  consists of three main parts:
  - (P1) the execution of  $f_1$  before retry;
  - (P2) the normal execution of  $f_1$  after retry;
  - (P3) the normal execution of  $f_2$ .
 Since  $f_1$  satisfies idempotence simulation, a normal execution of  $f_1$  without retries could exhibit all client-observable behaviors of (P1) and (P2). In this case, a normal execution of  $f$  without retries can simulate the execution of  $f^1$ .
- Retry happens between  $f_1$  and  $f_2$ . This execution exhibits the same client-observable behavior as another execution where retry happens immediately before the “return” statement in  $f_1$ . The proof is the same as the first case.
- Retry happens during the execution of  $f_2$ . Then the execution of  $f^1$  consists of four main parts:
  - (P1) the first normal execution of  $f_1$  without retries;

```

1 int f(int input)
2 {
3     int output1 = f1(input);
4     int output2 = f2(output1);
5     ...;
6     return fn(outputn);
7 }

```

**Figure 13:** A function composed of  $n$  sub-functions called  $f_1, \dots,$  and  $f_n$ .

- (P2) the execution of  $f_2$  before retry;
- (P3) the second normal execution of  $f_1$  without retries;
- (P4) the normal execution of  $f_2$  without retries.

Since  $f_1$  satisfies strong idempotence simulation, the second normal execution of  $f_1$  will not modify the shared state and return the same value as the input for the  $f_2$ . Therefore, this kind of execution of  $f^1$  exhibits the same client-observable behavior as the execution composed of (P1), (P2), and (P4). Since  $f_2$  satisfies idempotence simulation, there exists another normal execution of  $f_2$  that exhibits the same client-observable behavior as the execution of (P2) and (P4). Thus, the execution of  $f^1$  described in this case exhibits the same client-observable behavior as another normal execution of  $f$  without retries.

In conclusion, for any execution of  $f^1$ , there always exists a normal execution of  $f$  that exhibits the same client-observable behavior under concurrency. According to Theorem 4,  $f$  satisfies idempotence simulation.  $\square$

Then we extend sequential compositionality to a function composed of arbitrary number of code fragments.

**Lemma 6** For any positive integer  $n \geq 2$  and any function  $f$  in the form of Figure 13, if each  $f_i$  ( $1 \leq i < n$ ) satisfies strong idempotence simulation,  $f_n$  satisfies idempotence simulation, and the input of each  $f_i$  remains unchanged on retry, then  $f$  satisfies idempotence simulation.

**Proof** We prove it by induction on  $n$  ( $n \geq 2$ ). The premise is Lemma 5.

**Base case.** When  $n = 2$ , the conclusion is true, because it is equivalent to the premise.

**Inductive step.** Assume the conclusion is true when  $n = k$ . We prove that the conclusion is also true when  $n = (k + 1)$ . We can treat the code fragment containing the first  $k$  sub-functions as a function  $g$ . Since the conclusion is true when  $n = k$ , the function  $g$  satisfies idempotence simulation.  $f$  consists of two sub-functions called  $g$  and  $f_{k+1}$ , both of which satisfy idempotence simulation. From Lemma 5, we can imply that  $f$  satisfies idempotence simulation.

**Conclusion.** By the principle of induction,  $f$  satisfies idempotence simulation for any  $n \geq 2$ .  $\square$

Based on Lemma 6, we prove that our method of addressing unbounded loops with write operations is sound, which is

```

1 void checkCoupons(coupons, time) {
2     // C1
3     if(coupons.size == 0)
4         return;
5     // L
6     for(int j = 0; j < coupons.size(); j++) {
7         coupon := get("Coupon", coupons[j].couponId);
8         if(isExpired(coupon.date, time)) {
9             coupon.expired := true;
10            put("Coupon", coupons[j].couponId, coupon);
11        }
12    }
13    // C2
14    return;
15 }

```

**Figure 14:** An example of unbounded loop with write operations.

Theorem 2 in the paper. For convenience, we represent a function with an unbounded loop as  $\{C_1; L; C_2\}$ , where  $L$  is the unbounded loop,  $C_1$  is all code preceding  $L$ , and  $C_2$  denotes all code following the loop.  $B_L$  is the loop body of  $L$ .

**Theorem 7** Given a function  $f$  with the unbounded loop in case 2,  $f$  satisfies idempotence simulation if the number of iterations of the loop  $L$  remains unchanged on retry, and  $C_1$ ,  $C_2$  and  $B_L$  can satisfy the following requirements: 1) They all satisfy idempotence simulation; 2) Their inputs do not change on retry; 3) They will not affect the shared state on retry once the function has successfully executed them.

**Proof** Since the number of loop iterations is the same on retry, the execution of  $f$  comprises the execution of  $C_1$ , the execution of an unbounded number of  $B_L$ , and the execution of  $C_2$ . We can prove that  $f$  satisfies idempotence simulation based on Lemma 6. Although the number of loop iterations is unbounded, the loop body executed by each iteration is the same. Therefore, we just need to prove that  $C_1$ ,  $B_L$ , and  $C_2$  satisfy the requirements in Lemma 6. The requirements have been ensured by the premise of Theorem 7. Therefore, the conclusion is true and  $f$  satisfies idempotence simulation.  $\square$

We use an example to show how to use this theorem to perform the verification. In Figure 14, the `checkCoupons` function uses an unbounded loop to check whether coupons have expired. Obviously,  $C_1$  and  $C_2$  in `checkCoupons` satisfy all requirements in Theorem 2. The number of the loop iterations is the size of `coupons` which will be the same on retry. Thus, to prove the idempotence simulation of `checkCoupons`, we only need to focus on the loop body  $B_L$  (line 7-11). First, Flux can prove that  $B_L$  satisfies the idempotence simulation; Then, it uses static analysis to find that  $B_L$ 's input is `coupons` that keeps consistent on retry. Third, once it successfully updates `expire` to be `true` for a specific `coupon`, the value will remain unchanged as `checkCoupons` always updates it to be `true` on retry. According to the theorem, we have that `checkCoupons` satisfies the idempotence simulation.

(a) The verification time of a single function with ten database operations and different numbers of branches.

(b) The verification time of a single function with different numbers of database operations. The function has one execution path. Lines of code also increase linearly when the number of database operations increases linearly.

(c) The verification time of an application with different numbers of functions.

**Figure 15:** The verification time for different numbers of branch statements, database operations, and functions.

## Appendix D Scalability of the Verifier

We have created micro-benchmarks to evaluate the scalability of the verifier. Figure 15a shows that when the number of branches in a single function increases, the verification time increases exponentially, as the number of traces also increases exponentially. Besides, Figure 15b shows that when the number of database operations in a single function increases, the verification time increases linearly. This is because the number of generated traces increases linearly. Note that because these micro-benchmarks mainly contain database operations, LoC also increases linearly when the number of database operations increases. Thus, Figure 15b also demonstrates that when the LoC of a single function increases, the verification time increases linearly. Additionally, we evaluate the verification time for an application with different numbers

of functions. Each function has one execution path and two hundred database operations. Figure 15c shows that the verification time increases linearly when the number of functions in an application increases linearly. Because the number of traces increases linearly.

# Sharding the State Machine: Automated Modular Reasoning for Complex Concurrent Systems

## Abstract

We present IronSync, an automated verification framework for concurrent code with shared memory. IronSync scales to complex systems by splitting system-wide proofs into isolated concerns such that each can be substantially automated. As a starting point, IronSync’s ownership type system allows a developer to straightforwardly prove both data safety *and* the logical correctness of thread-local operations. IronSync then introduces the concept of a *Localized Transition System*, which connects the correctness of local actions to the correctness of the entire system. We demonstrate IronSync by verifying two state-of-the-art concurrent systems comprising thousands of lines: a library for black-box replication on NUMA architectures, and a highly concurrent page cache.

## 1 Introduction

Despite the importance of concurrent software, it is famously difficult to write correctly. The correctness of any one thread can, in principle, depend on changes from any other thread; developers often struggle to consider all possible thread interleavings. This reasoning becomes more difficult in aggressively optimized systems that use custom synchronization tools beyond standard abstractions like locks. Such systems often appear *anti-modular* in that they entangle synchronization logic with application logic. For example, a concurrent page cache (§5.2) might use a bit both for the synchronization purpose of read-locking a section of memory and for the logical purpose of indicating that an IO write is in progress.

In theory, formal software verification can produce provably correct code, but existing techniques have struggled to reach production-scale shared-memory systems (§9). Some work [19, 20] on verifying concurrent systems carefully focuses on networking and asynchronous disk IO, but avoids *shared-memory* concurrency. Other work [11, 12, 17, 36, 46] does tackle shared memory, but it relies on techniques which require considerable sophistication and manual effort from the developer. Still other work [38] offers simpler tools and greater automation, but the automation does not yet scale, requiring hours of CPU time for tens of lines of code (§7.1).

In contrast, IronSync enables verification of production-scale shared-memory concurrent systems, including those with custom synchronization protocols. Such verification comes with many reasoning challenges, and IronSync suc-

ceeds by carefully partitioning the system-level proof so that a developer can ergonomically tackle each challenge by formalizing her existing intuitions, supported at each stage by powerful automation.

At the lowest level, an IronSync developer uses an ownership type system to prove the data safety of her implementation. Oversimplifying, in an ownership type system, an *owned* value must be held (or referenced) by exactly one variable. A fast, deterministic type checker enforces this property, which IronSync, like Rust [28, 39] and other languages, in turn uses to enforce data safety, i.e., basic memory safety plus freedom from conflicting reads and writes. Our experience, and that of the Rust community, suggests using an ownership type system for such reasoning is relatively intuitive.

Going further, IronSync shows how the developer can additionally use ownership types to reason about the *logical correctness* of a thread’s local actions on data it owns. Intuitively, in any segment of code where a thread operates only on owned data, that data cannot affect or be affected by other threads. Hence, IronSync can reason about such code using *sequential* reasoning techniques and tools honed over decades of research and development. Reasoning sequentially is more intuitive for the developer as well.

Finally, the IronSync developer must connect the locally correct thread actions to global, *system-wide* correctness. To support this step, IronSync introduces the *Localized Transition System* (LTS), which abstracts each thread’s actions and the state they act upon, formalizing the intuition that in efficient concurrent programs, each thread acts only on a small fragment of the program’s global state. Using the techniques above, the developer locally proves that the LTS is a sound abstraction of their implementation. Finally, IronSync soundly abstracts the LTS into a simplified program representing the whole system. This new program (with threads, locks, and other implementation details abstracted away) is far simpler to reason about, and it connects naturally to previous automated techniques for, e.g., reasoning about asynchronous IO or distributed nodes [19, 20]. Since each step on this path is proven sound, proofs at this level also apply to the implementation.

To support the advanced read-sharing patterns found in production systems, IronSync also reuses the machinery above (with a small twist) to factor out reasoning about complex synchronization primitives, so that the developer can think about them separately from the core application logic, even if

\*Work done while at ETH Zurich

the implementation deeply entangles the two concerns.

The developer writes their implementation and performs all of the reasoning above in an extended version of the Dafny language [33] augmented with the trusted axioms and memory primitives in IronSync’s framework.

**Evaluation.** We introduce IronSync via a series of increasingly complex examples, culminating in two production-level case studies (§5). To illustrate IronSync at scale, we verify a Node Replication (NR) library that creates a linearizable NUMA-aware concurrent data structure from a black-box sequential one [9]. To show IronSync working both at scale and with prior work on crash safety [19], we verify Splinter-Cache [14], a production-scale disk-backed in-memory page cache created for use in commercial products [49].

Each case study’s performance matches its unverified production-level counterpart (§7.2), driving workloads of 5M updates/sec. with 192 threads (NR) or 3M ops/sec. (SplinterDB with verified SplinterCache), demonstrating IronSync has not impeded optimization through limited expressiveness or excessive proof burden. We also uncovered severe bugs (§7.3) in the unverified implementations.

**Limitations.** As in any verification system, the correctness of a verified IronSync program depends on the correctness of its spec, and the verification tool (Dafny [33]). Our encoding of the IronSync framework in Dafny is also trusted (although application-specific definitions are not). IronSync does not verify liveness, termination, or deadlock-freedom. We focus on data safety and functional correctness; i.e., *if* an operation returns a result, it is correct according to its spec. IronSync verifies programs against a high-level memory consistency model that distinguishes data-race-free memory from racy, sequentially consistent atomic memory. This compiles to efficient assembly on modern hardware, but it cannot exploit every optimization afforded by relaxed memory (§4.2).

**Contributions.** In summary, this paper:

1. Factors the proof of a production-scale concurrent system into intuitive reasoning steps that can each be supported with powerful automation.
2. Illustrates how the application of an ownership type system enables scalable, automated concurrent reasoning about both data safety *and* logical correctness.
3. Introduces Localized Transition Systems, which soundly connect *local* reasoning about a thread’s actions to *global* reasoning about the correctness of the full system.
4. Enables developers to verify complex, application-specific read-sharing synchronization tools in isolation from the program’s main application logic.
5. Demonstrates, via case studies, that IronSync effectively reasons about practical, complex, high-performance concurrent systems.

## 2 The Potential Pitfalls of Parallelism

To highlight the challenges of writing and reasoning about concurrent code, we begin with a simple bank application.

```
if accounts[A] ≥ amt {
  accounts[A] = accounts[A] - amt
  accounts[B] = accounts[B] + amt
}
```

Figure 1: Buggy code violating data safety

```
lock(accounts[A]);
sufficient_balance := accounts[A] ≥ amt;
unlock(accounts[A]);

if sufficient_balance {
  lock(accounts[B]);
  accounts[B] = accounts[B] + amt
  unlock(accounts[B]);

  lock(accounts[A]);
  accounts[A] = accounts[A] - amt
  unlock(accounts[A]);
}
```

Figure 2: Buggy code violating logical correctness

```
lock(accounts[A]);
lock(accounts[B]);
if accounts[A] ≥ amt {
  accounts[A] = accounts[A] - amt
  accounts[B] = accounts[B] + amt
}
unlock(accounts[A]);
unlock(accounts[B]);
```

Figure 3: Correct code (assuming that  $A < B$ , which is necessary to avoid deadlock, although proving deadlock-freedom is out-of-scope for IronSync)

This multi-threaded application maintains a list of accounts, each with an account ID and a balance, supporting one operation,  $transfer(A, B, d)$ , which moves  $d$  dollars from account  $A$  to account  $B$ .

Here, there are a handful of mistakes an inexperienced developer might make. First, they might write code as in Figure 1, which would be correct in a sequential program but critically flawed in a concurrent one, where, e.g., two different threads might both write to `accounts[A]`, one overwriting the other. In fact, it might be difficult to even fully characterize the buggy behavior on realistic hardware with weaker memory models [1, 2, 45], and in some programming languages, data races may even be undefined behavior [5, 52].

A naive fix would be to protect the code in Figure 1 with a global lock. Such a fix would be correct but embarrassingly inefficient. For efficiency, the developer might employ a finer-grained concurrency strategy by creating a lock for each account, reasoning that most transfers affect disjoint accounts.

Figure 2 uses a discipline of locking an account before reading/writing it, eliminating the *data-safety* problems above, since no other thread can simultaneously read/write the account information. Even with this fix, however, the program is still not *logically correct*: two different transfer operations might each check that account  $A$  has sufficient funds and then move forward even when  $A$  lacks the funds to complete both, leaving  $A$  with a negative balance.

Given enough debugging (or prior experience), the developer might eventually produce the code in Figure 3, which

holds locks on both accounts as it makes the transfer. How would the developer convince herself that she has finally produced a correct implementation?

She might first reason that the program is *data safe* because it holds the corresponding account lock whenever it accesses shared memory. Data safety rules out blatant data corruptions, making it feasible to reason about logical correctness.

Given data safety, she might then informally reason that holding both locks simultaneously gives the thread exclusive access to the portion of the state (accounts *A* and *B*) needed to correctly perform the transfer. Although other concurrent threads might simultaneously modify *other* program state, all such modifications are irrelevant to the transfer. Conversely, any changes the thread makes to accounts *A* and *B* must be irrelevant to any concurrent transfers, since those transfers must involve other accounts. Hence, she can *reason locally* about the correctness of the transfer implementation. Furthermore, from the perspective of the other threads, the transfer appears to occur atomically.

With IronSync, the developer formalizes her intuitions about data safety and logical correctness in a machine-checked way.

### 3 The Core IronSync Methodology

IronSync utilizes a variety of techniques, with the philosophy of using the right tool for each job. We introduce the techniques through a series of increasingly complex examples.<sup>1</sup> Here we focus on the toy banking application from §2 to illustrate IronSync’s core ideas: (1) the use of an ownership-based type system, (2) the abstraction of threads via a *localized transition system*, and (3) the way we soundly compose a *localized transition system* into a *global state machine* that can soundly reason about global properties of the full concurrent program.

In §4, we introduce increasingly sophisticated features and examples, building up to our production-level case studies in §5. We defer the formalism underpinning IronSync to §6.

#### 3.1 Achieving Data Safety in IronSync

IronSync mechanically enforces data-safety via an ownership type system. Such type systems are effective at enforcing data-safety both in unverified programming (e.g., in Rust [29]) and in verified *sequential* programming; e.g., in *Linear Dafny* [35], a version of the Dafny verification language [33] augmented with an ownership (or linear [51]) type system inspired by Rust’s. In IronSync, we extend Linear Dafny with tools for logical correctness in *concurrent* settings (3.2). First, though, we overview ownership types, explain how they enforce data safety, and how this aids in verification.

In Linear Dafny, an *owned* value must be held (or referenced) by exactly one variable. Any attempts to duplicate or drop the value are rejected by the type checker. In IronSync, this ensures that data is *uniquely owned*, and hence a

<sup>1</sup>All examples are fully verified and available in our open-source release.

thread can read or write to data it owns without interference from other threads. Owned values can, however, be stored in shared (read-only) variables; Dafny’s type checker ensures that the scope of such shared variables is contained within the scope of the originating owned variable, and that the owned variable is not modified until the shared variables expire.

```
method M(owned w: int, b: bool) returns (owned z: int)
  owned var x := w; // okay: consumes w
  owned var y := w; // error: w was already consumed
  if b {
    shared var s := x; // okay: shares x read-only
    x := x + 1; // error: borrowed value still live in s
  }
  x := x + 1; // okay: shared variable s has expired
  z := x; // okay: consumes x
```

Figure 4: Ownership in action

IronSync uses the ownership type system to ensure that code cannot read or write shared memory after it gives up permission to access it. Figure 5 shows an example of this approach in a portion of the API for an exclusive lock (which in turn is implemented and proven correct using lower-level IronSync primitives – see §4.2). The API uses owned and shared variables, as introduced above, and generic types (indicated by the type parameter <T>) as in Java or C#. Notice that the `Lock` itself is passed `shared`; hence, it can be referenced simultaneously from multiple threads, as expected of a lock. The caller obtains an owned `guard` value when it acquires the lock (`AcquireExcl`). The guard object, named after objects like C++’s `std::lock_guard` or Rust’s `RwLockWriteGuard`, is an object that exists for the duration the lock is held. Furthermore—and similarly to `RwLockWriteGuard`—the guard object provides a type-safe means to access the data being protected by the lock. That is, after the user relinquishes the guard on release (`ReleaseExcl`), the type system will reject any further attempts to use the guard to access the lock’s data.

```
method AcquireExcl<T>(shared m: Lock<T>)
  returns (owned guard: ExclGuard<T>)
method ReleaseExcl<T>(owned guard: ExclGuard<T>)
```

Figure 5: Example lock specification.

With these tools, an IronSync developer can rule out data-safety issues, because shared memory can only be accessed while holding the corresponding permission (e.g., the `ExclGuard`) from a lock (or a fancier primitive – see §4.2). Correct management of the permission is enforced by the ownership type system.

Using an ownership type system to enforce data safety is not unique to verification; e.g., this is a crucial feature of Rust. Novel to IronSync, however, is its further use of its ownership system to help the developer verify logical correctness.

#### 3.2 Local Logical Correctness

IronSync uses ownership to simplify and automate reasoning about the correctness of a thread’s actions on data it owns.

### 3.2.1 Ownership Simplifies Concurrent Correctness

With IronSync, we observe that a type-enforced ownership discipline dramatically simplifies reasoning about *correctness* in concurrent settings. To illustrate, consider this short Dafny program, using its traditional heap model (i.e., without ownership types):

```
method M(data: Data)
  modifies data
  requires data.x == 2
  ensures data.x == 3
{
  data.x := data.x + 1;
}
```

The Dafny verifier can easily prove that if the precondition in the **requires** clause holds, then the postcondition in the **ensures** clause will always hold. However, if this method were part of a concurrent program, Dafny’s standard sequential reasoning would not be sound, since another thread could change the heap-allocated data at any time.

With ownership types, however, we can rewrite it as:

```
method M(owned data: Data)
  requires data.x == 2
  ensures data.x == 3
{
  data.x := data.x + 1;
}
```

Because the type system ensures that the data value is uniquely owned, the verifier can once again make the assumption that no other thread is concurrently modifying data. Hence, the verifier can soundly use the same algorithms as before to easily verify this method.

In short, because IronSync mediates all access to shared resources via Linear Dafny’s ownership type system, we can verify the logical correctness of concurrent code operating locally on owned values by using algorithms and tools that have been honed for decades on sequential verification. In our experience, this brings a substantial boost in proof automation.

### 3.2.2 Maintaining Local Correctness with Invariants

However, even in a program that obeys an ownership discipline, one thread seldom owns a piece of data indefinitely; instead, threads hand off ownership of shared data via synchronization primitives like locks. Hence, the developer needs a mechanism to reason about what value(s) shared data may hold when a thread acquires ownership of that data.

In one such mechanism, IronSync allows the developer to reason about locked data by associating each lock with a *lock invariant*, i.e., a property of the data protected by the lock (Figure 6). The thread can *assume* the property holds when it acquires the lock, and in exchange, it must *prove* the property holds when it releases the lock. This in turn means that the next thread to take the lock may also “take” the assumption.

Again, we see the utility of ownership types: the verifier can soundly assume that the value of `guard.v` is not being modified by other threads while the lock is held, since the

```
function is_even(x: int) { x % 2 == 0 }

// Create a new lock with an invariant that its value
// is always even. Supply a compliant initial value (2).
shared var m := NewLock(2, is_even);
owned var guard := AcquireExcl(m);
assert guard.v % 2 == 0; // Passes
guard.v := guard.v + 1;
// ReleaseExcl(guard); // error: violates invariant `is_even`
guard.v := guard.v + 1;
ReleaseExcl(guard); // okay: satisfies invariant `is_even`
// guard.v := guard.v + 1; // error: guard already consumed
// ReleaseExcl(guard); // error: guard already consumed
```

Figure 6: Example of a lock invariant. Any commented line, if uncommented, would give the resulting error. Note that `ReleaseExcl` consumes the **owned** guard object, so it cannot be used later.

thread holding the lock uniquely owns the guard. Hence, we can continue to use the efficient sequential verification techniques from §3.2.1 to prove the correctness of a thread’s actions on data it obtains from other threads.

### 3.3 From Local to Global Logical Correctness

We have shown IronSync’s use of ownership to establish data safety and the logical correctness of a thread’s local actions on data it owns. The final step is to explain how threads cooperate to achieve a global (program-wide) logical goal.

This final step would be trivial in a program that protects all of its state with a global lock. In that case, proofs of local correctness would suffice for global correctness, since we would simply specify the program’s expected behavior via an invariant on the global lock. Such an approach would be correct but embarrassingly inefficient.

For better efficiency, the developer might employ a finer-grained concurrency strategy using many local locks. At this point, proving a global property directly becomes difficult since no thread has a global view of the system.

For such systems, IronSync provides the developer with tools to build up to global logical correctness in stages. First, the developer creates a simplified abstract model of the threads’ local actions (§3.3.1). Second, the developer uses the techniques from §3.2 to *locally* prove that each thread’s implementation can be soundly abstracted by the model (§3.3.2). Finally, IronSync reassembles the model’s local actions into a single global abstraction of the program (§3.3.3). At this level, the developer can reason about global properties of the system, without the complexity of low-level details like thread interleaving, memory management, or even locking strategy. Because each step above is proven sound, the global correctness properties hold for the implementation as well.

#### 3.3.1 Abstracting Local Actions

As a first step towards proving global correctness, an IronSync developer proves that their implementation corresponds to a simpler program, where threads, locks, and other implementation details are entirely abstracted away. Reasoning about the correctness of the new program is much simpler.

Returning to our bank, we would like the abstract program to operate over a simple state representing *all* of the accounts:

```
State: {accounts: map<AccountId, Balance>}
```

The challenge is to connect the application’s concrete state (e.g., as stored in array) to the abstract state above.

As discussed earlier, once the implementation commits to a fine-grained, per-account locking strategy (as in Figure 3), it becomes difficult for an individual thread to reason about the global concrete state. After all, any given thread holds at most two locks at a time, and hence it cannot authoritatively reason about the state of the rest of the accounts.

Hence, IronSync introduces the concept of a *Localized Transition System (LTS)* (formally defined in §6.1), which breaks the abstract program’s state into *shards* that match the “granularity” of the concrete implementation. The LTS then defines transitions that apply *locally* to only a subset of the shards. These transitions capture the work a thread performs on its local view of the state. We can later (§3.3.3) reassemble these local views into a global view.

Figure 7 shows the LTS definition for our bank example. The LTS defines a shard to be the information for a single account, matching the granularity of the locking scheme in Figure 3. The localized transition function `transfer` says that a thread that holds two shards (the “pre-state shards”), one for *A* and one for *B*, where *A*’s shard holds at least *amt* dollars, can exchange those shards for a new pair of shards (the “post-state shards”) with updated balances. This definition directly captures the intuition that a transfer only affects (and is affected by) the state of the two accounts involved. All other accounts (shards) are irrelevant.

Notice the abstraction the LTS provides: the update to the shards occurs atomically without any explicit mention of particular synchronization primitives. For complex systems, this simplification makes the application vastly easier to analyze.

In designing their LTS, a developer will typically choose a “granularity” for their shards and actions that matches the granularity of the implementation’s concurrency strategy. As we discuss below, this makes it feasible to use the local correctness techniques from §3.2 to tie the implementation to the LTS. Choosing a coarser granularity would complicate the proof of this connection, while choosing a finer granularity would introduce unnecessary complexity into proofs about the global system (§3.3.3).

In practice, this means that different programs will use different LTS designs. A program with a modest concurrency strategy can afford to use coarse-grained shards, doing most of the proof work “locally” using techniques from §3.2. A program with an aggressive fine-grained concurrency strategy will use finer-grained shards, and thus put more work into spanning the gap from the LTS to the global system.

### 3.3.2 Tying the Concrete Implementation to the LTS

To make use of the abstraction provided by the LTS, we must soundly (i.e., in a machine-checked way) establish that

```
Shard: {id: AccountId, balance: Balance}

localized transition transfer(A, B, amt):
  for some (bal_1, bal_2) where bal_1 ≥ amt,
  pre-state shards:
    {id: A, balance: bal_1}
    {id: B, balance: bal_2}
  post-state shards:
    {id: A, balance: bal_1 - amt},
    {id: B, balance: bal_2 + amt}
```

Figure 7: Bank LTS

the implementation’s behavior matches that of the LTS; thus properties proved about the LTS will meaningfully apply to the real implementation.

A key idea in IronSync is that we tie the implementation to the LTS by explicitly manifesting and manipulating the state shards of the LTS *abstraction* in the *implementation* code. The code then uses the local correctness techniques from §3.2 to prove that its manipulation of its concrete state correctly reflects LTS-defined actions on the corresponding shards.

In more detail, the implementation holds LTS shards in owned *ghost* variables. Ghost variables act like normal variables, but they serve only as “proof constructs” and are absent from the compiled executable. Making the shards owned ensures that they cannot be duplicated, preventing the implementation from holding on to two potentially contradictory shards (e.g., one that claims account *A* holds *v* dollars and another that claims it holds *v + x* dollars). Indeed, unique ownership prevents those shards from existing anywhere in the system, even spread across different threads.

In practice, an IronSync developer will typically embed the ghost shards into their implementation and tie the ghost state to physical state via invariants. The top of Figure 8 illustrates this idea for our bank example. The implementation stores each account’s concrete balance in an `Entry` datatype (similar to a `struct`) that also holds a ghost owned shard defined by the LTS. The account entries live in a sequence, each protected with a lock with an invariant that the ghost state in the shard matches the physical state of the implementation.

Looking at this program, a reader might understandably wonder what is accomplished by redundantly “doubling up” the state into a physical account balance and a ghost account balance. The key is that by doing so, we establish the formal correspondence between the concrete implementation state and the abstract state of the LTS.

The final step is to connect the implementation’s *actions* to the transitions in the LTS. To do so, IronSync provides a trusted, axiomatic API for the ghost shards, with API calls that update the shards by performing valid transitions of the verified LTS. Each call *consumes* the old owned shards, and *produces* new owned shards. As shown in Figure 8, this means that during a transfer, the developer can update the physical state of the account balances and then atomically exchange (via `LTS_transition`) the old shards for a new pair representing the LTS state after performing the abstract transfer transition. These new shards match the concrete

```

datatype Entry = Entry(bal: int, ghost owned shard: Shard)

shared var accts : seq<Lock<Entry>> where
  ∀i, accts[i] has lock invariant: (entry: Entry)
    ⇒ entry.shard == Shard({id: i, balance: entry.bal})

method DoTransfer(A: AccountId, B: AccountId, amt: Dollars)
  // Acquire locks on both accounts.
  owned var guardA := AcquireExcl(accts[A]); lock A
  owned var guardB := AcquireExcl(accts[B]); lock B

  // These follow from the lock invariant.
  assert guardA.v.shard.bal == guardA.v.bal;
  assert guardB.v.shard.bal == guardB.v.bal;

  // Physically move `amt` from one account to the other.
  guardA.v.bal -= amt; debit A
  guardB.v.bal += amt; credit B

  // Invariant is temporarily broken.
  assert guardA.v.shard.bal != guardA.v.bal;

  // Perform the transfer transition of the LTS
  // as a ghost operation.
  guardA.v.shard, guardB.v.shard := ghost transition
    LTS_transition("transfer", guardA.v.shard, guardB.v.shard, amt);

  // Lock invariants have been restored.
  assert guardA.v.shard.bal == guardA.v.bal;
  assert guardB.v.shard.bal == guardB.v.bal;

  // We can now release the locks.
  ReleaseExcl(guardA); unlock A
  ReleaseExcl(guardB); unlock B

```

Figure 8: An implementation of our bank example. Figure 9 illustrates one possible execution.

state, satisfying the corresponding lock invariants and hence allowing the locks to be released.

Hence, we can soundly reason about the implementation’s concrete actions on concrete state using the LTS’s abstract transitions on its abstract shards. IronSync’s trusted API allows the programmer to make this connection locally in the implementation code by showing that a sequence of physical steps are consistent with the “large” atomic steps of the LTS.

We illustrate this process in Figure 9a, which shows one invocation of the DoTransfer method from Figure 8. The illustration depicts the relationship between the ghost shards of the LTS (dashed blue boxes) and the physical values stored in memory. Time runs along the x-axis; each vertical gradation represents a fine-grained period, such as a single instruction.

Initially, Thread 2 holds no locks. It receives a client request to transfer \$7 from *A* to *B*. The developer knows that the relevant LTS transition requires atomically interacting with the *A* and *B* shards, so the thread’s first step is to acquire lock *A*. Lock acquisition brings into Thread 2’s scope both permission to observe the physical value of *A* (via a pointer; the physical value does not move from the heap, of course) as well as the ghost shard for *A*.

Later, Thread 2 likewise acquires the physical *B* state and its ghost shard. The ghost LTS transition requires that shard *A* has a value greater than the \$7 transfer. Thread 2 confirms this by checking the physical value of *A*, which it knows (from the lock invariant) matches the ghost shard for *A*.

Then Thread 2 debits \$7 from the physical value of *A*. Note that the ghost shard has not changed; no LTS transition allows debiting *A* all by itself. The lock invariant is temporarily false, which is fine, since Thread 2 still holds the lock. Next, Thread 2 credits \$7 to the physical value of *B*.

Thread 2 cannot release the locks until it restores their invariants. Hence, it invokes transfer(*A*,*B*,7), the ghost LTS transition from Figure 7, which consumes the shards *A* : 9, *B* : 1. As a ghost transition, this happens instantaneously. The transition yields (by postcondition) the new shards *A* : 2, *B* : 8, which the thread proves match the corresponding physical values. Having restored the lock invariants, the thread completes its work by releasing its locks, one at a time.

For simplicity, we do not illustrate any activity on Thread 1. However, observe that it could, with any interleaving, acquire noncontending locks and interact with their associated state.

### 3.3.3 Global Logical Correctness With the GSM

To reason about the logical correctness of the entire multi-threaded program, we reassemble the shards of the LTS into a representation of the program’s global state, and similarly, we translate the local transitions of the LTS into global transitions over the global state. We call the result (formally defined in §6.1) a Global State Machine (GSM).

Figure 10 shows the developer’s definition of the GSM for the bank example. The State now holds all of the accounts. The transfer transition is an atomic step that reads and writes the global state. As in Figure 9b, the GSM’s state only changes—atomically—at the moment Thread 2 invokes the ghost LTS transition. Hence, regardless of low-level thread interleaving, from GSM’s global perspective, the state advances through a sequence of atomic global transitions, even as the physical values are updated asynchronously. This greatly simplifies reasoning about global correctness.

Indeed, since the GSM is a standard state machine, we can employ standard reasoning techniques honed by decades worth of research [32], including prior work automating such reasoning [19, 20]. For example, we can easily prove that account balances never go negative, or that the total amount of money across all accounts is always preserved. In both cases, the proof proceeds by showing that the property holds in an initial state, and then showing that if it holds before an atomic transition, then it also holds afterwards. For the bank example, these proofs are produced fully automatically.

In contrast, it would be impossible to talk about such global properties from within the implementation, where a given thread only ever holds at most two locks.

**Soundly Assembling the GSM.** To compose the LTS shards into the GSM’s state, the IronSync developer must declare a datatype that can hold one or more shards. §6.1 discusses the formal rules the datatype must obey, but a common pattern is to use a (partial) dictionary from an application-specific identifier (e.g., an account ID) to the corresponding shard. The developer then proves the soundness of each LTS

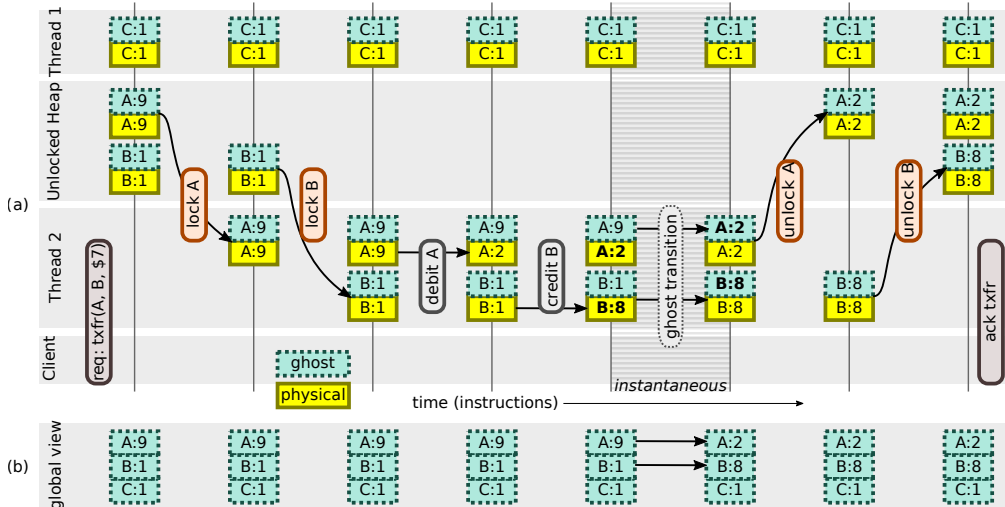

Figure 9: (a) Ghost values (dashed cyan boxes) travel alongside physical values (solid yellow). Ghost values are atomically updated according to the LTS rules (see §3.3.2 for details). (b) LTS transitions, in turn, are abstracted into the GSM (§3.3.3).

State: {accounts: map<AccountId, Balance>}

```
atomic transition transfer(A, B, x):
  if state.accounts[A] ≥ x {
    state.accounts[A] -= x;
    state.accounts[B] += x;
  }
```

Figure 10: Bank GSM

transition, with respect to this dictionary. Oversimplifying, this proof proceeds as follows. We imagine starting with a dictionary that contains at least the transition’s incoming shards (in Figure 7, the initial account information for A and B), and possibly some others as well. We remove the *incoming* shards from the dictionary and hand them to the localized transition. We then try to combine the *outgoing* shards with the dictionary. If this results in a well-formed dictionary (i.e., no keys are duplicated), the transition is valid and can be lifted to an atomic transition of the GSM (as shown in Figure 10).

## 4 Advanced IronSync Techniques

Verification of real concurrent programs often has additional challenges beyond those of our “toy” banking example. This section illustrates, via examples, IronSync’s solutions to two situations that arise in a real concurrent system:

- An abstraction of the program state (like the GSM) might still not be abstract enough to be a useful specification.
- Developers employ custom synchronization tools (beyond simple locks), plus optimizations like read-sharing.

We apply these solutions to the complex case studies in §5.

### 4.1 Specification via Refinement

For trivial programs like our bank, one might accept an invariant as the definition of correctness. For substantial programs, we prefer to express correctness via a trusted specification that precisely defines the program’s expected behavior, and then prove that the implementation refines it; i.e., every execution

Shard: {idx: nat, entry: (Key, Value)?}

```
localized transition insert(key, value):
  for some (i, j, k̄, v̄)
    where i = hash(key) and key ∉ {ki, ..., kj}
  pre-state shards:
    { for m = i .. j | {idx: m, entry: (km, vm) } }
    {idx: j+1, entry: null} // First empty slot
  post-state shards:
    { for m = i .. j | {idx: m, entry: (km, vm) } }
    {idx: j+1, entry: (key, value)} // Holds (key, value)
```

Figure 11: A Hash Table LTS Transition that inserts a new (key, value) pair at index j+1; the other shards are unmodified, but serve to justify that j+1 is the correct index.

of the implementation is an execution of the spec.

A hash table’s spec, for example, is a simple dictionary, succinctly expressible in 10-20 lines. Its implementation obeys the spec while providing good performance. For instance, a Robin Hood Hash Table (RHHT) [10] stores key-value pairs in an array and locates keys via *linear-probing* [30]: given a key, probing starts with the key’s hash index and continues sequentially until the key or an empty slot is found.

To exploit concurrency, a developer might add multiple threads and create a lock for each slot in the array. A straightforward concurrency strategy would have a thread lock the entire range of slots needed for each linear probe, complete its operation, and then release the locks. To express this strategy in IronSync, per §3, the developer defines an LTS (Figure 11) with shards at the granularity of the locking scheme: each shard of the LTS represents a single array slot.

Once the LTS is proven sound, the developer uses IronSync to reassemble the LTS into the GSM comprising the full sequence of optionally-occupied slots. They then prove that the GSM refines the spec by establishing invariants. One RHHT invariant is that each key in the table can be found in a contiguous range of non-empty slots starting from the key’s hash index. Proving refinement via such invariants is

straightforward using standard techniques [32] previously encoded in Dafny [19, 20].

## 4.2 Lower-Level Memory Primitives

The previous examples are built from locks, which help maintain data safety. In practice, many advanced concurrent systems do not use locks, but rather custom synchronization tools built from lower-level primitives. Supporting such advanced systems is a core IronSync goal, and hence IronSync makes these lower-level primitives its base and then verifiably constructs locks and other synchronization tools from them. In this section, we introduce IronSync’s primitives and, as a warm-up, see how they let us verify a basic mutual-exclusion lock.

Consider a lock implemented with two fields: a boolean *flag* indicating whether the lock is taken, and a slot for the *data* being protected by the lock. Defining operations on these fields must be done in terms of a *memory-ordering model*, which dictates when different threads may disagree on the ordering of reads and writes. Developers must take care to use special, slower instructions to synchronize threads when necessary, and such subtleties are notoriously difficult to handle correctly, especially since the details depend on the hardware platform (e.g., x86-TSO [45] or ARM [1]).

IronSync’s memory model is based on the C++11 memory model [5, 7], which abstracts over these hardware differences by providing a distinction between *non-atomic* memory (the most common, “normal” memory) and *atomic* memory. Non-atomic memory access compiles to fast instructions, while atomic memory (depending on how it is used) may compile to slower instructions, possibly involving memory fences. To make this dichotomy sound, the C++ model requires all non-atomic accesses be data-race-free (a burden placed on the programmer); however, the atomic memory allows contended access. In the lock example, multiple threads might contend to access the *flag*, but the thread that wins will have exclusive access to the *data* field, making its accesses data-race-free.

IronSync supports data-race-free non-atomic memory and sequentially-consistent atomic memory. Specifically, it takes advantage of the C++11 memory model’s *DRF-SC property*, which states that if all non-SC memory accesses are data-race-free, then the entire execution is sequentially-consistent. By allowing data-race-free memory for the common cases, IronSync takes advantage of much of the speed afforded by modern hardware, although it does not take advantage of the weaker atomic memory orderings (e.g., *release-acquire* ordering or *relaxed*).

In particular, IronSync supports these two modes of shared-memory-access through two of its trusted primitives, `Atomic` for word-sized atomic memory and `Cell<T>` for non-atomic memory storing arbitrary types *T*. To ensure that access to a shared `Cell<T>` is data-race-free, IronSync requires a thread to own a special ghost object of type `Permission<T>` for reading and writing. Meanwhile, IronSync treats the sequentially-

consistent atomics as if they were “virtual locks” that can be unlocked for a single atomic operation; they can then use lock invariants, as before, to verify code that manipulates ghost objects in the virtual lock. `Atomic` supports common atomic operations, like compare-and-swap and atomic addition.

With these tools, the developer can verify a lock as follows: they declare the *flag* field as an `Atomic` and the *data* field as a `Cell`. They store the ghost `Permission` object for the `Cell` in *flag*’s virtual lock. By reading and writing to *flag* (e.g., with an atomic compare-and-swap), threads can transfer ownership of the `Permission`, allowing them to access the *data* field in a data-race-free manner. This process is verified by IronSync, which checks that the invariant on the virtual lock is maintained.

## 4.3 Read Sharing

Crucially, data-race-freedom does not preclude all simultaneous access. While it prohibits a write from occurring simultaneously with a read or another write, it does permit multiple simultaneous readers. This read-sharing is crucial for performance in many applications; however, to make use of it, the developer must still ensure that threads obey some single-writer, multiple-reader protocol. In such a protocol, the developer ensures that there can be a single writer or multiple readers at any given time, but never both at the same time (and of course never more than one writer).

The challenge with read-sharing protocols is that there is no optimal way of accounting for the shared state. For example, a particularly common protocol uses reference-counting, e.g., in a reader-writer lock, but even here, there is no universal way to implement a reader-writer lock. Our case studies (§5), for example, employ two different custom-built reference-counting-based locks, and locks aren’t even the end of the story. Our NR case study (§5.1) uses a lock-free cyclic buffer, where multiple threads share read-access to entries, and where the safety is guaranteed by a protocol of head and tail pointers.

In IronSync, the developer can implement and verify a read-sharing protocol, including any of the above, by designing a particular kind of LTS, which we call a *guard protocol*, and proving that it enforces safe access to shared state. A guard protocol is an LTS whose state has an explicit notion of a stored (ghost) object, along with a notion of depositing and withdrawing that object. Intuitively, the program begins with a unique reference to an object (e.g., the ghost `Permission` for a `Cell` – see §4.2). To create read-shared references that it can give to other threads, the program “deposits” the object into the guard protocol, and in exchange it can obtain one or more *guards*. A guard is simply an LTS state shard that acts as a “witness” that the object has been deposited (and not yet withdrawn). Once all the guards (i.e., read-shared references) are returned, IronSync allows the program to “withdraw” the reference from the LTS and use it once again for mutation.

To demonstrate the soundness of their guard protocol, the library developer must show that it satisfies two obligations.

First, they show that guard shards only exist when an object has been deposited (and not yet withdrawn). This prevents the library from synthesizing bogus read-shared references. Second, they show that the LTS’ withdrawal transition only occurs when an object is in fact deposited and there are no outstanding guards.

Once the guard protocol is proven sound, IronSync provides the library developer with an extended version of the trusted shard API from §3.3.2. Recall that the standard API consumes and produces owned shards. The API for guard protocols, however, allows a thread holding a read guard to acquire a shared version of the protected data; e.g., a shared `Permission` for a `Cell`, which the `Cell` API requires for read access to its concrete memory, but which doesn’t suffice to use the API for writing. Hence, the developer can ergonomically manipulate shared data using Dafny’s shared variables, with the assurance that all accesses are data-race free.

Crucially, IronSync’s general approach to read sharing enables a developer to devise protocols that are drastically different from a read/write lock. For example, in the cyclic buffer (§5.1), threads read entries (via ghost guard objects) and use a head pointer to indicate when they are done; other threads look at these head pointers to determine when it is safe to garbage collect the entries and overwrite them (requiring a withdraw).

## 5 Case Studies

IronSync, we have seen, comprises a collection of tools: (ghost) ownership types, LTS abstraction, state-machine refinement, and automated verification. To test that this collection suffices to verify modern production-scale systems (i.e., systems notable for their performance, which they achieve through non-trivial concurrency patterns), we select two such systems and produce verified implementations within IronSync. These particular systems were chosen, in part, because there was independent interest in verifying their correctness from the systems’ designers. We compare our case studies to those in prior work in §9.

By producing implementations that match the originals in design and performance (§7), we show that writing a system in IronSync does not sacrifice performance-critical concurrency patterns. Of course, our implementations are not identical to the originals: ours are written in Dafny (and compiled to machine-generated C++ code), and they make a few minor deviations from the originals (§7.2). Nonetheless, the exercise does, as a bonus, yield some insight into the originals (§7.3).

**Overview.** Both case studies are complex; for each, correctness depends on myriad interlocking moving parts. Hence, we show how an IronSync developer divides the proof work into manageable subtasks, and chooses the right IronSync tool for each.

Specifically, NR (§5.1) shows how to pull together all the IronSync features discussed earlier. With SplinterCache (§5.2), we also verify the program’s use of an external disk.

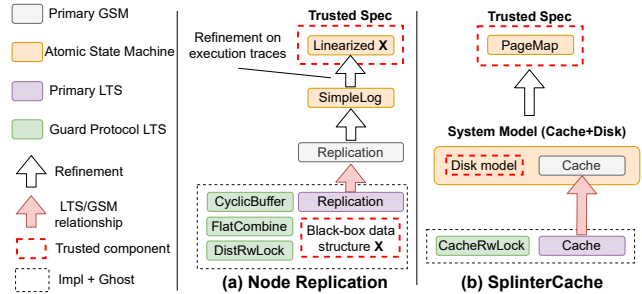

Figure 12: Proof architecture of our case studies.

**Common Architecture.** Each case study follows a similar high-level structure. Each has a *primary LTS* (and a corresponding GSM), which is used, via state-machine refinement (§4.1), to establish that the program meets its specification. In addition, each program uses complex synchronization logic that makes data safety challenging, so each case study also uses several secondary LTSes as guard protocols (§4.3). Figure 12 summarizes the architectures for the case studies in terms of these components.

### 5.1 Node Replication NR

NR [9] is a concurrency library that transforms a black-box, sequential data structure into a linearizable, NUMA-aware concurrent version. NR works by replicating the sequential data structure on each NUMA node, using an operation log to maintain consistency. Replicas benefit from read concurrency using a reader-writer lock designed to minimize reader contention [50] and from write concurrency using *flat combining* [22], which batches operations from multiple threads to be executed by a single *combiner* thread. The combiner appends the batched operations to the log; other nodes read the log and update their local replica copies. The original, unverified NR implementation is ~1000 lines of Rust. NR has recently been adopted by NrOS [6], which uses it to implement scalable versions of a wide range of OS subsystems.

**Verification Objective.** Our verified implementation also takes a user-provided black-box data structure, this time one with a functional spec. Verified NR produces the replicated data structure *and* a proof that this replicated system meets the same functional spec *linearizably*.

**Proof Overview.** As in our earlier examples, we can coarsely divide our tasks into data safety and logical correctness. In some places, the reference implementation uses Rust’s unsafe code, so these parts pose challenges for our verified implementation. In Rust, unsafe means that the code foregoes Rust’s usual safe aliasing checks and places the burden of correctness on the programmer. In IronSync, this means that we cannot (solely) rely on the ownership type system to ensure data safety. Luckily, IronSync has a verified alternative: the guard protocol.

As an example, consider the cyclic buffer at the center of NR’s coordination, used to broadcast messages from one node to all other nodes. Using a stringent protocol of head and tail

pointers, NR ensures that each node reads each message after it is written but before it is garbage collected, and further, that these reads and writes are properly synchronized. Notice how this custom protocol of head and tail pointers is used in place of a general utility for safe data access (like a mutex). Figure 13 shows pseudocode for parts of this protocol, delineating the read sections and write sections for buffer messages. Data safety, here, approximately amounts to saying that the write section never overlaps any another section. This read-sharing pattern is exactly what guard protocols are designed to support. We can construct such a protocol by identifying the instructions relevant to data safety (marked ★ in Figure 13) and abstracting them into an LTS.

NR has two more places where we need to do something similar. One is a specialized lock that protects the per-node replicas. These locks are designed with multiple reference counters to reduce thread contention; using a guard protocol, we can verify the lock and provide an API similar to the lock API discussed in §4.3. Finally, NR uses a flat-combining algorithm, and so we must reason about the synchronization of data between a client thread and a combiner thread.

With the three guard protocols, DISTRWLOCK, CYCLICBUFFER, and FLATCOMBINE to “patch up” holes in the ownership type system, the only remaining task is to prove a linearizable specification. We use an LTS, REPLICATION, to track (i) all in-progress updates and reads, (ii) the states of node-local replicas, (iii) the full history of event messages, and (iv) version numbers for the replicas. Since so much of the synchronization logic is already handled by the guard protocols, the LTS abstraction is dramatically simpler than the NR system as a whole: we have relegated entire subsystems to being “mere implementation details.”

Now, from REPLICATION, we can construct the GSM as an abstraction of the global system behavior. Next, we need to establish a state machine refinement to a linearizable specification. This is challenging because REPLICATION has *future-dependent linearization points*; hence, we cannot prove that REPLICATION refines a linearized state machine with a single-state abstraction function. Instead, we have to prove a theorem operating over arbitrary execution traces. To simplify this task, we split it into two steps: first we prove, via a single-state abstraction function, that REPLICATION’s GSM refines a simpler state machine, SIMPLELOG, which only tracks a log and the index of the latest linearized operation. Abstracting out replicas makes SIMPLELOG much easier to analyze, and the theorem over execution traces becomes tractable.

Notice that in Figure 13, the CYCLICBUFFER and REPLICATION subsystems are heavily interleaved, with some instructions even being part of both. We discuss this in §8.

## 5.2 SplinterCache

*SplinterCache* is a production-grade in-memory page cache used by the key-value store SplinterDB [14], which was created for use in VMware’s vSAN [49]. SplinterCache is built

```

fn append(ops):
  tail := globalTail;
  if tail + ops.length > globalHead + SIZE:
    wait and retry;
  compare_and_swap(globalTail, tail, tail + ops.length); ★ ■

  for i in 0 .. ops.length:
    j := (tail + i) % SIZE;
    live_bit := ((tail + i) / SIZE) % 2;
    log[j].op = ops[i]; // Non-atomic write ★
    log[j].alive = live_bit; // Synchronizing write ★

fn dispatch():
  head := nodeLocalVars.localHead; ★ ■
  tail := globalTail; ★ ■
  for i in head .. tail:
    j := i % SIZE;
    live_bit := (i / SIZE) % 2;
    wait until:
      log[j].alive == live_bit; // Synchronizing read ★
    op := log[j].op; // Non-atomic read ★
    applyUpdateToReplica(op);
    atomic_max(maxReplicaVersion, tail);
    nodeLocalVars.localHead := tail; ★ ■

```

Figure 13: Pseudocode of key NR algorithms, omitting ghost shards. Shared variables are **bold** for atomics and *italics* for non-atomics. ★ is code relevant to CYCLICBUFFER; ■ to REPLICATION. Ranges show where it is safe to read and write `log[j].op`; CYCLICBUFFER proves disjointness.

for loads where it may have 100GiB of RAM available and for use with low-latency IO devices. Clients can acquire a lock (reader or writer) on a disk page by its address, and the cache abstracts the details from the client. Internally, it loads that page into memory if necessary, and it handles writeback and eviction. Its optimizations include prefetching and batched IOs. It attempts to flush pages to disk before they need to be evicted. The reference code is ~ 2000 lines of C.

**Verification Objective.** We characterize the behavior of the cache operating together with an external disk, using a trusted model of the disk. Our high-level spec, PAGEMAP, maps each block address to two 4KiB pages, an on-disk and an in-memory version. The system may nondeterministically overwrite the on-disk version with the in-memory one.

A cache makes weaker promises than a key-value store or file system, which might offer snapshot consistency. However, this doubled-up mapping spec still constrains behavior in the event of a crash, demonstrating how IronSync programs can integrate with prior approaches to verifying crash safety [19].

**Proof Overview.** Once again, we divide our proof into data safety and logical correctness.

The SplinterCache uses a complex locking scheme to protect the in-memory cached pages. The cache implementation needs to acquire a write lock to write to a page or a read lock to read from a page, but there are some subtleties: even if the client intends to only read a page, the cache may still need to load it from disk, which means writing the contents into memory, which requires a write lock on the memory page.

For efficiency’s sake, the locking protocol has a variety of special states for handling situations like the above. More specifically, the lock has bit flags for states (not all mutually exclusive): (i) `WriteBack`: the page is being written to disk, effectively an extra read-lock; (ii) `Loading`: the page is being

Figure 14: (a) Left, transitions for the lock status of a single cache entry in CACHERWLOCK. Dashed ovals represent read-locked states; double ovals represent write-locked states. (b) Right, transitions for the status of a single cache entry in CACHE. Both figures are simplified abstractions.

loaded from disk; (iii) Free: this entry is not assigned to a disk page; and (iv) Claimed: the claiming thread has the exclusive right to upgrade a read lock to a write lock. These states allow optimizations; e.g., an entry marked Free cannot be locked, so a thread that loads a page into a free entry can skip the usual check that there are no readers. Even beyond these states, the lock has the same multiple-reference-counters optimization as NR’s DISTRWLOCK described earlier. Figure 14a summarizes all the states.

As usual, we handle the reader-writer lock with a guard protocol. This leaves logical correctness, which we prove with the CACHE LTS. It tracks the information needed to prove consistency properties between cache and disk; e.g., it maintains a two-way mapping between cache entries (indexed by *entry numbers*) and disk pages (indexed by *page numbers*). It tracks the status of each entry, which may be either *empty* (i.e., not corresponding to any page), *loading*, *clean*, *dirty*, or *writeback-in-progress*. This is summarized in Figure 14b.

Next, we can construct the CACHE GSM as a sound abstraction of our implementation. We then apply previous techniques [19] to integrate CACHE with a (trusted) model of the asynchronous disk. This yields a state machine CACHE+DISK which abstracts the behavior of the entire system. Here, we prove relevant invariants: the bidirectional mapping is self-consistent; outstanding IO requests agree with the *loading* and *writeback* statuses; an in-memory clean page matches the on-disk page. We finally prove that CACHE+DISK refines PAGEMAP as the high-level specification.

## 6 Formalism and Implementation

IronSync’s Trusted Computing Base comprises the following:

- A trusted programming language and verifier.
- A trusted library of shared-memory primitives (§4.2).
- A trusted library of formal definitions and axioms for LTSes, guard protocols, and state machine refinement.

**The Language.** IronSync is built on Linear Dafny [35]; we added ghost ownership types to its existing (non-ghost) ownership types, and we also supply `Atomic` and `Cell` types (§4.2) for shared memory. To prevent unsoundness with concurrent threads, IronSync disallows Dafny’s traditional support for aliasable mutable objects.

IronSync code compiles via Dafny’s C++ backend, and uses `std::atomic` to implement IronSync’s `Atomic`. Therefore, the C++ compiler is also part of the trusted toolchain, notably including its mapping from C++’s memory ordering model to the hardware’s. Specifically, we rely on the compiler to insert memory fences appropriately for any `Atomic` memory locations, thereby providing the sequential consistency guarantees for the language runtime.

### 6.1 Formal Definitions

We briefly summarize the mathematical formalism underpinning IronSync’s LTS (§3.3.1) and the guard protocol (§4.3). These definitions are exposed to the IronSync developer via an axiomatically trusted library in Dafny.

IronSync introduces LTSes to formalize the idea that a transition updates and depends on only a portion of the state, while the rest of the state is *irrelevant*. This formalization encodes shards as elements of a *monoid*, an established tool from concurrency reasoning from separation logic [26].

**Definition 1 (LTS: Localized Transition System)** *A Localized Transition System is a triple  $(M, \text{Init}, \tau_{\text{local}})$ . Here,  $M$  is a commutative monoid, that is, a set with a composition operator  $(\cdot) : M \times M \rightarrow M$  which is associative and commutative, and with a unit element  $\epsilon \in M$  (i.e.,  $\forall m \in M. m \cdot \epsilon = m$ ). Meanwhile,  $\text{Init} : M \rightarrow \text{bool}$  represents valid initial states, and  $\tau_{\text{local}} : M \times M \rightarrow \text{bool}$  is a “local transition function.”*

This essentially says that an element  $m \in M$  represents partial information about a state of the system, while the composition of two elements gives us a way to combine the partial information about different components. Thus a transition  $\tau$  makes sense even on pieces of partial information. In the bank example discussed at the end of §3.3.3, each  $m$  is a (partial) dictionary from account IDs to account info.

The IronSync framework then defines the global state machine (GSM) in terms of the LTS by taking elements of  $m$  that represent a complete view of the system (e.g., a dictionary containing all of the bank’s accounts). Specifically, we define a transition on a complete state by splitting it in two: one part to be operated on, and one part that is irrelevant to the transition, and then performing the transition on the first part:

**Definition 2 (GSM: Global State Machine)** *Given an LTS  $(M, \text{Init}, \tau_{\text{local}})$ , we define a global transition function,*

$$\tau_{\text{global}}(s, s') \triangleq \exists d, d', e. \tau_{\text{local}}(d, d') \wedge (s = d \cdot e) \wedge (s' = d' \cdot e).$$

*We call  $(M, \text{Init}, \tau_{\text{global}})$  the Global State Machine.*

In the bank example,  $d$  would be a dictionary holding keys for the two accounts involved in a transfer, and  $e$  would be a dictionary holding all of the other accounts.

### 6.2 Guard Protocols

A Guard Protocol consists of (i) an LTS with a notion of ghost objects that may be *deposited* or *withdrawn*, and (ii) a notion of a *guard*, a state shard that locally guarantees a particular

ghost object is deposited. Concretely, a Guard Protocol is defined by its relation to the following state machine that formalizes “deposited state.”

**Definition 3 (Safety-Deposit State Machine)** *Given a set  $T$ , a Safety-Deposit State Machine is a state machine defined over the state  $T \cup \{\text{empty}\}$ , with transitions, for all  $t \in T$ :*

$$\begin{array}{lcl} \text{empty} & \xrightarrow{\text{deposit}(t)} & t \\ & & t \xrightarrow{\text{withdraw}(t)} \text{empty} \\ \text{empty} & \xrightarrow{\text{internal}} & \text{empty} \\ & & t \xrightarrow{\text{internal}} t \end{array}$$

Here,  $T$  is the set of ghost objects that can be deposited.

A developer defines an LTS for their Guard Protocol and proves it sound based on the definition below, and in exchange, IronSync gives them access to a set of ghost shards representing their protocol: a thread can deposit ghost objects from the set  $T$  into the protocol and withdraw them later. Crucially, the trusted IronSync API from §4.3 allows code that holds a guard shard to obtain a **shared** copy of the deposited value  $t$ , which allows the code to ergonomically and soundly manipulate read-shared data.

Formally, we define a Guard Protocol as follows.

**Definition 4 (Guard Protocol)** *Given a set  $T$ , a Guard Protocol is an LTS that has three transition types,  $(M, \text{Init}, \tau_{\text{local}}^{\text{internal}}, \tau_{\text{local}}^{\text{deposit}(t)}, \tau_{\text{local}}^{\text{withdraw}(t)})$ ; an invariant  $\text{Inv} : M \rightarrow \text{bool}$ ; and an abstraction function  $\text{Abs} : M \rightarrow T \cup \{\text{empty}\}$ . We define  $\tau_{\text{global}}^{\text{internal}}, \tau_{\text{global}}^{\text{deposit}(t)}, \tau_{\text{global}}^{\text{withdraw}(t)}$  of the GSM as in Def. 2.*

We say the Guard Protocol is sound if  $\text{Inv}$  is an inductive invariant on the GSM, i.e.,  $\forall$  transition labels  $\ell$ :

$$\begin{array}{l} \forall m \in M. \text{Init}(m) \implies \text{Inv}(m) \\ \forall m, m' \in M. \text{Inv}(m) \wedge \tau_{\text{global}}^{\ell}(m, m') \implies \text{Inv}(m') \end{array}$$

and if the GSM, as interpreted by  $\text{Abs}$ , refines the Safety-Deposit State Machine. Given a sound Guard Protocol, we say that  $g \in M$  is a read-guard of  $t \in T$  if,

$$\forall b \in M. \text{Inv}(g \cdot b) \implies \text{Abs}(g \cdot b) = t.$$

Here,  $\text{Abs}$  gives the GSM a notion of a “deposited object.” The read-guard condition says that in any valid global state (as given by  $\text{Inv}$ ) with  $g$  as a sub-shard,  $t$  is guaranteed to be the deposited object (as given by  $\text{Abs}$ ). This means that a thread holding the guard shard  $g$  can soundly read the shared value  $t$ , and that all such readers will read the same value.

When the IronSync user defines a new guard protocol and proves it sound, IronSync gives them access to an API to manipulate ghost shards according to the transitions, as with any other LTS. In this case, the functions that perform exchanges can also perform deposits and withdraws; furthermore, there are new functions for the read-guard objects: if  $g$  is a read-guard of  $t$ , then the user can use a **shared** ghost shard  $g$  to obtain a **shared** ghost shard  $t$ . Linear Dafny’s type system ensures that the guard reference outlives  $t$ .

Figure 15: Across all case studies the proof:code ratio is 7.5.

In addition to the formulation above, IronSync provides a more advanced version that allows multiple objects to be stored at once. This is useful for NR’s cyclic buffer §5.1, for example. Both of these formulations are proved correct, based on a set of low-level axioms for manipulating monoid-based ghost state with **shared** variables in Linear Dafny; those axioms in turn are based on a concurrent separation logic for temporary read-sharing called Burrow [18].

## 7 Evaluation

In our evaluation, we aim to answer the following questions:

- What is the verification effort for IronSync development, both by the developer and the computer verifier (§7.1)?
- Is IronSync suitable for verifying state-of-the-art systems without compromises (§7.2)?
- What does verification tell us about the original reference implementations (§7.3)?

### 7.1 Verification Effort

Verifying all four concurrent examples consumes under an hour of CPU (5 minutes real time) on an 8-core 64 GiB cloud machine. 88% of files verify in under a minute; the slowest takes less than five. The four examples comprise 2747 lines of non-ghost implementation, plus 316 of shared library.

Figure 15 shows detailed information for each case study. Within implementation files, the proof-to-code ratio is about 4:1, where the proof code includes both the manipulation of ghost shards and standard Dafny proof annotations, like preconditions and postconditions. The full system proofs augment the implementation files with LTS code and refinement proofs, raising the overall proof:code ratio to 7.5.

As two points of comparison, we consider GoJournal [12] and Armada [38] (see §9 for details). GoJournal [12] reports a 19:1 proof-to-code ratio for its shared-memory code, while Armada’s largest example takes 4.9 hours of CPU time (about 40 min. of real time) to verify 70 lines of code. These are not direct apples-to-apples comparisons: Armada and GoJournal arguably prove more substantial theorems about machine semantics. Still, verification time and developer effort have historically limited the use of verification tools, and thus IronSync constitutes a major practical improvement.

## 7.2 Case Study Fidelity

We evaluate IronSync’s expressiveness by porting our two production-level case studies, NR (§5.1) and SplinterCache (§5.2), to IronSync to confirm that IronSync does not require sacrificing performance-critical concurrency patterns. We refer to the case studies’ existing publications [9, 14] (both within the last 5 years) to justify that they can reasonably be called “state-of-the-art.” We evaluate how faithful our IronSync implementations are to the reference implementations both qualitatively and by comparing performance.

First, we report on intentional compromises we made while mimicking the reference code of NR and SplinterCache, from most significant to least. First, in some cases, Reference NR uses release-acquire atomics. IronSync does not support these, so we use sequentially-consistent atomics instead. Second, IronSync does not support callbacks, so we refactored code to avoid them, and we could not implement the secondary, callback-based APIs in SplinterCache or NR. Third, IronSync’s SplinterCache adds a runtime check in one method whose correctness was otherwise dependent on properties of SplinterDB’s allocator, which was out-of-scope.

As evidence that these artifacts otherwise meet a high degree of fidelity, we benchmark against their references, using methodology similar to the reference publications [9, 14]. Each case study has different hardware requirements.

**NR.** We evaluate NR’s performance against other locks and to its reference Rust implementation from NrOS [6]. We wrap a single-threaded radix tree with IronSync-NR, Reference-NR, or a lock, including a verified DISTRWLOCK (§5.1), an MCS lock [40], a shuffle lock [27], and the standard C++ shared mutex. The benchmark pre-populates the tree with 128M entries (using 8B keys and values) and executes *get* and *update* requests with a uniform key distribution while varying the update ratio and the number of threads.

Figure 16 shows the performance measured on a machine with 4 Xeon Gold 6252 CPUs with 24 cores per NUMA node,

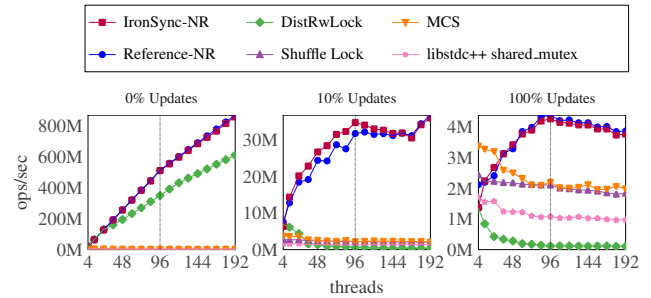

Figure 16: Comparing throughput scalability of IronSync-NR, Reference-NR, and locks. Higher is better.

totaling 96 cores and 192 hardware threads. The threads are pinned to fill up cores on a NUMA node first before moving to the next. NR adds one replica for each NUMA node, so at  $x=96$  threads, NR uses 4 replicas. Beyond 96 threads, no more replicas are added, and we begin hyperthread-sharing. IronSync-NR and Reference-NR perform similarly and generally outperform the rest, especially for read-heavy workloads.

For 0% updates, IronSync-NR, Reference-NR and the DISTRWLOCK scale linearly, but the other mechanisms suffer under lock contention. NR performs better than DISTRWLOCK due to perfect NUMA locality. With 10% updates, DISTRWLOCK’s performance drops to match the other locks, while IronSync-NR and Reference-NR benefit from flat combining. IronSync-NR outperforms Reference-NR slightly, though we do not yet know the cause.

Only at very high update rates (e.g., 100%) do MCS and shuffle locks outperform NR at low scale on one NUMA node; otherwise both NR implementations dominate. Hence, we conclude that IronSync-NR provides performance parity with Reference-NR and that it preserves NR’s replication and flat combining benefits at all scales.

**SplinterCache.** We evaluate the performance of IronSync-SplinterCache against the reference implementation both with macrobenchmarks as part of SplinterDB using the YCSB benchmark [15], and with cache-specific microbenchmarks.

Results are from a Dell PowerEdge R630 with a 28-core 2.00 GHz Intel Xeon E5-2660 CPU, 192 GiB RAM and a 960GiB Intel Optane 905p PCI Express 3.0 NVMe device.

**Macrobenchmarks.** Our YCSB configuration largely follows prior work [14]. We perform the Load, and A-F standard workloads on SplinterDB using either IronSync- or Reference-SplinterCache. Each workload uses 24B keys, 100B values and 14 threads. Run E performs 14M operations and the others each perform 69M operations, so that each workload logically reads/writes roughly 80GiB of data.

We use three target memory sizes: 4 GiB to stress eviction and IO; 20 GiB to reflect a common system configuration; and 100 GiB to stress in-memory and concurrency. Figure 17 shows that SplinterDB with IronSync-SplinterCache is always within 9% of the reference performance.

**Microbenchmarks.** We first allocate pages and flush them

Figure 17: YCSB Benchmark. 69M ops/workload (E is 14M) with 14 threads. Y-axis is mean of 3 runs. Higher is better.

Figure 18: SplinterCache microbenchmark with a 4 GiB cache. Y-axis is mean throughput of 5 runs. Higher is better.

without evicting them. Then each thread performs a fixed number of operations, choosing pages either randomly or sequentially, then either acquiring a read lock or a write lock. We use three configurations in a 4 GiB cache: general “uncontended” in-memory, with 2 GiB of data, (Figures 18a and 18d), “contended” in-memory, with 128 KiB (32 pages) of data (Figures 18b and 18e), and “IO bound”, with 8 GiB of data (Figures 18c and 18f). IronSync-SplinterCache is within 11% of the performance of reference on all microbenchmarks.

### 7.3 Bugs and Insights

We confirmed the 3 bugs below with the original developers.

**NR.** In the reference code, we identified a bug which could cause a read-read linearizability violation between two different nodes if they took place concurrently with an update. This bug could only occur if a thread dispatched log entries during garbage collection.

This bug surfaced when we realized our first attempt at defining REPLICATION would not be linearizable. We fixed the bug by always holding the lock appropriately, and the verified implementation now puts an extra ghost shard behind the lock to represent the lock’s role in REPLICATION.

**SplinterCache.** We identified two bugs in the reference code. First was a data race on `disk_addr`, which maps cache entries to disk addresses. This race could occur when a read

lock races with both eviction and a subsequent load.

Second, the code for batching write IO did not check that `disk_addr` was the expected value after locking a page for writeback. This could result in data written to the wrong location, among other corruptions. We identified these while porting the implementation, as we realized certain ghost shards would not be available following the reference logic.

## 8 Discussion on Modularity

Concurrent systems can seem dauntingly anti-modular when they entangle low-level synchronization with high-level application logic, making the tasks of ensuring data safety and logical correctness seem inseparably intertwined. By verifying two such case studies, IronSync shows how these two levels of concern can be disentangled *within the proof*.

In NR (§5.1), for example, the `localHead` variables play two distinct roles: (i) buffer entries cannot be garbage-collected past any node’s `localHead` (relevant to CYCLICBUFFER), ensuring data safety, and (ii) `localHead` matches the version of the local replica state (relevant to REPLICATION), ensuring logical correctness. Figure 13 illustrates the overlap of these roles in two methods where the overlap is notably dense. Note that some operations might advance both state machines at the same time; however, this fact is not relevant to proofs associated with either either half.

Likewise in SplinterCache (§5.2), the `WriteBack` flag plays a role in both logical correctness (CACHE) and low-level data safety (CACHERWLOCK). The code ties these two distinct roles together by using the same flag bit: when a thread modifies the physical `WriteBack` flag, it advances *both* state machines (Figure 14), but again, this is an implementation detail to which both abstractions are agnostic.

In short, we modularize proofs of a sophisticated system by abstracting it in *multiple* ways. Difficult concurrent reasoning takes place on simplified abstractions, but IronSync ensures the abstractions compose soundly; thus proofs about the individual components say something meaningful about the whole. The implementation still ties the abstractions together with physical state, but this step is straightforward from a verification standpoint, thanks to the ownership type system and Dafny’s automation. Ultimately, this method decouples the modularity structure of the *proof* from that of the *code*.

## 9 Related Work

Logics for concurrent programs reflect different trade-offs between generality, expressiveness, modularity, and usability. IronSync strikes a balance between very general state machines at high levels of abstraction, while at lower levels leaning on language features like Hoare logic and ownership types for usability. IronSync trusts these language features instead of proving theorems directly against operational semantics, unlike work like Armada [38] or Iris [24].

Concurrent separation logic (CSL) [44] lets threads take temporary ownership of state to perform isolated reasoning.

Propositional CSL is in general undecidable [8], so tools either require manual assistance from the user, as in Iris Proof Mode [31] where the user can manually match hypotheses to goals, use incomplete heuristics and user hints, as in Diaframe [42], or solve restricted fragments, as in Viper [43] and Steel [16]. Meanwhile, IronSync encodes CSL propositions using explicit ownership in the type system. Thus, ownership is directed manually by the user, but this method lets us additionally take direct advantage of automation from standard sequential reasoning tools such as SMT solvers and the weakest-precondition-style encoding used by Dafny.

Recent CSLs are extremely sophisticated. Iris [24] and Steel [16] employ monoids to extend CSL with flexible ownership protocols, used in recent systems like Perennial [11] and GoJournal [12], and Iris can handle future-dependent linearization points with prophecy variables [25]. However, the proof rules in these systems are intricate and may be intimidating to non-experts (e.g. Iris needs the “later modality” to allow impredicative invariants, which allow Iris to express some invariants beyond what IronSync can handle directly). In contrast, IronSync aims to make these concepts approachable by integrating invariants and monoids into its ownership type system, and connecting them with state-machine refinement. As a rough comparison, IronSync’s case studies achieve a 7.7:1 proof-to-code ratio, while GoJournal [12] reports a 19:1 ratio for a comparably sized case study.

Like IronSync, Armada [38], IronFleet [20], and VeriBetrKV [19] all employ state-machine refinement. The latter two use Dafny’s Hoare reasoning for the implementation of sequential code, whereas IronSync uses it for concurrent shared-memory code. In contrast, Armada verifies concurrent code using state machine refinement throughout the entire proof stack, foregoing Hoare-style reasoning in favor of detailed, low-level state machines. This provides more expressiveness; for example, two of Armada’s case studies rely on racy memory accesses using memory ordering weaker than SC, which IronSync does not currently support. However, Armada’s expressiveness also imposes costs; e.g., Armada’s Pointers case study is 13 LoC and generates 6,997 lines of proof, while in IronSync the proof is trivial, since the correct usage of the owned pointers is automatically determined by type checking. Similarly, Armada’s Owicki-Gries counter requires 130 lines of manual proof and generates 169,270 lines of Dafny proof to verify, while in IronSync it requires 230 lines of manual proof that verify directly in 8 seconds. We studied Armada’s largest case study, a lock-free queue with 70 lines of code, and implemented an analogous queue in IronSync. Theirs requires 601 lines of proof (compared to 580 for IronSync) and 8 proof layers ( $\sim 700$  LoC), and takes 4.9 hours of CPU time to verify almost 200K lines of generated proof, versus 100 seconds of CPU time for IronSync.

Many other systems utilize ownership types. Cogent [3] and VeriBetrKV [19] use ownership types for systems verification, albeit with no shared-memory concurrency, and

with the latter introducing Linear Dafny. CIVL [21] (based mainly on reduction [37]) uses ownership types, but primarily to handle thread identifiers, not general ghost state. Rust [28, 39] uses ownership types to enforce memory safety between threads [23] but lacks verification of deeper correctness properties. GhostCell [53] (an inspiration for our `Cell`) proposes owned “ghost tokens” in Rust to express ownership of groups of objects, though only for memory safety. Tools like Prusti [4] verify single-threaded Rust programs; IronSync can help extend them to multi-threaded Rust code.

Several approaches use Dafny-style automation for concurrent reasoning. Chalice [34] is a Dafny-like language with lock invariants but no tools for global reasoning. GoJournal [12] does integrate Dafny’s sequential reasoning into a verified concurrent system, but it performs its shared-memory concurrency reasoning in Iris, so it does not leverage Dafny’s automation for *concurrency* reasoning the way IronSync does.

CertiKOS [17] and SeKVM [36, 46] encapsulate concurrent operations inside modular interfaces, where programmers write proofs about the operations directly in Coq. We expect that IronSync-style ownership could simplify these proofs.

Prior work has verified concurrent hash tables, both bucketing [13] and linear-probing [18]. Prior work has also verified flat-combining [47] and producer-consumer queues [41, 48], but we are not aware of a verified cyclic buffer like NR’s, which requires multiple consumers to read each entry.

## 10 Conclusion

IronSync offers scalable verification of concurrent shared-memory systems by factoring their complex proofs into separate concerns. It automates proofs of data safety and local logical correctness via a fast, deterministic ownership type system combined with powerful tools for *sequential* correctness. IronSync’s LTS connects these local techniques to a simplified view of the entire system, where a developer can more easily reason about global properties. Our case studies demonstrate the success of this approach and show that we can tease apart application and synchronization logic for proof purposes, even when the implementation entangles them.

## 11 Acknowledgments

Work at CMU was supported, in part, by the Alfred P. Sloan Foundation, a Google Faculty Fellowship, a gift from VMware, a grant from the Intel Corporation, and the NSF/VMware Partnership on Software Defined Infrastructure as a Foundation for Clean-Slate Computing Security (SDI-CSCS) program under Award No. CNS-1700521. We also acknowledge the support of the Natural Sciences and Engineering Research Council of Canada (NSERC). Andrea Lattuada was supported by a Google PhD Fellowship.

We thank Mihai Budiu, Manos Kapritsos, Jay Lorch, and Oded Padon, along with the anonymous reviewers and our shepherd, Eddie Kohler, for helpful feedback. We also thank Rob Johnson for discussions on SplinterCache.

## A Artifact Appendix

### Abstract

Our artifact contains everything needed to verify the IronSync projects with Linear Dafny and run the benchmark experiments.

### Scope

Our artifact can be used to reproduce the results in Section 7, specifically:

- The table in Figure 15, with line count information and verification times.
- Other figures, such as proof-to-code ratio, mentioned in Section 7.1.
- Benchmark results in Section 7.2, specifically, the claim that for both NR and SplinterCache, the performance of the IronSync applications are comparable to their corresponding reference implementations.

### Contents

The artifact contains:

- Linear Dafny source for the IronSync framework.
- Linear Dafny source for the case studies mentioned in the paper (the bank, the hash table, SplinterCache, and NR)
- Our modified version of Linear Dafny needed to run IronSync.
- The open-source reference implementation of NR.
- The open-source reference implementation of SplinterDB (which includes SplinterCache).
- A Docker container with all Dafny dependencies.
- A benchmark harness for each.

### Hosting

The artifact is hosted at <https://github.com/secure-foundations/ironsync-osdi2023>, commit d361111cbc87b5573d14975227de845e8a717ca5. See the README.md file for instructions.

### Requirements

The artifact requires x86 Ubuntu. (Note that, although our artifact includes a Docker container, which may be used on other platforms, the Docker container is only used for running Linear Dafny; it cannot be used for running the benchmarks.)

The ideal hardware for the NR benchmarks is a NUMA machine with 96 cores. The benchmarks in our paper were run on a machine with 4 Xeon Gold 6252 CPUs with 24 cores per NUMA node. However, a machine with fewer cores should still be able to reproduce our graphs up to a certain number of threads.

The ideal hardware for the cache benchmarks is a machine with a low-latency storage device, such as an Intel 905P Optane SSD. The machine also needs at least 100GiB to run the largest benchmark. The benchmarks in our paper were

run on a Dell PowerEdge R630 with a 28-core 2.00 GHz Intel Xeon E5-2660 CPU, with 192 GiB RAM.

If the ideal hardware is not used, you will not be able to reproduce the exact performance characteristics of our paper, though we still expect to see that the IronSync implementations perform comparably to the reference implementations. Our artifact contains additional recommendations for selecting hardware.

## Abstract

Datacenter applications have been increasingly applying RDMA for ultra-low latency and low CPU overhead. However, RDMA-capable NICs (RNICs) of different vendors or different generations of the same vendor do not cooperate well, which could cause bandwidth imbalance in the production network and introduce new root causes of the PFC storms. Our key observation is that although the data path functions of heterogeneous RNICs follow the same RoCEv2 specifications, their control path functions are vendor and version specific. To this end, we propose Flor, an open framework that provides a unified hardware data plane atop heterogeneous RNICs and a flexible software control plane running over host CPUs or NPUs of RNICs and DPUs. The hardware plane requires no changes to current specifications. The software plane on-loads congestion control and reliability management in the large-scale lossy Ethernet with no PFC dependency. We implemented and evaluated Flor in both testbed and production clusters over Intel E180, Mellanox CX-4 and CX-5 and Broadcom RNICs. Experiments show that Flor achieves comparable performance to vanilla RDMA in many scenarios, including 1/4096 packet loss, 6000:1 incast, and large-scale cross-pod communication. Flor mitigates the performance gap of CX-4 and CX-5 RNICs from 24.3% to 1.3% when they are deployed together.

## 1 Introduction

Remote Direct Memory Access (RDMA) over Converged Ethernet has been widely deployed in datacenters [3, 5, 11, 14, 30]. It provides low latency and high throughput for many applications, *e.g.*, key-value store [21, 35], distributed transactions [8, 55], distributed memory [9, 56], remote procedure call (RPC) [20, 22, 47], storage systems [11], graph computing [43] and machine-learning systems [29].

With the increasing deployment of RDMA, modern datacenters adopted RDMA-capable NICs (RNICs) of different generations and vendors, *e.g.*, Mellanox ConnectX-(CX-4)/5/6 [49, 50, 52], BlueField [51], Intel E810 [17], and cloud-provider customized RNICs [10, 12, 42]. On the one hand,

adopting more than one vendor avoids vendor lock-in, *i.e.*, relying on devices of a particular vendor, which is a serious risk during global supply chain crises such as the COVID-19 pandemic [18, 45]. On the other hand, the disaggregated deployment of storage and computation systems separates the back-end services from the front-end services into different clusters, where each cluster can host different types of RNICs.

The coexistence of heterogeneous network devices in datacenters introduces new challenges [11, 14, 25]. First, devices may adopt different implementations of RDMA engines. It happens among not only different vendors but also different generations of devices of the same vendor. We have investigated the impact of various devices in a large-scale storage system that involves two generations of Mellanox RNICs, which have different variants of DCQCN. In a hybrid deployment of 16 50Gbps CX-4 and CX-5 NICs, we observed a severe bandwidth imbalance, where the average throughput of CX-4 NICs degrades to 28Gbps over a full-mesh traffic pattern. Furthermore, we test the congestion control behaviors of NICs from different vendors. Specifically, Mellanox RNICs set the same congestion control rate for packets with the same destination IP, while Intel E810 RNICs enforce congestion control based on flows with the same five-tuple. In addition, Broadcom RNICs [7] implement DCTCP [2, 6] as the congestion control algorithm, while Intel E810 RNICs implement a window-based DCQCN variant [19]. The different congestion control algorithms can further amplify the bandwidth imbalance.

Second, RDMA requires Priority-based Flow Control (PFC) to maintain a lossless network fabric. Diverse devices increase the risk of generating PFC pause frames, which can propagate to the whole network and cause the network to stop forwarding traffic. In addition, the parameter tuning for the PFC configuration is time-consuming on newly deployed devices [25, 57], which usually takes weeks or months in large-scale networks with multiple vendors. During the long-term operation of production networks, we have observed multiple sources of PFC pause frame generation at both end-hosts and switches. Specifically, we found that implementation bugs

of switches and RNICs are one important root cause of PFC storms [11, 14]. In our datacenter, we record that the high loss rates occur due to diverse devices abnormality, system mis-configuration, and congestion of burst traffic in the production system, which has also been reported in prior work [58].

To cope with these issues, we need an open and unified framework to address the growing diversity of datacenter devices and give users the flexibility of RDMA programming to reduce the operational complexity of large-scale datacenter networks. Our key insight is that the RDMA data path, including memory semantics, needs fast and high-performance packet processing. In contrast, the control path including congestion control algorithms and the reliable re-transmission mechanisms, which are RTT-based operations, is relatively slow but needs to guarantee efficiency. This inspires us to rethink the functions division between hardware and software by on-loading congestion control and reliability modules to the software plane while strengthening the data path transport by following the standard RoCEv2 specifications [3–5] in the high-speed hardware.

We present Flor, an *open, unified* framework to support applications over heterogeneous networking devices. Flor *separates the data-path and control-path of RDMA transport with a hardware and software co-design* [24, 28, 37, 45, 52]. The data-path functions, *e.g.*, packet processing and bulk memory transfer semantics, remain on the hardware. Flor’s data-path follows RDMA primitives without any modifications in hardware to maintain high performance. Flor strengthens Reliable Connection (RC) transport through hardware/software co-design to overcome the low-efficient hardware-based Go-Back-N retransmission [14]. Furthermore, we leverage Unreliable Connection (UC) transport [4] as the first citizen for out-of-order demands in datacenters [42, 46] as it supports the out-of-order delivery of messages between RDMA operations without any requirements on the hardware change. We adopt UD as a key element to enable selective retransmission [36] for RoCEv2 and deliver messages to the applications in an out-of-order manner [42].

The control-path includes a load-aware dynamic chunking module, an RDMA-semantic-compatible reliability module, and a congestion control module. The load-aware dynamic chunking module balances between the performance and the software control granularity. Flor proposes a software selective retransmission scheme by leveraging UC to process *out-of-order delivery*. Flor implements an RTT-based congestion control algorithm similar to Swift [26] but improves the RTT measurement accuracy of previous work [28] by  $10\times$  on 99<sup>th</sup> percentile and 99.9<sup>th</sup> percentile RTT. By onloading these functions to hosts or programmable devices [40] (*e.g.*, IPU core [18], DPU core [51], CPU or even GPU [1]), the software developers have the flexibility of customizing and generalizing these functions across heterogeneous RNICs. For example, Flor can also adopt emerging congestion control schemes [26, 30] and optimization of transport protocols

(*e.g.* Swift, HPCC) instead of waiting for months or years of hardware upgrades.

We evaluate Flor through extensive experiments in an RPC benchmark and real production systems. We compare Flor with a customized RDMA library, XRDMA [32]. XRDMA implements the RPC interfaces with vanilla RDMA primitives. Compared to XRDMA, which suffers significant performance loss with 1/4096 packet loss ratio with lossy RoCE accelerations [53], Flor maintains steadily high throughput. Specifically, by deploying an RTT-based congestion control algorithm, Flor can handle 6000:1 incast with no throughput loss at run time. Flor achieves comparable performance as XRDMA for intra-pod communication and better performance than XRDMA for inter-pod communication. Our evaluations show that Flor reduces the bandwidth gap from 21.8% to 1.3% in the hybrid CX-4 and CX-5 deployment clusters and mitigates the performance gaps by 220% for RNICs of different vendors. For the production systems running big-data applications and cloud storage service, compared with XRDMA, Flor improves the job completion time of a big-data application job by 10% and achieves comparable latency and IOPS on the latency-sensitive cloud storage service. Specifically, the process of upgrading the existing RDMA framework, *i.e.*, XRDMA, to Flor has little performance impact on the running applications. Our practical experience with Flor shows that Flor provides a non-stop and smooth upgrade from lossless RDMA to lossy Flor.

In summary, this paper makes the following contributions:

- The interoperability of devices in RDMA networks needs be better addressed. We study the impact of heterogeneous RNICs in the production network.
- We revitalize the RDMA support by introducing an open unified framework accommodating primary RNICs in the lossy datacenter networks.
- We implement the framework and verify its effectiveness and low software overhead in both testbed and realistic production systems.
- As far as we know, this is the first systematic work considering the operation with heterogeneous devices, which innovates future RDMA system design from the perspective of service providers.

## 2 Background & Motivation

### 2.1 RDMA Preliminaries

RDMA is a hardware transport that exposes network operation through verbs API. User-space applications initiate data transmission requests to RNICs by posting Work Queue Elements (WQEs) into queue pairs (QPs). After transmitting the data, the RNICs generate Completion Queue Elements (CQEs) into Completion Queues (CQs) as the transmit completion signals for users. RDMA supports three transport types: Reliable Connection (RC), Unreliable Connection (UC), and Unreliable Datagram (UD) [4]. Correspondingly, it

Figure 1: Throughput difference of a Mellanox RNIC and a Broadcom RNIC sending to an Intel RNIC in a Mellanox-Broadcom-Intel hybrid deployment with a full mesh traffic pattern.

NIC when the number of connections increases, *i.e.*, 64 QPs and 512 QPs. This causes unfair bandwidth share between applications hosted atop different RNICs. Figure 2 shows the throughput of each NIC with a full mesh traffic test (*i.e.*, all-to-all traffic) among the three NICs. We stack the throughput of each RNIC to the same receiver RNIC. For example, when a Broadcom NIC and an Intel NIC send traffic to a Mellanox NIC, the Broadcom NIC and the Intel NIC get the throughput of 43Gbps and 15Gbps, respectively (left bar). We can observe a similar performance variation when any two of the RNICs are competing with each other.

provides two well-known primitives: *SEND/RECV* are two-sided operations supported by all transports. *WRITE* is a one-sided operation supported by RC and UC, but *READ* is only supported by RC.

The difference in RNICs throughput is significant and leads to the computing tasks load imbalance on the nodes. We find that the root cause is the congestion control implementation difference or the congestion control algorithm difference among these heterogeneous RNICs. After we apply a unified congestion control algorithm, the performance gaps are eliminated (§7.5).

For connection-oriented services (UC and RC), QPs maintain Packet Sequence Number (PSN) and expected Packet Sequence Number (ePSN), respectively, on the sender and the receiver. RC QPs only receive packets with PSN correctly matching ePSN and increase ePSN after successful receiving. For RC, RNIC is responsible for retransmissions, where the receiver RNICs send acknowledge (ACK) packets. Once a packet is dropped, the sender must start retransmitting the lost packet. For UC, the transport does not retry messages with errors, and users must handle the error. Specifically, for UC QPs, when a packet of a verb is lost, the RNICs drop the whole verb, update ePSN, and continue to receive other verbs. Thus, compared with RC, it is more flexible for users to deal with out-of-order messages and potentially provide effective upper-level RPC service through software-defined reliability.

**Operational challenges caused by PFC storming.** PFC storm is a well-known problem [14, 15, 54, 57] that threatens the system’s availability if the pause frames are sent to the whole cluster [14]. RDMA systems in production adopt multiple mechanisms to mitigate the impact of these risks, such as PFC monitoring and watchdog, limiting the scale of PFC in a pod.

## 2.2 Production Experience

However, the PFC risk is not thoroughly eliminated and happens repeatedly with new causes. In addition to the known reasons of PFC storms, *e.g.*, the *slow receiver* [14] and switch hardware bug [11], we found that Machine Check Errors (MCE) caused by memory Error Correcting Code (ECC) and the lack of memory bandwidth can lead to the PFC storm when we introduce new RNICs in the datacenter. When MCE occurs on a server, RNIC receives data but can not DMA the data to the server memory. Thus, it sends excessive PFC pause frames to the neighbour switches and then spreads to the network. The occurrence frequency of MEC can be up to 1% [34], which leads to operational difficulty.

We present our production experiences demonstrating the difficulties of deploying the RDMA NICs of various generations and vendors in the same datacenter.

**Interoperability of heterogeneous RNICs.** We first investigate the performance gap between RNICs of different generations belonging to the same vendor. We run IB Perftest<sup>1</sup> in a cluster where 8 servers are equipped with CX-4 and another 8 servers are equipped with CX-5 RNICs. Given a full-mesh traffic pattern, *i.e.*, all servers send requests to each other, the throughput of CX-4 and CX-5 is 28Gbps and 41Gbps respectively. The throughput gap is 13Gbps (46.4%).

The lack of memory bandwidth also leads to PFC storms because CPUs and RNICs share the memory bandwidth on a server. When the CPU running applications preempts too much memory bandwidth, the memory bandwidth left for the RNIC is less than the network bandwidth [41]. Then the RNICs send PFC frames to prevent packet loss due to the RNIC buffer overflow. It is difficult to guard against every possible cause of the PFC storm. We expect to eliminate PFC from our production system while achieving performance compatible with a lossless network.

We then investigate the performance gaps among RNICs of different vendors. As shown in Figure 1, when a Mellanox RNIC [51] and a Broadcom RNIC [7] send traffic to an Intel RNIC [17] simultaneously. The configurations of the RNICs are depicted in §7.5. The Mellanox NIC gets 66Gbps, and the Broadcom NIC gets 20Gbps (220% of the performance gap) when each initiates one connection, *i.e.*, 1 QP. The Mellanox NIC gains less bandwidth, *e.g.*, 3Gbps, than the Broadcom

## 2.3 Motivation

These practical issues prompt us to rethink the usage of RDMA from the perspective of service providers. We aim to design an open and unified RDMA framework, which meets the following objectives:

- **Compatibility.** The open framework needs to be backward compatible with the legacy devices configured in the cluster.

<sup>1</sup>IB Perftest is a benchmark tool for measuring the throughput and latency of RDMA operations [13].

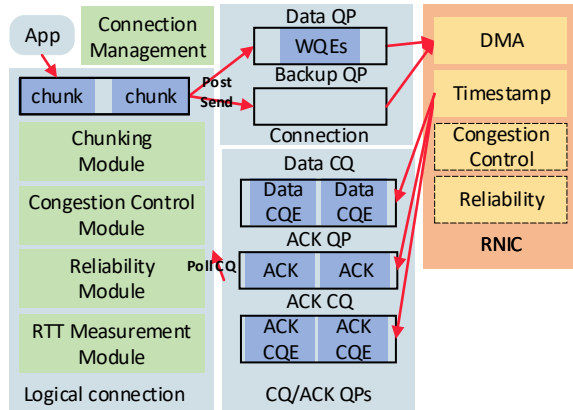

Figure 3: The framework of Flor

To this end, we abstract common features of available RNICs of main vendors and simplify the design by using the minimum set of functionalities in the hardware, *e.g.*, packetization, packet processing, message assembling, etc.

- **Flexibility.** To meet various application requirements and dynamic deployment of disaggregated services, the framework should support high feature velocity. It is programmable to realize efficient user-defined control mechanisms like new congestion control.
- **Availability.** The modern large-scale datacenters are built on Ethernet, which is a lossy network with multiple paths. Our framework is able to mitigate the impact of lossy Ethernet but fully utilizes the available network resources and maintains high performance [34, 42, 46].

## 3 Flor Design

### 3.1 Design Rationale

By investigating the RNICs of primary vendors, we notice that they follow the same RoCEv2 specifications in data-path but develop vendor-specific (even version-specific) control-path. Our key insight is that the RDMA data-path should be stable by following the standard specifications. At the same time, control-path needs to guarantee flexibility and availability. We can onload a subset of the transport functions to the software to provide programmability to developers. The design rationale is

#### Maintaining RDMA data-path specifications in hardware layer.

RDMA data-path, including packet processing and memory semantics, is a per-packet-based operation which is fast and high-performance. To maintain low latency and low CPU utilization features of RDMA, Flor places the data-path in hardware, which covers packetization, packet processing, message assembling, and direct memory access between RNICs and host memory. Therefore, Flor is compatible with primary RNICs.

**Onloading control-path to software layer.** The most flexible features in the control-path are congestion control and transmission reliability with regard to the lossy Ethernet.

The corresponding algorithms rely on the signals of packet latency, ECN notification, Inband Network Telemetry (INT), etc., the response interval of which can be several RTTs. Thus, Flor can onload the relatively slow control to the software layer by leveraging its programmability but has little influence on system efficiency. Notably, with the development of programmable devices, we can realize functions of control-path in not only hosts but the NPU [18] of RNICs or DPUs [51].

### 3.2 Architecture

Flor is an open, unified, high performance RDMA framework over lossy Ethernet in large-scale datacenters. The architecture is shown in Figure 3.

**Data path.** Since the process details of RDMA operations on QPs are dictated in the RDMA protocol [4], utilizing standard RDMA operations, which are supported by all RNICs, to transfer data among heterogeneous RNICs can achieve comparable performance. Flor takes RDMA **WRITE** and **SEND** as the base WQEs for the data transferring and receiving because they both support RC and UC and maintain high performance of RDMA. Notice that RDMA **READ** has a known performance issue [21] and only supports RC. Flor uses the RDMA **SEND** WQEs to transfer small messages (*e.g.*,  $\leq 32\text{KB}$ ) and **WRITE** to transmit large messages. For large messages, Flor needs an extra round-trip to exchange remote memory address and buffer size with remote servers. Note that the memory information exchange requires once for each large message. Flor prioritizes the **SEND** WQEs over large messages to avoid that head-of-line blocking to the small messages. On top of the RDMA verbs, Flor provides a *message-based* communication interface to support RPCs favoured by most datacenter applications [20].

**Control path.** The control-path of Flor consists of five flexible software modules: *Connection Management*, *Chunking*, *Reliability*, *Congestion Control*, and *RTT Measurement*.

- *Connection Management.* This module establishes and releases connections and manages backup QPs. Data are transmitted through QP and backup QPs, which take over the RDMA requests in place of the malfunctioned primary QP. The data CQs provide data completion events. The ACK QPs and CQs are used for sending and receiving software ACKs when using software reliability. Through QP management, Flor can abstract these backup QPs and present them as one QP to upper-level applications.
- *Chunking.* The *Chunking* module splits large messages into small RDMA requests, *i.e.*, *chunk*. Flor takes the *chunk* as the base unit of the selective repeat algorithm and congestion control algorithm, instead of a packet at the traditional transport [26, 57]. A chunk is sent to the network via a **WRITE** or **SEND** Work Queue Element (WQE).
- *RTT Measurement.* The *RTT Measurement* module collects the NIC hardware timestamp, synchronizes the hardware and software timestamp, and then updates RTT, which is

used as the signal of network congestion, retransmission and link failure detection.

- **Reliability.** Each WQE is passed to the *Reliability* module, which stores the transport information and maintains the state for packet loss detection and RTT calculation. We develop a software selective retransmission mechanism by tracking every request sent to the network.
- **Congestion Control.** The *Congestion Control* module takes the congestion signals, e.g., RTT, ECN, INT [39], and drop events, to calculate the congestion window or sending rate according to the congestion control algorithms. By default, we apply an RTT-based congestion control algorithm to eliminate the impact of complicated parameter tuning of congestion control on diverse switches [26].

### 3.3 Optimization and Deployment.

The key challenge for Flor is to offer flexibility while providing comparable performance to the vanilla RoCEv2 stack. We make the following optimizations:

- **Maintaining RDMA performance using the software/hardware co-design.** The RDMA hardware solution provides high throughput, low latency, and low CPU overhead. To maintain these advanced properties, we adopt a dynamic chunking mechanism to tune the size of messages for slow control-path when tracking the software congestion control and loss recovery. The overhead of the control-path functions onloading to the software layer is low because we apply large granularity of messages instead of packet processing (§ 4).
- **Enhanced UC with Selective Retransmission.** The packet loss rate in datacenters is actually low, which will not trigger frequent re-transmission. Designing a correct reliability mechanism while keeping the zero-copy memory semantic is the main challenge that Flor handles. UC has the property that RNICs can deliver the messages to the host without waiting for the previous ones to complete. Flor leverages this property to design a more efficient retransmission scheme, i.e., selective retransmission [36] without any hardware change to speed up the application processing [42] (§ 5).
- **Enhanced RC with Correctness.** RC is one of the data-path transport supported by Flor. Go-back-N, the RC's retransmission mechanism, is known to have low efficiency [36]. Flor enhances the Go-back-N mechanism by adding an additional software retransmission scheme. We address the correctness issue introduced by the software retransmission, where the retransmitted RDMA operators may overwrite the memory region that has been submitted to applications (§ 6).

Flor users can select a combination of these software modules in different scenarios. The software congestion control and reliability modules can be bypassed or replaced by the hardware functionalities. Table 1 shows some recommended configuration combinations for different deployment

Scenarios	Chunking	Reliability	CC
Intra-pod, PFC-enabled	No	RC	HW
Intra-pod, PFC- and ECN-disabled	Yes	RC or UC	SW
Across-pod Applications	Yes	UC	SW
CX-4/5 Hybrid	Yes	RC or UC	SW

Table 1: Recommended choices of modules in some scenarios. CC represents congestion control. HW indicates hardware-offloaded modules, SW indicates software-implemented modules.

scenarios in our production. For example, in a PFC- and ECN-disabled CX-4 cluster, Flor provides RDMA service by enabling chunking and software congestion control with hardware-based (RC) or software-based (UC) reliable transport. For cross-pod applications, software-based (UC) reliability is recommended to tolerant packet loss.

## 4 Dynamic Chunking

The chunking algorithm determines the granularity of RDMA requests bursting into the network. A large chunk size may result in a traffic burst that causes congestion and incurs high recovery costs in case of packet loss, while a small one leads to more CPU costs. Therefore, the key design point is dynamically adapting chunking size according to the current network status, which helps achieve both good performance and fine-grained traffic control. More specifically, it tries to adopt large chunk sizes with hardware SEND or WRITE operations to reduce CPU cost when the loss rate is low. Once packet loss occurs, it applies chunk-slicing and retransmission of dropped chunks by software.

Flor uses the estimated RTT as the default feedback signal of network status for the dynamic chunking strategy. The estimated RTT is not only used as the feedback signal of the dynamic chunking algorithm but also used as the congestion control signal, as well as a timeout signal for reliability.

### 4.1 Accurate RTT Measurement

The accuracy of RTT measurement directly impacts the performance of all these components. Different from the approach [26] where measures RTT based on per-packet timestamp, Flor measures RTT for the chunks with different sizes. RoGUE [28] firstly devises a way of RTT measurement for dynamic verb sizes on RNICs and utilizes the hardware timestamp functionality of RNICs to get an accurate timestamp to calculate RTT. Flor takes the RoGUE's methodology to measure RTT for the RC transport and further improves the RTT measurement accuracy for UC transport.

Figure 4 shows the RTT measurement method in Flor for the UC transport. Note that leveraging hardware timestamp to measure RTT requires synchronizing the software and hardware clock (Appendix A.2.1). On the sender side, the timestamps of the data WQE sending completion ( $T_1$ ) and the corresponding ACK receiving completion ( $T_4$ ) can be obtained from the hardware. On the receiver side, the timestamp of the data WQE arrival ( $T_2$ ) is read from the hardware and the timestamp of the corresponding ACK WQE

posting time ( $T'_3$ ) is accessible through software. ( $T'_3 - T_2$ ) is computed in the receiver and sent back to the sender by a subsequent ACK packet. Thus RTT can be calculated with:

$$RTT = (T_4 - T_1) - (T'_3 - T_2). \quad (1)$$

However, the measurement is not absolutely accurate as  $T'_3$  is the post time rather than the actual send completion time of the ACK ( $T_3$ ) due to the queuing of sending requests in NICs. In addition, under a heavy load, the ACK can be delayed up to milliseconds upon receiving by the sender software due to the head-of-line blocking by the data WQEs and the QP scheduling policies. As a result, on the one hand, the measured RTT can be increased by this overhead, which inaccurately reflects the network congestion; On the other hand, this also prolongs the congestion feedback loop such that the sender can not respond to the network congestion in time.

Flor uses two optimization approaches to improve RTT measurement accuracy and shorten the feedback loop delay. First, Flor uses a high-priority UD QP to send and receive ACKs to avoid head-of-line blocking and scheduling delays on RNICs. Second, Flor uses a separate completion queue for ACKs and polls it prior to the data completion queue in each batch. Our measurement shows that the measured tail RTT without optimization can be up to several milliseconds due to QP scheduling (Figure 16 in Appendix A.2.2). The overestimated RTT can cause an unnecessary window decrease. Using a separate QP and completion queue for ACKs improves the RTT measurement accuracy by  $10\times$  on tail RTTs.

## 4.2 Chunking Strategy

Flor extracts the chunking algorithm as a module such that users can specify their own chunking algorithms. Here we present the default algorithm used by Flor. The key idea is to dynamically reduce the chunk size when the RTT of network gets worse and increase the chunk size when its status gets better. We initialize the chunk size by the minimum value of the available congestion window ( $acwnd$ ) or bandwidth-delay product (BDP) ( $chunk\_size \leftarrow \min\{acwnd, BDP\}$ ). Then we update the chunk size for each RTT.

As shown in Algorithm 1, we use estimated RTT, which reflects network queuing, as the feedback signal of chunking in Flor. We maintain two smoothed RTTs ( $rtt_s$  and  $rtt_l$ ) with Exponentially Weighted Moving Average (EWMA) [31] using different indexes  $\alpha$  (the parameter that controls the weight of new feedback). The short-term RTT  $rtt_s$  demonstrates the up-to-date congestion status, while the long-term RTT  $rtt_l$  indicates the common status of the connection.

Generally, we define a span of expected RTT denoted by  $(\beta_{max} * rtt_l - \beta_{min} * rtt_l)$ . Here  $\beta_{max}$  and  $\beta_{min}$  are configurable parameters to identify the upper and lower bounds.  $(\beta_{max} * rtt_l - rtt_s)$  indicates the position of short-term RTT in the RTT span. The Algorithm divides the RTT span linearly, as shown in line 4 of Algorithm 1.  $size_{max}$  is the maximal chunk size

<sup>2</sup> For example, if the  $rtt_s$  reduces to the lower bound of RTT

<sup>2</sup>By default,  $size_{max}$  is 64KB, which is a trade-off between the CPU

span ( $\beta_{min} * rtt_l$ ), it indicates that the status of network is good and the chunk size increases to the  $size_{max}$ . On the contrary, if the  $rtt_s$  increases to the upper bound of RTT span ( $\beta_{max} * rtt_l$ ), it indicates that the load of the network is high and we should reduce the chunk size to the  $UNIT\_SIZE$ .

---

### Algorithm 1 An RTT-based Chunking Algorithm

---

**Input:** RTT  $rtt$ , available congestion window  $acwnd$

**Output:**  $chunk\_size$

- 1: update short-term RTT  $rtt_s$  with  $rtt$ ,  $\alpha_s$  via EWMA
  - 2: update long-term RTT  $rtt_l$  with  $rtt$ ,  $\alpha_l$  via EWMA
  - 3:  $size_t \leftarrow size_{max} * (\frac{\beta_{max} * rtt_l - rtt_s}{\beta_{max} * rtt_l - \beta_{min} * rtt_l})$
  - 4:  $chunk\_size \leftarrow \min\{size_t, acwnd\}$
  - 5: **return**  $chunk\_size$
- 

Note that the chunking module still applies to have a fine-grained traffic control if Flor uses a rate-base congestion control, e.g., DCQCN. To support the reliability design (§3.2), Flor aligns the  $chunk\_size$  to  $UNIT\_SIZE$  (the minimal  $chunk\_size$ ), i.e.,  $chunk\_size$  is exactly multiple times of  $UNIT\_SIZE$ . Note that to prevent deadlock of the congestion window, the  $chunk\_size$  is set to  $UNIT\_SIZE$  when the available congestion window is smaller than  $UNIT\_SIZE$ . The  $UNIT\_SIZE$  can be equal to the value of the current MTU. To mitigate the impact of packet loss, Flor adopts different chunking mechanisms for RC or UC transport, respectively. For RC transport, Flor directly reduces the large chunk sizes to the minimum chunk size of one  $UNIT\_SIZE$  to reduce retransmission overhead and avoid the live lock of retransmission. For UC transport, Flor relies on congestion window, which will cut its size by a half upon a packet loss. And finally, the chunk size becomes  $UNIT\_SIZE$  when continuous packet loss happens. In particular, Flor can adopt Selective Retransmission with UC in Section 5 to reduce chunk retransmission under high packet loss and achieve better transmission efficiency than Go-Back-N.

## 5 Selective Retransmission with UC

UC transport only drops the verbs that have packets dropped but does not drop the subsequent successfully-delivered verbs. Thus, based on the chunking mechanism that splits RDMA messages into varied sizes of WQEs, Flor is able to design reliability mechanisms (sequence number, acknowledgement, and retransmission) at the granularity of chunking WQEs. The transmission of RDMA *WRITE* operations does not need any reordering buffer because *WRITE*s are directly DMA-ed into the host buffer. However, there are still some challenges to implement reliability in software for one-sided RDMA *WRITE* operations:

- **Challenge #1: Additional data copy.** Since RDMA *WRITE* writes an array of memory pieces to one continuous

efficiency to transmit large chunks and the retransmission overhead of packet loss to transmit smaller ones.

Figure 4: RTT measurement for UC in Flor.  $T1$ – $T4$  are timestamps of events.

remote address, Any extra content added to the chunks of a large message, including information needed by reliability mechanisms such as sequence numbers, can break the original message, which then incurs a memory copy at software to assemble the scattered memory into the original message.

- **Challenge #2: Software ACK.** *WRITE* is a one-sided RDMA operation that bypasses the CPU of the receiver. The receiver can not know whether a *WRITE* succeeds or fails, which is one of the main issues when the one-sided operator is used in practice. Flor uses WQEs to encode software ACK messages as UC does not generate hardware ACK packets. Without careful design of the ACK message, the high frequency of the software ACK will significantly degrade the performance.
- **Challenge #3: Repetitive memory access.** The retransmission of RDMA *WRITE* operation may cause a data integrity issue as RNICs can write to a piece of memory already submitted to the application.

To solve these problems, some novel designs, including sequence number space for *WRITE\_WITH\_IMM*, software ACKs, and two-sided retransmission, are adopted in Flor’s reliability mechanism.

**Sequence number space for *WRITE\_WITH\_IMM*.** To assemble the chunks into the original message on the receiver without the extra data copy (**Challenge #1**), Flor uses *WRITE\_WITH\_IMM* to generate signals to software for the arrival of chunks. One feature of *WRITE\_WITH\_IMM* is that it can carry an extra 32-bit *imm\_data* set by the sender. With *WRITE\_WITH\_IMM*, the receiver can detect the arrival of RDMA verbs and receive the chunk number without polluting the application memory. For *SEND*-transported small requests, Flor adds an additional header in the payload to carry additional information, including the sequence numbers.

However, to reassemble the initial messages from the chunks, we need another sequence number for the chunks. Note that chunks of a large message are also not continuous in the sending queue since some *SENDS* operations (*e.g.*, retransmissions and the address-exchanging messages of *WRITE*) are prioritized in Flor.

Similar to QUIC [27], Flor encodes two sets of sequence numbers into each RDMA WQE: *global sequence number*

Figure 5: Performance impact of ACK coalescing.

and *reliability sequence number*. The global sequence number is a 64-bit value, and all the RDMA WQEs have a unique global sequence number to identify the sequence within a QP. The reliable sequence number is used to identify the sequence within the same type of WQEs, *i.e.*, *WRITE* WQEs and *SEND* WQEs have separate reliable sequence number space. These two sequence number spaces also allow Flor to identify the original WQEs and the retransmitted WQEs by different global numbers such that ACK information and the timestamp carried in ACKs are clear. The retransmission WQEs share the same reliable sequence number with the original WQE. More details can be found in Appendix A.1.1. **Software ACK.** Flor acknowledges every WQE, but generating an ACK for each WQE can cause high overhead for small-message traffic (**Challenge #2**). Flor puts multiple sequence numbers into one software ACK to reduce the CPU overhead. The detailed ACK format is explained in Appendix A.1.2. However, ACKs should be sent timely since ACKs carry RTT and WQE numbers used in the congestion control and reliability mechanism. Thus, Flor sets these trigger rules for receivers to send an ACK immediately: (1) the cumulative number of WQEs; (2) the cumulative size of WQEs; (3) the last WQE in the congestion window signed by a hint bit in the header or *IMM\_DATA* field; and (4) an out-of-order reliable sequence number, whichever reaches first. Flor also sets a timer as a trigger because the tail of a flow or small bursts may not have enough data to trigger the cumulative counters.

To show the impact of different ACK triggering frequencies, we set up an experiment with a client and a server, and each is equipped with a CX-4 dual-port NIC. There are 8 threads and 64 QPs on each node. Figure 5 shows the IOPS in a 128-byte request and response RPC benchmark with different ACK triggering mechanisms. The ACK coalescing mechanism improves ~40% IOPS compared to a per-WQE ACK mechanism (*No coalescing* in Figure 5). In addition, among different coalescing WQE sizes and timers, the setting of 120 $\mu$ s timer and cumulative counter of 32 WQEs achieves a satisfying IOPS, which is the default configuration of Flor.

**Two-sided retransmission.** When the sender detects an out-of-order delivery from an ACK or a timeout event, it retransmits the WQEs. Flor handles the retransmissions by *SEND*, since spurious retransmissions of *WRITE* may cause a data integrity issue (**Challenge #3**). The data integrity issue can happen when WQEs are queued in the network for a long time, which incurs timeout retransmission at the sender. In this case, the original WQE is received by the receiver, and the whole message is submitted to the upper-layer application. The application can write the content of the message as it needs. However, the subsequent retransmitted *WRITE* WQE arrives at the receiver and overwrites the memory region that the application has already changed without informing the CPU of the receiver. Flor retransmits WQEs by *SEND* through the same QP for the lost one to avoid uncontrolled

memory access from RNICs. In a *SEND* operation, the data is written into a piece of pre-posted memory. Flor then copies the data into its desired location if the message has not been submitted to the application. If the retransmission *SEND* arrives earlier on the receiver, the following original *WRITE\_WITH\_IMM* will be dropped by the receiver RNIC because its hardware packet sequence number is smaller than the expected hardware packet sequence number, which is updated because of the arrival of the *SEND*.

## 6 Enhance Hardware Retransmission

Flor is compatible with hardware reliability by using RC to reduce software costs and achieve better performance. Note that Flor supports both one-sided and two-sided RDMA operations on RC QPs. The hardware retransmission of RDMA operations is out of the control of software congestion control. This has potential risks of incurring network congestion since the size of inflight data can be much larger than the software congestion window. Flor improves the hardware reliability by adding a software retransmission scheme. Flor sets short retransmission retry times in RC QPs to limit the size of data exceeding the software congestion control window.

If the retransmission fails for the retry times, the QP is turned into error states by the RNIC hardware. Turning the error states of the QPs into the working states takes a long time, e.g., 5ms. Instead, Flor resubmits the uncompleted inflight WQEs to another pre-connected QPs, called backup QPs [28], and flips the backup QP to be the primary QP to continue data transmission. At the same time, Flor re-connects the original QP in the background. The inactive backup QPs do not consume additional cache resources on RNICs and thus have no side effect on performance [28]. Our practical experience shows that using one retry time incurs too many QP switches in some extreme cases e.g., large-scale incast. By default, Flor uses two retry times and two backup QPs for each connection. Compared to QP reconnecting, switching to backup QPs costs less time, i.e.,  $\sim 60\mu\text{s}$ .

A racing issue occurs when QPs turn into the error state occasionally: the sender may return a failure of a WQE while the receiver successfully receives it. This case happens when the QP at the sender turns into the error state with successful inflight operations. In such a case, the sender posts a duplicated WQE mistakenly on the backup QP of the logical connection. Another corner case that causes the same problem is that the sender times out when the hardware ACK is on the flight. Flor retransmits the WQEs with RDMA *SEND* and checks if the message has been submitted to the application before the data are copied into the destination application's memory.

## 7 Evaluation

We evaluate Flor by answering the following questions:

1. The software overhead of Flor in the 100Gbps network (§7.2) and its robustness against packet loss (§7.3)?

Cluster	Nodes	RNICs
A	100	CX-4 Lx 25Gbps dual-port
B	16	8 × CX-5 25Gbps dual-port 8 × CX-4 Lx 25Gbps dual-port
C	48	CX-5 100Gbps dual-port
D	3	Intel E810 100Gbps dual-port Broadcom P2100G 100Gbps dual-port Mellanox BlueField-2 100Gbps dual-port

Table 2: Clusters setups used in our evaluation.

2. The behaviour of Flor in both intra-pod and inter-pod communications when PFC is disabled (§7.4)?
3. The effectiveness of Flor in a hybrid deployment with heterogeneous RNICs (§7.5)?
4. The performance of Flor's default *Congestion Control* in large-scale incast scenario (§7.6)?
5. The impact on services when upgrading from the current network to Flor in production systems (§7.7)?

### 7.1 Experiment Setup and Benchmarks

**Cluster setup.** Table 2 lists four clusters used in the evaluation. The default RDMA configurations of our clusters are that: (1) for CX-4 lossless RNICs, PFC is enabled on ToR and Leaf switches but disabled on Spine switches; (2) for CX-5 lossy RNICs, PFC is disabled on all switches, and the *lossy RoCE acceleration features* [53] are enabled.

**Baseline and workload.** Our RPC system used in evaluation supports XRDMA, Flor, user-space TCP, and kernel TCP. XRDMA is a vanilla RoCEv2-based RPC library, which is deployed in the clusters listed in Table 2 before upgrading to Flor. The user-space TCP is based on DPDK. Two applications run on top of our RPC framework: a Map-Reduce-like application and a distributed block storage service.

**Configuration for Flor.** In the clusters, we configure one specific priority queue on both switches and RNICs. The PFC and ECN are enabled on this priority queue (lossless queue). Besides, we reserve another priority queue (lossy queue) for Flor in which PFC and DCQCN are disabled. The coalescing ACK parameters are 120 $\mu\text{s}$  timer, 32 WQEs and 32KB data at most. The base RTT used in the software congestion control is 50 $\mu\text{s}$ . The minimal and maximal chunk size is 1KB and 64KB, respectively.

### 7.2 Software Overhead.

Flor introduces additional CPU cost due to the software implementation of reliability mechanism and chunking. To evaluate its impact, we compare the single-core performance of different network protocol stacks with our RPC benchmark, including XRDMA, Flor (RC), Flor (UC), user-space TCP, and kernel TCP. The I/O depth (i.e., the maximal number of inflight RPC requests) is 8. We vary the RPC request size from 4KB to 1MB and fix the response size at 128 bytes. The servers are equipped with Intel CPUs (2.9GHz) which have 96 logic cores, and CX-6DX 100Gbps dual-port RNICs (not listed in Table 2).

Figure 6(a) demonstrates the throughput of all the stacks with different RPC sizes. The single-thread throughput of Flor

Figure 6: Single-thread throughput and CPU usage of Flor and other different network stacks.

and XRDMA can reach to  $\sim 88$ Gbps while user-space TCP and kernel TCP achieve up to  $\sim 30$ Gbps even with large RPC size, i.e., 1MB. Notice that due to the hardware and RoCEv2 protocol overhead, such as headers of Ethernet, IP, UDP, and IB with 1024B MTU, the standard RDMA benchmark, i.e., Perfest [13] achieves a maximum bandwidth of 88Gbps. This shows that the *Chunking* mechanism does not hurt the single-thread throughput of Flor. We observed that the performance degradation of Flor (RC/UC) happens at 64KB due to extra memory information exchanges for using RDMA WRITE to transmit each large message and dismisses as message sizes increase. The throughput of large requests in XRDMA is lower than Flor because XRDMA uses RDMA READ operation to transfer the large requests, and RDMA READ operation has inflight bound on RNICs along with some well-known performance issues [16, 23]. When using a chunk of 4KB, Flor can handle over 770K chunks per second with a single thread. Flor is able to maintain high throughput as the chunk size is usually larger than 4KB, and applications often adopt multiple threads.

We then estimate the corresponding CPU usage. The CPU usage is obtained from *perf* [38] tool since we use polling mode for RDMA. Notice that in our production storage system, it adopts a run-to-completion model based on a co-routine IO framework [11], where the network polling for disk read or write uses the same core with storage protocol processing in concurrent execution. As shown in Figure 6(b), Flor takes less than 0.3 CPU core for large data size of 1MB message in 100 Gbps network. Most modern servers usually have large numbers of cores ( $>96$ ) and 0.3 CPU cores usage ( $<0.4\%$  usage) has little impact on the production system.

Flor maintains low CPU cost because it leverages zero-copy features of RDMA and mainly deals with lightweight control events for congestion control and reliability. In addition, Flor is compatible with different platforms, which can further reduce the host CPU cost by offloading Flor to SmartNICs, and FPGA in computation-intensive hosts.

We also measure the single-core throughput of Flor at 200Gbps RNICs and show that Flor can achieve comparable throughput as vanilla RDMA. Besides, we show that Flor outperforms the other network stacks, i.e., SNAP [33], eRPC [20]

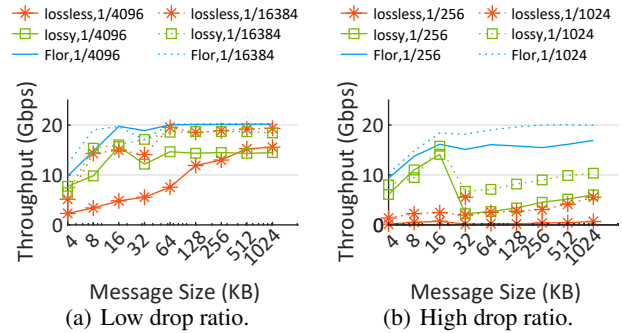

Figure 7: The throughput of lossless, lossy XRDMA and Flor under different packet drop ratio.

(as shown in Table 4).

### 7.3 Performance with Packet Loss.

To validate the effectiveness of the software *Reliability* mechanism of Flor, we take two CX-5 RNICs from cluster B in Table 2 and disable one port on each RNIC. We manually configure packet drop ratios on the RNIC of the receiver. We compare Flor against XRDMA using the lossless and lossy configuration of CX-5. The congestion control is disabled to avoid transmission rate back-off due to packet loss.

We use various request sizes (4KB~1MB) under four packet drop ratios (two high ratios of 1/256 and 1/1024, and two low ratios of 1/4096 and 1/16384). As shown in Figure 7, Flor outperforms the lossy and lossless setup across all the drop ratios. Due to software selective retransmission, Flor is able to maintain a performance close to that of zero packet drop at the low packet drop ratios. Its performance decreases slower than the lossy and lossless setup at the high drop ratios. We observe that the lossy acceleration feature achieves higher throughput with the occurrence of packet loss compared to the lossless setup, i.e., the lossy acceleration features of CX-5 does improve the packet loss recovery performance. However, the throughput of lossless and lossy RDMA both decrease dramatically when the drop ratio is larger than 1/4096. It indicated that the lossy acceleration features of current hardwares still cannot maintain good performance under high packet loss. Flor achieves similar results by performing the same experiments through manually configuring the random packet drop ratio on the port of the ToR switch connecting to the live port of the RNIC at the host.

### 7.4 Intra- and Inter-Pod Traffic

Flor uses an advanced congestion control to enable lossy RDMA support, eliminating the PFC dependency while maintaining high performance. We validate the performance gain of Flor in large-scale intra- and inter- pod transmission through cluster A (pod1) and B (pod2) (Table 2). We use the default configuration in our clusters in the tests of XRDMA: PFC for RoCE traffic is only enabled on ToR and Leaf switches (i.e., intra-pod) and disabled on Spine switches

Figure 8: The throughput of XRDMA and Flor in cross-pod scenarios.

(i.e., inter-pod). Similarly, we configure the intra-pod traffic of Flor (UC) on the lossless queue and the inter-pod traffic of Flor (UC) on the lossy queue. For each node, a client sends large RPC requests (512KB) to each server on other nodes with IO depth of 8. The size of the RPC response is 128 bytes. Each client and server uses 4 threads in the tests.

As shown in Figure 8(a), for intra-pod traffic, the average throughput of Flor (UC) is comparable to XRDMA which is stable at  $\sim 35$  Gbps. For inter-pod traffic test, as shown in Figure 8(b) and 8(c), the throughput of XRDMA in one pod shakes fiercely between 35 Gbps and 45 Gbps, and the throughput in the other pod oscillates between 35 Gbps and 20 Gbps. The unstable and unbalanced throughput of XRDMA is caused by packet loss as PFC is disabled in inter-pod switches, and DCQCN can not prevent packet loss. In contrast, the throughput of Flor (UC) is stable and balanced between the two pods. In summary, Flor can achieve higher and more stable throughput than XRDMA for lossy inter-pod tests. The clients in pod1 suffer more from throughput loss because they send more cross-pod traffic and experience more packet loss in this full-mesh traffic pattern.

## 7.5 Heterogeneous RNICs

To evaluate the effectiveness of Flor over heterogeneous RNICs, we test with 8 CX-4 and 8 CX-5 RNICs in cluster B (Table 2) with PFC and DCQCN enabled. We run the RPC benchmark with a full-mesh traffic pattern atop of Flor and XRDMA. When using XRDMA, the average throughput of CX-4 and CX-5 RNICs is 33.2 Gbps and 41.3 Gbps, respectively. The throughput gap between CX-4 and CX-5 is 8.1 Gbps (24.3%). When using Flor, the throughput of CX-4 and CX-5 RNICs with Flor is 37.1 Gbps and 36.6 Gbps, and the throughput gap is 0.5 Gbps (1.3%). This indicates that Flor eliminates the throughput gap between CX-4 and CX-5 RNICs by replacing the hardware congestion control with a unified software congestion control, which minimizes the performance difference introduced by the control path of heterogeneous hardware.

To verify the effectiveness of Flor over RNICs from different vendors, we run perfest among 100 Gbps RNICs, including Mellanox BlueField-2 [51], Intel E810-C RNIC [17] and Broadcom NetXtreme P2100G RNICs [7]. For congestion control, BlueField-2 only supports DCQCN, P2100 only supports DCTCP, and E810-C supports DCQCN, DCTCP and

Timely. To clarify the unmatched performance introduced by different congestion control algorithms, we choose to set DCQCN for BlueField-2 and E810-C, and DCTCP for P2100G with PFC and ECN enabled on RNICs and the connected switches. Each sender issues 512 QPs and sends traffic with 64KB data blocks. Four Flor configurations, i.e., *PFC with hardware congestion control (CC) and Flor*, *hardware CC and Flor*, *Flor*, and *Flor with fixed cwnd* are tested. *Flor with fixed cwnd* means the software congestion control algorithm has a fixed congestion window and does not change throughout the whole experiments. We set the fixed congestion window size as one bandwidth-delay product in this experiment.

Figure 9 shows the throughput of each NIC under the full-mesh traffic pattern. BlueField-2 and P2100G get the same bandwidth when they are competing with each other to send traffic to E810-C. Compare with Figure 2, with the configurations of PFC + hardware CC + Flor (1), hardware CC + Flor (2) and Flor (3), and we see that Intel NIC gets the same throughput, i.e., 18 Gbps, when competing with Mellanox NIC and Broadcom NIC. We see the performance gap between Intel NIC and Mellanox NIC when they send traffic to the Broadcom NIC, even if we only apply the Flor’s congestion control (3), where the Intel NIC gets 19 Gbps, and the Mellanox NIC gets 56 Gbps, 194% of the performance gap.

The reason is that Flor’s congestion control takes the RTT as the congestion signal. Intel NIC has a higher packet processing time, which causes the estimated RTT between the Intel NIC and the Broadcom NIC to be higher than the one between the Mellanox NIC and the Broadcom NIC. Thus, the RTT-based congestion control algorithm reduces window size in Intel NIC and results in lower throughput. This indicates Flor’s congestion control needs to be further improved by taking the NIC processing delay into account. If we fixed the congestion window, i.e., Flor with fixed cwnd (4), the bandwidth is less-skewed shared between the Mellanox NIC and the Intel NIC.

## 7.6 Large-scale Incast

We build a group of incast tests in cluster A (Table 2) to evaluate the performance of Flor’s congestion control. We measure the throughput and Out-of-Sequence (OOS) counter. We configure Flor running on the lossy queue, i.e., disabling

Figure 9: Bandwidth in a Mlnx-Broadcom-Intel hybrid deployment with Flor. Configurations: 1 = PFC+hardware CC+Flor, 2 = hardware CC+Flor, 3 = Flor, 4 = Flor +fixed cwnd.

Figure 10: Flor performance in large-scale incast test.

Figure 11: Run time in big data application.

PFC and DCQCN. For incast traffic, we install RPC clients on  $N$  machines and RPC server on one remote server. Each client has 8 threads connecting to the server, and each thread issues 32KB RPC requests with IO depth of 8. Thus, the number of QPs on each client is  $8 \times 8 = 64$ , and the number of QPs on the server is  $N \times 64$ . Thus, the maximum incast degree is  $\sim 6000$  when the node number is 90 in this test.

Figure 10 shows the throughput and OOS counters with different incast nodes of  $N$  and the minimal chunk sizes. Given the minimal chunk size of 4KB or 1KB, the throughput is consistent of 50Gbps with the increasing scale of incast. However, given the minimal chunk size of 4KB, the number of OOS increases when the incast nodes are larger than 50 (about 4000 : 1 incast). This is because the minimum chunk size of 4KB is the minimal congestion window size for each QP, and the volume of burst traffic is too large in such a large-scale incast. Therefore, we apply the minimal chunk size of 1KB, which avoids the generation of OOS in the large-scale incast. Notably, we set the minimal chunk size of 4KB in the storage production network because we have optimized the storage application to balance the load across nodes, which avoids such large incast events in practice [11].

## 7.7 Evaluation in Production Network

**Big-data applications.** ServiceX is a Map-Reduce-like big-data application that runs on top of the distributed storage service. The completion time of the shuffle processing influences the performance of the whole task, and it desires fast and stable network transmission. To estimate the impact of Flor in the production system, we run ServiceX atop of Flor and XRDMA in cluster C (Table 2) with a lossless network. We conduct the task of sorting 1TB of data. The number of mapper tasks and reducer tasks are both 1K, and each mapper processes data of 1GB. We apply two key metrics: the average running time of a mapper and the average shuffle time, *i.e.*, the time of transferring data in the network. As shown in Figure 11, in comparison with XRDMA, Flor reduces the average running time by 10% and accelerates the average shuffle time by 16% due to an efficient congestion control strategy.

**Non-stop upgrade.** Flor allows to upgrade online with negligible down time of service, which is crucial to meet service level requirements in modern datacenter. We measure the impact of upgrading from XRDMA to Flor on applications

such as Pangu [11] through the measurements of normalized throughput and latency and PFC counters. In the experiment, the software upgrading takes place at the 0.5<sup>th</sup> minute. As shown in Figure 12(a), the read and write throughput of the application have a slight jitter ( $< 2\%$ ) when switching to Flor. Figure 12(b) shows that the latency increases by 10% at 0.5 minute, lasting less than 30s. Figure 12(c) shows the generation of PFC pauses (packets per second, pps) and its duration time ( $\mu s$ ), which appears in a very short time period. At the 5.5<sup>th</sup> minute, we then disable DCQCN and PFC. The throughput is unaffected, and the latency decreases slightly ( $\sim 3\%$ ). This latency might be caused by the interference between DCQCN and the software congestion control. When running Flor with and without PFC and DCQCN, all the metrics are healthy.

**High-performance block storage service.** Flor is applied for latency-sensitive applications such as the Enhanced SSD (ESSD) product of Elastic Block Storage (EBS). ESSD provides block storage service (virtual disks) as local devices through high performance network. We compare the latency and requests per second (IOPS) of an EBS application running with XRDMA or Flor in cluster C (Table 2). We adopt the workload of a real ESSD storage application with an I/O size of 4KB. XRDMA is tested with RoCE lossy accelerations enabled. Flor is tested with these features disabled. There are three kinds of configurations for Flor: (i) Flor with hardware reliability and hardware congestion control (Flor HW R/C); (ii) Flor with hardware reliability and software congestion control (Flor HW R); and (iii) Flor with software reliability and congestion control (Flor SW).

Figure 13 (a) shows the normalized single-operation latency of XRDMA and Flor. Flor demonstrates comparable average latency performance with XRDMA among all the operation types. Although software-based modules are involved, the latency of Flor is still slightly lower (1%–8%) than XRDMA due to the optimized software stack of Flor. Flor (HW R/C) has the lowest average latency through hardware-based implementation. Flor (SW) and Flor (HW R) have slightly higher latency ( $< 3\%$ ) due to the overhead of software stack. Figure 13 (b) shows that Flor achieves the comparable normalized IOPS as XRDMA for 4KB *Read* and *Write*. In conclusion, in supporting block storage service, Flor has comparable latency and IOPS with XRDMA.

Figure 12: The system performance of upgrading from XRDMA to Flor.

Figure 13: Performance of Block Storage Service.

## 8 Discussion

**Hybrid RDMA NICs’ deployment in datacenters.** In the production network with over 100K servers, new servers and new NICs are incrementally deployed, which results in the mix of the latest generation and earlier generations (or different vendors) of RDMA NICs co-existing in the same datacenter network. In addition, the malfunctioning servers in the built-up clusters can be replaced by servers configured with NICs of different generations or vendors. The new generation of RNICs is released by the vendors every 2 or 3 years. From our experience in Block Storage Service, we first deployed storage servers with CX-4 RDMA NICs in 2016. In 2019, we started to deploy new servers of CX-5 RDMA NICs because of higher performance and price ratio. As a result, there exists the hybrid deployment of both CX-4 and CX-5 RDMA NICs. The same deployment choice was made when we introduced CX-6DX RDMA NICs in 2021.

**Programmable control plane.** Flor provides a new perspective of layered architecture to achieve high velocity and performance with diverse hardware. Flor envisions the "programmability" of reliability and CC modules of RDMA in the control plane, which can be implemented in programmable hardware, such as smartNICs with embedded CPU or NPU, e.g., ConnectX-6, Bluefield, Intel IPU. In this way, we can make use of the programmable hardware capability such as hardware timestamp, rate-limiting, and packet drop detection to further improve the efficiency of CC and reliability while keeping the unified control policy among heterogeneous RNICs with the same Flor architecture.

**Concerns of implementation.** Currently, not all NICs support UC. First, this research work has demonstrated, for the first time, the effectiveness of using UC for high-performance out-of-order transmission in product networks. Second, UC is a standard transport defined in the RoCE specification, and its logic is simple and easy to implement by hardware.

Network Protocol	MTU (B)	Throughput 100/200 (Gbps)
Linux TCP	1500	22
SNAP	1500	39.1
SNAP (+I/OAT)	5000	67.5 (82.2)
eRPC on IB	3840	73
Perftest	1024	88/193
XRDMA	1024	88/174
Flor	1024	84/173

Table 3: The single-core bandwidth of different network transport stacks in 100 and 200Gbps networks.

Therefore, this work provides a new choice for the community, and we expect more vendors to support UC. In addition, when migrating Flor to SmartNICs, e.g., Bluefield 2, which has multiple ARM cores and sufficient DRAM memory, thanks to Flor’s architecture that clearly separates each component, each individual component is easy to move to the BlueField’s ARM cores. The main differences from the host CPU implementation are that the ARM core is less performant than the host CPU core, and the L3 cache size of Bluefield 2 is limited, requiring the developers to optimize the system carefully. With the capability of directly operating data in the host memory introduced by Bluefield 3, the limited L3 cache size caused performance degradation can be resolved.

## 9 Related Work

**Software solutions.** We compare Flor with different network protocols. Table 3 shows the single-thread throughput between two nodes in the 100Gbps and 200Gbps network. The throughput of SNAP [33] and eRPC [20] are from the published papers. We can see that network protocols with hardware-offloaded RDMA semantics, *i.e.*, Perfest [13], XRDMA and Flor, achieve higher throughput than other network stacks. In addition, the throughput of XRDMA and Flor are comparable with Perfest, which plays the raw IB verbs without any overhead of RPC. The RDMA-based protocols can also maintain high bandwidth utilization in a 200Gbps network, where the throughput of Flor is the same with XRDMA. Though the throughput of eRPC and SNAP increases as the MTU size increases, using large MTU sizes requires a unified and standard configuration, which adds operation complexity in a complicated production environment. Besides, software solutions suffer from higher latency [33] and CPU overhead [20] without hardware

Functionalities	Lossless RDMA	Lossy RDMA	eRPC	IRMA	Flor
Transport granularity	Verbs	Verbs	MTU	Op (4KB)	Variable chunk (e.g., 4KB-64KB)
CPU Involvement	One/Two-sided	One/Two-sided	Two-sided	One-sided	One/Two-sided
Congestion control & Signal & Type	HW, ECN, rate	programmable HW, ECN+RTT, rate	SW, credit, window	SW, RTT, window	SW/HW, RTT/ECN, window/rate
Reliability & Retransmission	HW, GBN	HW, SR for RDMA Operation	SW, GBN	SW, unknown	SW/HW, intra-chunk GB0 & inter-chunk SR/GBN
PFC dependency & Loss tolerance	Yes, poor	No, high	No, poor	No, unknown	No, high
HW dependency	All RNICs	CX6-dx	DPDK/all RNICs	Customized NIC	All RNICs
Datapath zero copy	Yes	Yes	No	Yes	Yes

Table 4: Comparison on transport features of Flor and other network solutions.

acceleration.

**Hardware solutions.** To get rid of PFC, Mellanox brings up Resilient RoCE [48] and Lossy RoCE Accelerations [53] on lossless RNICs, *i.e.*, Go-Back-N-based RNICs. Resilient RoCE utilizes congestion control, *i.e.*, DCQCN, to deal with network congestion and avoid packet loss. A recent study [44] shows that the Resilient RoCE can prevent packet loss in some specific scales but still suffers unfairness from packet loss in large-degree incast events. Hardware-based lossy RDMA solutions such as Mellanox CX-5/6 [50, 52] and IRN [36] rely on strengthened hardware to run on a lossy network. They can not be deployed with CX-4 RNICs, and also lack the flexibility for users to customize each function as the implementation is highly ingrained into the hardware.

**Hardware & software co-design solutions.** RoGUE [28] designs a software congestion control for RDMA but relies on hardware reliability mechanism to recover from packet loss. It uses a large static chunk size, *i.e.*, 64KB, which needs to be revised to deal with the large-scale incast scenario. IRMA [45] is a high-performance network system that provides congestion control and reliability in software. IRMA also enables one-sided RDMA operations based on novel hardware with RDMA READ-like operation. However, it can not work on commodity RNICs, so it has little help for existing RDMA systems. Table 4 shows the clear difference between Flor and other network frameworks.

## 10 Conclusion

We present Flor, a flexible lossy RDMA framework for heterogeneous RNICs that solves a set of problems raised in production RoCEv2 clusters. These problems include PFC dependency, the interconnectivity of heterogeneous RNICs and hardware-bonded congestion control schemes. Flor onloads the reliability and congestion control function from RNICs to the software. Flor proposes a software selective retransmission for the first time at the RoCEv2 network and uses a software RTT-based congestion control to deal with the performance gap among the heterogeneous RNICs. Our evaluation of the testbed and production clusters shows that Flor achieves high performance and flexibility in many scenarios, including packet loss, heterogeneous hardware, large-scale incast, and distributed systems. Flor

also shows that the process of upgrading the existing RDMA framework to Flor has little performance impact on the running applications.

## APPENDIX

### A Design Details

#### A.1 Software Reliability

##### A.1.1 Chunk sequence number

Flor has two sequence number spaces, *i.e.* global sequence number (GN in Figure 14) and reliable sequence number (RN in Figure 14). The global sequence number is a 64-bit value and all the RDMA WQEs have a unique global sequence number to identify the sequence within a QP. The reliable

Figure 14: An example of the numbering system of Flor. An 40KB of *WRITE* WQE is split into a 8KB and a 32KB *WRITE* WQE. The 8KB *WRITE* WQE and 1KB *SEND* WQE are lost and get retransmitted. The retransmissions of 8KB *WRITE* WQE are transmitted via two 4KB *SENDS*.

sequence number is used to identify the sequence within the same type of WQEs, *i.e.*, *WRITE* WQEs and *SEND* WQEs have separate reliable sequence number space. Flor identifies the original WQEs and the retransmitted WQEs with different global numbers such that ACK information (and timestamp information carried in ACKs) is not ambiguous. The global sequence numbers for *WRITE* WQEs are maintained only at the senders and not transmitted to the receiver. The *SEND* WQEs carry both the reliable numbers and the global sequence numbers to the receiver. The retransmission WQEs share the same reliable sequence number with the original WQE. Note that Flor uses *SEND* WQE to retransmit *WRITE* WQE. This *SEND* WQE that is used for *WRITE* retransmission carries the original *WRITE* reliable sequence number, a new reliable number and a new global sequence number to the receiver such that this retransmission is able to be identified both by the sender and receiver.

The reliable sequence number of *WRITE* WQEs consists of 1-bit hint, 21-bit message id (MID in Figure 14) and 10-bit *chunk\_offset* (OFF in Figure 14). The hint bit is set when the WQE is the last WQE in the congestion window. We align the *chunk\_size* to the chunk unit size (*e.g.*, `UNIT_SIZE`). The *chunk\_offset* represents the offset of the memory address of a chunk ( $addr_c$ ) from the starting memory address of the same message ( $addr_m$ ), *i.e.*,

$$chunk\_offset = (addr_c - addr_m) / UNIT\_SIZE$$

The receiver can validate the integrity of the message by checking whether it has received data of all chunk offsets covered the message size and assemble the messages to notify the application. If using `UNIT_SIZE = 4KB`, then 10-bit chunk offset supports up to  $4KB \times 2^{10} = 4MB$  message. To support larger message in applications, users can allocate more bits for chunk offset field.

Figure 14 shows an example how this numbering system works. Here a large message of 40KB is split into 2 *WRITE* WQEs, *i.e.*, 8KB and 32KB and a *SEND* message is sent between these two *WRITE* WQEs. Each WQE has a unique global sequence number (GN) and the *WRITE* WQEs do not carry the GN to the receiver while the *SEND* does.

In the case that 8KB *WRITE* WQE and the 1KB *SEND* WQE are retransmitted. The 8KB *WRITE* WQE is split into two 4KB *SEND* WQEs, where the minimal *chunk\_size* is

4KB. Each *SEND* WQE for *WRITE* retransmission carries the original reliable sequence number of the *WRITE* WQE and has a new *SEND* reliable sequence number and a new global sequence number. Each *SEND* WQE for *SEND* retransmission carries the original *SEND* reliable sequence number and a new global sequence number to the receiver.

### A.1.2 ACK Format and Compression

Figure 15: Software ACK format.

Figure 15 shows the software ACK format. A 32-bit bitmap (4B) in ACK packet indicates that each ACK packet signals at most 32 WQEs. A  $i^{th}$  bit set in the bitmap indicates that the  $i^{th}$  ACKed number is a global sequence number for a **SEND** WQE, otherwise, the  $i^{th}$  ACKed number is the reliable sequence number for a **WRITE** WQE. It is possible that the ACK packet contains the number of ACKed number is less than 32. As Figure 15 shows that the first ACKed number starts from 24<sup>th</sup>B and each ACKed number is 4B. The number of ACKs carried in one packet is calculated as follows:

$$(ack\_length - 24B) / 4B,$$

where *ack\_length* is the packet length of the ACK packet. For example, an ACK of packet length 40B carries  $(40B - 24B) / 4B = 4$  acked numbers. If the bitmap is 0XC0000000, then the first 2 ACKed numbers acknowledge **WRITE** WQEs and the 3<sup>th</sup> and 4<sup>th</sup> ACKed numbers acknowledge **SEND** WQEs.

We limits the acked number to be 32-bit to shorten the length of the ACK packets. The reliable sequence number of a **WRITE** WQE and the global sequence number of a **SEND** WQE will be ACKed back to the sender. Recall that the reliable sequence number is 32-bit and the global sequence number is 64-bit. Thus, we compress the 64-bit global sequence number to a 32-bit ACKed number as follows:

$$acked\_num = global\_num - least\_acked\_global\_num,$$

where the *least\_acked\_global\_num* is the smallest global sequence number in a ACK packet. The WQEs with global sequence number larger than

$$least\_acked\_global\_num + 2^{32} - 1$$

are dropped by Flor if received. This window size is large enough in practice. The silently dropped WQEs, if there are, are detected by timeout.

## A.2 RTT measurement

### A.2.1 HW/SW Clock Synchronization

The timestamps are generated by the NIC hardware clock. Except from obtaining timestamps from completions events to calculate, Flor may also need time for other usages, e.g., setting retransmission timers. However, querying current time from RNICs is a time-consuming operation (e.g., costs 1 $\mu$ s in CX-4). Thus Flor maintains a software clock based on *rdtsc*() and synchronizes the clock with hardware clock. When Flor sends or receives an operation and the clock is not corrected for 100 $\mu$ s, then Flor queries a timestamp from RNIC and update the offset when the error exceeds threshold 10 $\mu$ s. According to our observation, the successfully correct ratio (i.e., the ratio that the error exceeds 10 $\mu$ s) is less than 1%.

### A.2.2 Improve RTT Measurement Accuracy

Figure 16: RTT accuracy with shared and isolated QP.

Figure 16 shows the measured RTT values with and without Flor optimization, i.e., *ACK on isolated QP* and *ACK on shared QP*, respectively. The experiment setup is the same as Figure 5 except using a larger RPC request size, i.e., 1MB.

### A.2.3 RTT Measurement for UC

Figure 17: Evaluation of optimizations on ACK designs.

Note that Flor ACKs coalescing mechanism can also cause the ACKs being delayed. Thus, we measured the ACK delay (i.e.,  $T_3 - T_2$ ) and local delay duration (the time between  $T_4$  and ACK processing time) with different acknowledgement frequencies. Figure 17 reports the 99<sup>th</sup> percentile of these delays as the acknowledgement frequencies changes. As expected, the ACK delay increases as the number of WQEs' ACKs coalescing increases, this is because the receiver needs to wait more WQEs to finish or a timer to generate an ACK. The local delay stays the same because Flor prioritizes to poll the ACK completion queue and Flor processes one

ACK regardless the number of the number of WQEs' ACKs coalescing. Finally, the RTT measurement results show that RTT measurement accuracy does not impact by the ACK frequencies with this improvement.

# ShRing: Networking with Shared Receive Rings

## Abstract

Multicore systems parallelize to accommodate incoming Ethernet traffic, allocating one receive (Rx) ring with  $\geq 1\text{Ki}$  entries per core by default. This ring size is sufficient to absorb packet bursts of single-core workloads. But the combined size of all Rx buffers (pointed to by all Rx rings) can exceed the size of the last-level cache. We observe that, in this case, NIC and CPU memory accesses are increasingly served by main memory, which might incur nonnegligible overheads when scaling to hundreds of incoming gigabits per second.

To alleviate this problem, we propose “shRing,” which shares each Rx ring among several cores when networking memory bandwidth consumption is high. ShRing thus adds software synchronization costs, but this overhead is offset by the smaller memory footprint. We show that, consequently, shRing increases the throughput of NFV workloads by up to 1.27x, and that it reduces their latency by up to 38x. The substantial latency reduction occurs when shRing shortens the per-packet processing time to a value smaller than the packet interarrival time, thereby preventing overload conditions.

## 1 Introduction

Software systems drive Ethernet NICs through producer-consumer “rings.” A ring is a logically circular memory array shared between software and NIC, such that each ring entry points to a buffer big enough to store an Ethernet packet. Software sends data by placing packet buffers in a transmission (Tx) ring, thereby handing them to the NIC to be sent. Software receives data by removing packet buffers from a receive (Rx) ring after they have been filled by the NIC, immediately replacing them with free buffers to be used in their stead for future incoming traffic. Thus, Rx rings are always fully populated with (free or filled) buffers, whereas Tx rings are commonly partially populated or empty. Consequently, Rx rings are more memory-consuming than Tx rings.

By default, a receive ring consists of  $\geq 1\text{Ki}$  entries [11, 21, 60, 65, 86, 86, 92], each pointing to a 1500B buffer, Ethernet’s maximum transmission unit (MTU) [36]. A typical Rx ring thus requires ( $1\text{Ki} \times 1500\text{B} \approx$ ) 1.5MiB. NICs support hundreds of such rings [12, 50, 66, 71], which software uses for synchronization-free parallelism, assigning different rings to different cores in both kernel [30, 33, 68, 77, 82, 84, 90] and user [2, 8, 24, 38, 52] network stacks. The combined size of Rx buffers across all cores—henceforth denoted as  $\alpha$ —can therefore reach tens of MiBs, which might be bigger than the

last-level cache (LLC). Notably,  $\alpha$  constitutes a lower bound for the size of the NIC working set [25], as the NIC sequentially operates on all Rx buffers, one after the other, so all buffers in the circle must be used before they can be re-used. As a result,  $\alpha$  exceeding LLC capacity can be problematic for high-throughput, low-latency workloads that sustain network traffic of up to hundreds of gigabits per second (Gbps).

The problem stems from these workloads relying on data direct I/O (DDIO) [20] technology or similar. DDIO allows NIC direct memory accesses (DMAs) to read and write packets to and from the LLC while avoiding high main memory access costs [15, 29, 63, 64, 78, 79, 87, 91]. But an  $\alpha$  larger than the LLC undermines DDIO’s effectiveness, as the NIC working set is too big to be cached. Consequently, CPU memory accesses become slower, contending with DMAs for insufficient cache capacity. Accesses are thus increasingly served by main memory, making the per-packet processing time longer. This overhead translates to degraded throughput and latency of networking workloads that experience the memory as a bottleneck resource.

We exemplify this problem in §2, using run-to-completion systems [6, 26, 35, 52, 58, 69, 73] common in microsecond-scale workloads like network function virtualization (NFV). In these systems, each thread of execution consists of a loop that iteratively polls an Rx ring, receives a packet from the wire, processes it to completion (without context switches or interrupts interfering), and then sends a response.

In §3, we consider addressing the problem by reducing the size of Rx rings [91]. We find that a size smaller than 1Ki might cause a core to experience many more packet drops when the incoming traffic targets this specific core. For example, a core may sustain 2x more packets without drops using 1Ki entries instead of 128. (Increasing Rx sizes beyond 1Ki has no benefit in our workloads.) In contrast, in multicore setups, using 128 entries per Rx ring reduces  $\alpha$  without incurring additional drops, provided the incoming traffic is evenly spread between the cores, which curbs the traffic and bursts that each individual Rx ring experiences.

Motivated by this finding, in §4, we propose “shRing,” a system that alleviates the above problem by sharing a 1Ki-sized Rx ring between a set of  $N$  cores. ShRing satisfies the simultaneous needs of all sharing cores when incoming traffic is even or uneven. Sharing balances buffer usage, allowing cores that sustain heavier traffic to utilize more Rx entries at the expense of cores sustaining lighter traffic while keeping  $\alpha$  small.

ShRing is advantageous if (1) cache misses due to ineffective DDIO usage cause non-negligible overhead, and (2) the workload avoids pathologically imbalanced conditions, where a subset of the sharing cores are continuously overloaded while their peers are underloaded. (NFV studies commonly assume non-pathological conditions [4, 10, 26, 59, 63, 73, 75, 76, 97], which might indicate the system is misconfigured.) If DDIO usage *is* effective, then shRing’s synchronization overhead might degrade the performance, and if the workload *is* pathologically imbalanced, then the overloaded cores might monopolize all the entries of the shared ring. ShRing thus dynamically identifies the above two conditions, and it turns itself on or off accordingly.

When operational, shRing boosts LLC hits by shrinking the working set, which reduces the per-packet processing time ( $P_t$ ) and thus increases throughput. If shRing’s shorter  $P_t$  becomes smaller than packet interarrival time ( $I_t$ ), queuing theory dictates that ring occupancy drops from full to empty, dramatically shortening latency from linear in the ring size to essentially  $P_t$ . But even if shRing’s  $P_t$  remains greater than  $I_t$  (ring fully occupied, so latency is linear in ring size), latency still improves by a factor of  $1/N$ , as the per-core Rx ring size is effectively  $1/N$  smaller, being shared by  $N$  cores.

Shared data structures commonly underperform due to software synchronization overhead [9, 22, 26, 55, 80, 90]. ShRing reduces this overhead by avoiding synchronization when deciding which core will process which newly arriving packet. By using per-core completion rings (CRs), the NIC spreads incoming packets between cores, adding the integer index of each packet’s entry to the CR of the core that owns the packet [37]. Cores still require synchronization when notifying the NIC that ring entries can be reused. ShRing bounds this overhead by limiting  $N$ , the number of sharing cores. We use  $N=8$ , but other values may be preferable in other setups.

We explore two shRing variants. The first, “RxArr,” is a shared cyclic Rx array structured similarly to a private ring. Because it is shared, its packet buffers routinely become ready for reuse out of (array) order, as they are processed by different cores. The problem is that, for correctness, RxArr is permitted to notify the NIC that entry  $i$  can be reused only after all preceding entries (such as  $i-1$ ) are likewise made reusable. This constraint necessitates coordination between cores, which increases the overhead of synchronization.

Our second shRing variant, “RxList,” simplifies coordination by turning the shared ring into a linked list using a “next” field added to Rx entries. When storing incoming packets, the NIC follows list (rather than array) order. This change allows cores to make entries immediately available for NIC reuse; they no longer have to wait for preceding entries. We find, alas, that RxList performs poorly, as the linked list structure undermines the NIC’s ability to prefetch Rx entries, ruling this design out for the time being. We propose a modest NIC ASIC modification that resolves this problem (but prevents us from experimentally evaluating this improved design).

We demonstrate in §5 that RxArr shRing works as expected, improving NFV macrobenchmark throughput by up to 1.27x and latency by up to 38x. In §6, we experimentally show that our findings are also applicable to more traditional applications that use kernel-based TCP sockets. Finally, we discuss related work in §7 and conclude in §8.

## 2 Motivation

We begin by providing the necessary background (§2.1) and by characterizing the problem that shRing tackles, which is the increasing working set size of the NIC as compared to the LLC size (§2.2). We then experimentally demonstrate how this problem affects performance as well as shRing’s ability to address its root cause (§2.3).

### 2.1 Background

**Interacting with NICs** Software and Ethernet NICs interact via logically cyclic producer-consumer queues called *rings*. The roles of producer and consumer depend on perspective: for received (Rx) traffic, the NIC can be viewed as producing incoming packets that software consumes; alternatively, software can be viewed as producing free buffers that the NIC consumes by filling them with incoming data. Transmitted (Tx) traffic can be viewed similarly. Software chooses the ring size and allocates it in main memory. The entries of a ring are architected *descriptor* structures consisting of several fields, one of which is a pointer to packet buffer.

Software pre-allocates packet buffers for all Rx descriptors. Each buffer can hold MTU bytes ( $\approx 1500$  by default). When a packet arrives, the NIC DMA-writes it to the buffer pointed to by the *tail* descriptor of the Rx ring (“next free” index), incrementing the tail to point to the subsequent descriptor if the tail does not surpass the *head* ring descriptor. Symmetrically, software dequeues Rx packets for processing from the head descriptor (“next full” index), iteratively incrementing it so long as it does not surpass the tail; software replaces the current head’s buffer, which the NIC has just filled, “reposting” a new free buffer instead and informing the NIC about this by “ringing the doorbell” (writing to a NIC register).

Tx traffic occurs similarly, with NIC and software flipping roles (NIC responds to software actions rather than the other way around). Thus, in contrast to the Rx case, Tx ring descriptors are initially empty and therefore consume less space.

A ring’s head and tail are maintained as consumer- and producer-controlled registers, residing in NIC memory mapped I/O (MMIO) and holding ring indexes. Software may configure the NIC to trigger an interrupt when it updates a register, or it may instead poll the ring and observe changes.

The NIC distributes incoming traffic load between multiple Rx rings, and therefore between multiple cores, using receive side scaling (RSS [68], which computes a hash over the packet’s header to produce a ring identifier) or accelerated

receive flow steering (ARFS [90], which consults software-controlled packet steering tables).

**NFs** In this work, we mostly focus on improving the performance of network function (NF) workloads. NFs are packet-processing applications that were once implemented using rigid proprietary hardware middleboxes and are now increasingly implemented with software on off-the-shelf servers [4, 23, 26, 27, 53, 54, 58, 74]. Common NF examples include switches, routers, firewalls, virtual private networks (VPN), deep packet inspectors (DPI), network address translators (NAT), and load balancers (LB). Evidence suggests that nearly 60% of all data center network traffic relies on NFs [74].

To attain high throughput and low latency, NFs commonly employ a packet processing model based on kernel bypass and direct NIC access [4, 23, 27, 53, 58] as provided by, e.g., the data plane development kit (DPDK) [51]. To improve efficiency and minimize overheads, this model typically foregoes abstractions like blocking I/O, context switching, and multi-tasking. Instead, it is designed as a simple run-to-completion, polling system, which does away with costly device interrupts as means of driving networking activity. Thus, each NF thread  $T$  gets its own dedicated core and rings.  $T$  continuously polls its Rx ring, and when a packet arrives,  $T$  processes the packet, generates a response, sends the response by placing it in its Tx ring, and resumes its Rx polling.

**DDIO** High-throughput, low-latency apps like NFs benefit from Intel’s direct data I/O (DDIO) technology [20] (other processor vendors support similar technologies [5, 93]). When possible, DDIO satisfies DMA operations from the LLC rather than main memory, which is faster/cheaper and may thus improve throughput and latency. Specifically, DDIO services DMA reads from the LLC if the target data is already there, which, in addition to being faster, also reduces memory bandwidth contention. Symmetrically, DDIO can perform DMA writes directly to the LLC instead of to main memory by either overwriting existing LLC lines, if they reside in the LLC, or by allocating new lines in up to two LLC ways.

## 2.2 The Problem: I/O Working Sets

Let the *I/O working set* be the memory area that an I/O device (e.g., NIC) reads/writes via DMA in a given time interval. For NFs, this set should preferably fit in the LLC due to DDIO. An I/O-intensive workload whose I/O working set size exceeds (or even approaches) LLC capacity implies: that I/O-related data likely competes for cache capacity; that DMAs are thus increasingly served by main memory instead of the LLC; and that LLC contention and memory bandwidth bottlenecks might occur as a result [15, 29, 63, 64, 78, 79, 87, 91].

Rx ring size is a key factor in determining the I/O working set size. Recall that all Rx descriptors are pre-populated with MTU (1500B) packet buffers upon startup. Subsequently, whenever software replenishes the ring’s head descriptor with

year	Intel NIC	gen. (GbE)	max ring num. ( $r_m$ )	default size (s)	Xeon CPU	LLC	cores
2001	[40]	1	1	256	[41]	256 KiB	1
2007	[42]	10	64	512	[43]	12 MiB	4
2014	[46]	40	1536	512	[45]	38 MiB	15
2020	[49]	100	2048	2048	[48]	77 MiB	56

Table 1: The first Intel NIC model in each GbE generations shown alongside the Intel CPU launched at the same year whose LLC was the largest in that year. The number of supported NIC rings and the default ring size are increasing.

a free buffer  $B$ , the head-tail protocol (§2.1) dictates that the NIC will DMA-write a new packet to  $B$  only after the associated Rx ring tail wraps around back to  $B$ ’s position. Thus, the aggregate Rx size (denoted  $\alpha$ ) serves as a lower bound for the I/O working set. If software utilizes  $r$  Rx rings of size  $s$ , then this lower bound is  $\alpha = r \times s \times 1500B$ .

The problem that motivates our work is that  $\alpha$  grows faster than the LLC and nowadays routinely exceeds it, with Rx rings increasing both in number ( $r$ ) and size ( $s$ ). Underlying this phenomenon are, notably, the following technology trends. NIC throughput has been growing faster than CPU packet processing speed for over a decade [32, 87]. The higher bandwidth increases variability and necessitates bigger network queues [28, 47, 94]. Moreover, the ever-growing traffic volume implies that the days when a single CPU core was able to drive an Ethernet NIC to its full capacity are long gone [31]. Thus, modern systems must employ multicore parallelism [9, 22, 26, 80, 90]. NICs have therefore evolved to offer multiple Rx/Tx rings, allowing each core to interact with the NIC through its own private ring instances in isolation. We refer to this architecture as *privRing*.

To demonstrate the rapidly increasing  $\alpha$  phenomenon (along with the underlying technology trends), we collected the ring maximal number ( $r_m$ ) and default size ( $s$ ) from the datasheet and driver, respectively, of every Intel NIC model released during 2000–2022. Table 1 shows a representative summary; to conserve space, we only include the first NIC of each Ethernet generation with increasing throughput. Early 1GbE NICs supported only a single ring, but as multicore CPUs became more common, subsequent 1GbE NICs supported up to 16 rings (not shown). Later, the first generation of 10GbE, 40GbE, and 100GbE respectively introduced support for 64, 1536, and 2048 rings.<sup>1</sup> The default ring size likewise increased from 256 to 2048. Network stacks and libraries adopt similar sizes. For instance, the default Rx ring size in all sample apps in the DPDK library is currently 1024 [60].

The right side of Table 1 matches each NIC with an Intel CPU model launched at that year, whose LLC was the largest

<sup>1</sup>It makes sense for  $r$  to be much bigger than CPU core number in order to support, e.g.: per-application rings [38, 95]; per-container rings [2, 24]; a ring for every SRIOV [44] instance of every virtual CPU of every virtual machine that runs on the host machine [82, 84]; and a hypervisor ring per VM ring for fallback when flow rule offloading is not yet configured [33, 77].

Figure 1: Aggregate Rx size ( $\alpha = r \times s \times \text{MTU}$ ) grows faster than LLC size and has already exceeded it in even the most minimalist configuration (based on data from Table 1).

at the time. Using this data, Figure 1 plots the size of the LLC and the minimal and maximal  $\alpha$  of the associated NIC. We see that the maximal aggregate Rx size (assuming all  $r_m$  supported rings are used) was always too big to fit in the LLC size in this time range. But in 2020, the aggregate Rx size of even the most minimalist configuration—just one Rx per core—became too big. This is the source of the problem.

The situation is exacerbated if considering logical, rather than physical cores (the 4.3x in the figure would have become 8.6x). We predict that this trend will continue, as upcoming NICs will bring more features (and queues), with speeds of up to 800 GbE expected in 2025 [13, 14].

## 2.3 Implications

Assume that the I/O working set size of some NF exceeds the LLC capacity and/or the LLC space it needs for satisfying DMA-writes of incoming data (constrained by DDIO to only two ways per LLC set by default) is insufficient. In this case, we claim that the overhead is significant to the point that it may be preferable to abandon dedicated private rings (privRings) in favor of shared rings (shRings), despite the synchronization cost associated with the latter.

To demonstrate, we use a synthetic FastClick NF microbenchmark configured to iteratively receive a packet, access an array, perform routing, and send the packet out [8]. The NF uses all (16) cores of our 2.1 GHz CPU, experiencing a theoretical incoming load of 200 Gbps of MTU packets (line rate), which in practice is 195.6 Gbps (due to 34B Ethernet overhead for each 1500B MTU packet). We execute this experiment using the baseline privRing, as well as three shRing variants that unify the rings of 2, 4, and 8 cores, respectively denoted as shRing/2, shRing/4, and shRing/8. (The full details of shRing are specified in §4, and the full details of the experiment are specified in §5.)

Figure 2a distills our case. It shows the average number of cycles it takes to handle one packet, breaking it down to synchronization overhead (“sync”) vs. actual processing time (“orig”). While synchronization overheads are substantial and

increase with the level of sharing, we see that it is nevertheless advantageous to pay the cost, as cycles-per-packet improves by about 4% each time we halve the I/O working set size.

The NF throughput, shown in Figure 2b, is approximately inversely proportional to cycles-per-packet (Figure 2a) as long as the CPU constitutes a bottleneck resource and line rate is not yet attained. Specifically, let  $C$  denote the average number of cycles required to process one packet, let  $hz$  ( $=2.1$  GHz) denote the cycles-per-second clock speed of the CPU, and let  $n$  ( $=16$ ) denote the number of running CPU cores, then  $n \times \frac{hz}{C}$  is the number of packets that the CPU handles per second, and so  $\text{Gbps}(C) = 1500\text{B} \times 8\text{bit} \times n \times \frac{hz}{C}$  is the throughput.

Using this equation, we can compute  $C_{bdgt}$ , the budget of per-packet cycles that the system must meet to achieve the 195.6 Gbps line rate (denoted “bdgt” in Figure 2a) as follows:  $C_{bdgt} = 1500\text{B} \times 8\text{bit} \times n \times hz / 195.6 \text{ Gbps} = 2061$  cycles per packet. Only shRing/8 meets the budget here.

We have argued that the reason underlying shRing’s improved performance is its smaller I/O working set, which curbs memory bandwidth consumption by increasing cache efficiency. This argument is directly supported by Figures 2c (memory bandwidth) and 2d (LLC misses as experienced by both CPU and NIC). In the latter figure, we see that privRing’s NIC PCIe miss rate is as high as 85%, which is why privRing’s average NIC PCIe read latency grows to  $1.45 \mu\text{s}$  (Figure 2e). Such a long PCIe latency is enough to saturate the DMA engines within the NIC (designed to hide PCIe latency with parallelism), and so it hampers the NIC’s ability to quickly process rings, which in turn generates high ring occupancy of 94% on average (Figure 2f). The implication is that, on average, each privRing packet  $P$  must wait for 966 packets ( $=94\%$  of ring size) to be processed before  $P$  is finally processed itself, which explains privRing’s high latency (Figure 2g).

In contrast, shRing/8’s occupancy is small, as it meets the  $C_{bdgt}$  budget and so its processing rate ( $\mu$ ) is larger than the arrival rate ( $\lambda$ ). Because  $\mu > \lambda$ , latency is much lower. Even when shRing does not meet the  $C_{bdgt}$  budget (the /2 and /4 variants), it improves latency, as its per-packet processing time is lower than in privRing.

## 3 Fewer or Smaller Private Rings

Conceivably, we can reduce the I/O working set size without ring sharing in two straightforward ways. One can use much smaller per-core Rx rings, or one can employ a single core (using a bigger Rx ring) as the system’s centralized “dispatcher” for all incoming traffic. Here, we briefly explain why neither is satisfactory for high-bandwidth networking applications.

The single-core, single-ring centralized dispatcher approach is used by such systems as Shinjuku [57] and Shenango [72]. It can be an effective way to reduce I/O memory consumption, and it has been shown to work well for NIC bandwidth of up to 40 Gbps. But more powerful NICs might not be served well by this approach, as the dispatcher’s

Figure 2: *ShRing*'s synchronization costs are significant but are nevertheless worthwhile, as they are cheaper than the overheads associated with *privRing*'s larger I/O working set. When *shRing*'s cycles-per-packet meet the line rate budget (a), its packet processing rate exceeds the packet arrival rate, generating low occupancy in the ring (f) and thus substantially reducing the latency (g).

limited compute capacity becomes a bottleneck [31].

The other potential approach, of reducing the size of all rings while retaining the ring-per-core design, is compatible with multicore parallelism. But we contend that the existing ring size is necessary and that reducing it has negative repercussions. To illustrate, we run the standard RFC2544 no-drop rate (NDR) test [10] with DPDK Layer-3 MTU packet forwarding (13fwd) on 8 cores. This test finds the maximum throughput attainable without loss. We run it once with traffic evenly spread across the cores (“multicore”) and again with traffic directed at one of them (“single core”).

Figure 3a shows that small rings work well for multiple cores if traffic is evenly spread between them, curbing the load and bursts that each core/ring experiences, which allows the fewer Rx buffers to cope. But small rings cease to deliver when traffic is uneven: the overloaded (“single”) core’s ring overflows and causes packet drops if it is smaller than 1Ki. In contrast, Figure 3b shows that one shared 1Ki-ring is enough to sustain optimal NDR of either 8 competing cores (each using 128 entries on average) or just one overloaded core, as *shRing* allows more loaded cores to use more Rx entries at the expense of their less loaded peers that are adequately served by fewer entries at that particular time.

## 4 ShRing’s Design and Implementation

*ShRing* is an architecture for driving high bandwidth NICs. Instead of using private per-core default-sized Rx rings, it shares each default-sized Rx ring between a set of cores. (*ShRing* leaves the Tx path unmodified.) *ShRing* can improve throughput, latency, or both, depending on the workload (§4.1).

Sharing a receive ring among cores requires us to synchronize the ring accesses of the CPU (using locks or atomic instructions), which incurs overhead compared to the synchronization-free *privRing*. *ShRing* curbs this overhead by limiting the number of cores sharing a ring to  $N$ ; we use

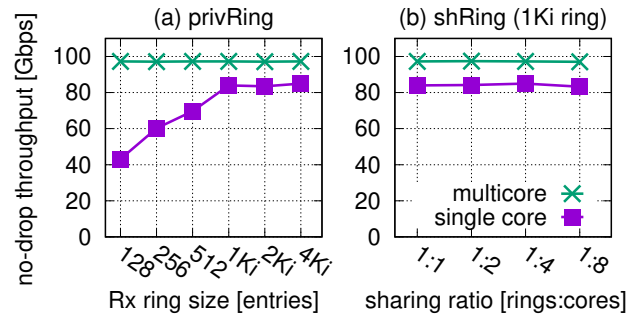

Figure 3: DPDK 13fwd no-drop rate. Small *privRings* work well when traffic is evenly spread across cores but cause drops otherwise. *ShRings* work well in both cases at a fraction of the buffer size.

$N=8$ , but other values may work better for other setups. Also, *shRing* reduces synchronization overhead by leveraging per-core completion rings (CRs) with which the NIC spreads incoming packets between cores [37], ridding them from having to compete for newly arriving packets (§4.2). As a result, *shRing*'s benefits outweigh its synchronization costs for workloads that suffer from ineffective DDIO use.

We propose two *shRing* designs that represent the ring as an array (RxArr, §4.3) or a linked list (RxList, §4.4). Both can be implemented with recent NVIDIA NICs. RxArr’s synchronization is costlier, but RxList’s interferes with the NIC’s Rx entry prefetching, so we rule it out (but propose a modest NIC ASIC modification that will fix this problem).

*ShRing* dynamically turns itself on/off depending on whether or not the workload is benefiting from it (§4.5). We describe the implementation details in §4.6.

### 4.1 Benefits and Constraints

*ShRing* can improve throughput and/or latency, depending on the workload. Next, we define the workload properties

necessary for shRing to be advantageous, and we explain the expected benefits of shRing and how it provides them. When shRing is counterproductive (necessary properties are absent), it dynamically disables itself.

ShRing is relevant only for workloads that avoid *pathological core overload*, where a subset of the sharing cores are continuously overloaded while their peers are underloaded. Pathological conditions may occur due to continuous, highly skewed per-packet processing time differences, or because of chronic incoming traffic imbalance. For reasons detailed later on (§4.5), when cores share a ring under pathological conditions, the fact that only some of them are overloaded implies that the packets of the overloaded cores increasingly and disproportionately accumulate within the ring, to the point that no room is left for packets of underloaded cores. This pathology causes new packets directed at underloaded cores to get dropped despite there being available processing capacity.

We term these conditions “pathological” because (1) they are suboptimal and may indicate the system is misconfigured, and (2) they are atypical when measuring NFV performance, as many NFV studies [4, 26, 63, 73, 75, 76, 97] and IETF benchmarking methodology [10] generate packet headers using randomization, balancing load across cores with hash-based packet spreading (e.g., RSS).

**Throughput** ShRing improves a workload’s throughput if (1) its I/O working set with privRing exceeds the LLC DDIO capacity and (2) the penalty of the resulting cache misses is non-negligible compared to the overall packet processing time. Relative to privRing, shRing multiplicatively decreases the number of rings by a factor equal to the number of cores sharing each Rx ring ( $N=8$  in our case). This decrease results in a corresponding  $1/N$  reduction of the I/O working set, possibly to below the LLC DDIO capacity. ShRing therefore mitigates and possibly eliminates the I/O-related cache miss penalty and thus enables more effective packet processing.

**Latency** ShRing improves a workload’s latency if the associated cores are saturated because packet service rate (number of packets processed per second, denoted  $\mu$ ) is smaller than packet arrival rate (number of packets arriving per second, denoted  $\lambda$ ). Latency is linear in the ring size  $s$  in this case, as queuing theory dictates that  $\mu < \lambda$  implies fully occupied Rx rings, which means every newly arriving packet waits for  $s - 1$  preceding packets to be processed. But in contrast to privRing, where each core has its own default-sized ring, shRing shares each such ring between  $N$  cores, so the “effective” ring capacity that each core experiences is  $s/N$ , which means the latency proportionally becomes  $1/N$  smaller (recall that we assume no pathological core imbalance).

Moreover, whenever shRing improves throughput, it also improves latency, as this throughput improvement stems from making the per-packet processing time ( $P_i$ ) shorter. Notably, if shRing’s shorter  $P_i$  transforms the overall service rate from slower than arrival rate (under privRing) to faster ( $\mu > \lambda$ )

Figure 4: PrivRing (private Rx rings) vs. shRing (shared Rx ring) with  $N = 3$  completion rings.

instead of  $\mu < \lambda$ ), queuing theory says that Rx ring occupancy drops from fully to barely occupied. Namely, latency drops sharply, essentially becoming  $O(P_i)$  with shRing instead of  $O(P_i \times s)$  with privRing. This shRing property underlies Figure 2g.

## 4.2 Synchronization with Completion Rings

In principle,  $N$  cores may share a receive ring by synchronously accessing the ring’s head. But this approach creates a synchronization bottleneck [9, 22, 26, 80, 90]. ShRing sidesteps this problem by reusing RSS to spread incoming packets between different sharing *cores* (in addition to spreading them between different *rings*, which is the usual role of RSS). So when the NIC stores incoming packets in a shared ring, it communicates to each of the  $N$  sharing cores which packets belong to that core via a per-core *completion ring* (CR), as depicted in Figure 4.

A CR is a circular array in host memory. There are  $N$  CRs associated with each shared ring  $R$ : one for each core  $C$  that shares  $R$ . The CR stores indexes of  $R$ ’s packet descriptors, specifying which descriptors are ready to be processed by  $C$ . Similarly to descriptor rings, a CR has head/tail entries whose indexes reside in NIC memory. When the NIC stores in  $R$  an incoming packet  $P$  that is mapped to core  $C$ , it writes the index of  $P$ ’s descriptor to the tail of  $C$ ’s CR and advances this tail. To receive packets,  $C$  polls its CR head awaiting notification about the next available packet in  $R$ . When  $C$  removes this packet from  $R$ , it advances its CR head.

Thus, per-core CRs allow cores to poll without synchronizing with their peers. CRs negligibly increase the I/O working set size, as a CR entry occupies only a single cacheline (for storing metadata about the associated packet, such as size and header offsets). Nonetheless, CRs do not obviate the need for synchronization when a core reposts a descriptor for the NIC to consume. RxList and RxArr address this synchronization problem in different ways.

**NIC Support** Recent NVIDIA NICs already support associating multiple CRs with a shared Rx ring as part of a shared receive queue (SRQ) buffers feature [37, 61]. The motivation for this feature is reducing DRAM pinning for RDMA (see §7), as opposed to shRing’s goal of improving throughput

and latency for Ethernet.

We expect support for Ethernet Rx ring sharing among CRs to become widely available in the future, because it is included in the infrastructure datapath function (IDPF) specification [17] and the Open Compute Project NIC specification [18], which are proposed industry standards for network device interfaces.

### 4.3 Array Ring Sharing (RxArr)

In the baseline `privRing`, each core  $C$  processes and reposts descriptors of its private ring in array order, one after the other. Namely, after  $C$  processes a descriptor  $D_i$ , it reposts  $D_i$  by advancing the head of the ring past  $D_i$  to  $D_{i+1}$ , thereby indicating that  $D_i$  can be reused by the NIC to store some other incoming packet in the future.

In contrast, `RxArr shRing` implements a ring array that is shared between  $N$  cores. It therefore cannot automatically advance the ring's head in this way, as  $D_i$  might become ready for reuse before its  $k$  preceding descriptors  $\{D_j\}_{j=i-k}^{j=i-1}$ . For example, if they were assigned to cores different than  $C$  and require a longer processing time as compared to  $D_i$ . Or if RSS happened to assign all of them to some other core  $C'$ , which must now work harder than  $C$  to catch up.

`RxArr` must thus guarantee that the NIC is notified that  $D_i$  can be reused only when all preceding descriptors are also ready for reuse. For this purpose, `RxArr` maintains a bitmap with a bit per descriptor, tracking which ring descriptors between head and tail have been processed and made available for reuse. After core  $C$  consumes  $D_i$  and re-arms it with a new empty buffer,  $C$  (1) atomically sets bit  $i$  in this bitmap, (2) consults the bitmap to find the maximal contiguous sequence of descriptors available for reuse beginning at the head  $\{D_j\}_{j=head}^{j=maxContig}$ , and (3) atomically clears the corresponding bits and advances the head past them.

The drawback of `RxArr` is its synchronization overhead, as its bitmap is a shared and frequently updated data structure that requires core coordination. Also, `RxArr` is suboptimal in that it delays the reuse of descriptors made ready by some cores, if prior descriptors have not yet been processed by other cores. Conceivably, packet loss might occur under `RxArr` despite available CPU and buffer capacity. In the `privRing` baseline, in contrast, ready descriptors reside in different rings and so the NIC can reuse them as they become available.

Listing 1 shows the `RxArr` receive function, which dequeues a batch of packets for processing. It receives a shared descriptor ring (`sd_ring`), the calling core's CR (`c_ring` completion ring), and an output array of packet pointers (`pkts`) of length `len`. It returns the number of received packets. Lines 10–15 poll the CR to find the location of a ready descriptor assigned to the calling core and store the descriptor's buffer in the output array, replacing this buffer with a new one. Lines 16–22 mark received descriptors in the shared bitmap (`sdr->bitmap`) while batching updates within 64-bit

```
1 #define BIT(x) (1 << ((x) & 63))
2 #define WORD(x) ((x) >> 6)
3 #define ISSET(bmp, x) \
4     (bmp[WORD(x) & (bmp->size - 1)]) & BIT(x))
5 int shRing(sd_ring *sdr, c_ring *cr,
6           void **pkts, int len) {
7     int rcvd = 0, lidx = -1;
8     uint_64t lbits = 0
9     while (rcvd < len) {
10        c_ring_ent *cre = get_cre(cr);
11        if (cre == NULL)
12            break;
13        int idx = cre->idx;
14        pkts[rcvd++] = sdr->desc[idx].buf;
15        sdr->desc[idx].buf = alloc_buf();
16        if (lidx == -1) lidx = WORD(idx);
17        else if (lidx == WORD(idx)) {
18            atomic_or(&sdr->bitmap[lidx], lbits);
19            lidx = WORD(idx);
20            lbits = 0;
21        }
22        lbits |= BIT(idx);
23    }
24    if (rcvd == 0) return 0;
25    if (lbits != 0)
26        atomic_or(&sdr->bitmap[lidx], lbits);
27    cr->ci += rcvd;
28    *cr->doorbell = cq->ci;
29    lock(sdr->lock);
30    while (ISSET(sdr->bitmap, sdr->ci) != 0) {
31        setb = ffs(~sdr->bitmap[WORD(sdr->ci)]);
32        atomic_clear(&sdr->bitmap[WORD(sdr->ci)],
33                    setb - 1);
34        sdr->ci += setb - 1;
35    }
36    *sdr->doorbell = sdr->ci;
37    unlock(sdr->lock);
38    return rcvd;
39 }
```

Listing 1: `RxArr` shared ring receive code.

words. This is done using atomic instructions, as other cores may be concurrently setting/clearing other bits in the bitmap. Line 24 handles the corner case of an empty CR. Lines 25–26 handle the remaining accumulated bitmap updates after exiting the loop. Lines 27–28 ring the CR's doorbell.

Lines 29–37 identify the maximal contiguous sequence of descriptors beginning at the ring head that is available for reuse, notifying the NIC about them. These operations are performed under a lock to guarantee the atomicity of (1) inspecting and modifying the bitmap and of (2) notifying the NIC. Line 31 uses the find-first-set instruction to identify the contiguous set bits. Lines 32–33 atomically clear them. Finally, Line 34 advances the ring's head (consumer index, `sdr->ci`) accordingly, and Line 36 writes the updated head to the shared ring's doorbell.

### 4.4 Linked List Ring Sharing (RxList)

`RxList` is a `shRing` design that alleviates `RxArr`'s bitmap coordination problem, eliminating the requirement to repost

Figure 5: RxList vs. Batched RxList designs for one shared ring with three completion rings. In (b), the batch size is 4.

descriptors in array order. To this end, RxList represents the empty packet buffer descriptor queue as a linked list. The NIC correspondingly follows list order when storing incoming packets. The list itself is overlaid on the Rx descriptor array, with each descriptor holding a “next” field pointing to the next list item. (Linked list functionality is part of the SRQ feature [7].) Initially, each descriptor points to the subsequent descriptor in the array. But as packet processing occurs and cores process and repost descriptors out of array order, the descriptor order in the list changes. We denote the first and last descriptors in the empty descriptor list as *hwHead* and *hwTail*, respectively, to distinguish them from the “head” and “tail” used in the rest of the paper to describe the first and last descriptors holding packets.

Figure 5a depicts RxList’s structure using three cores sharing a single Rx ring. Observe that RxList’s descriptor ring entries are not contiguous: there are multiple non-vacant descriptors in the array between *hwHead* and its successor vacant descriptor in the list, which is impossible in an array-based design. The figure also shows dashed links between non-vacant descriptors. These represent the order in which these descriptors were filled by the NIC, i.e., their order in the list when they were vacant.

We now detail RxList’s receive flow, whose code is shown in Listing 2. The function’s inputs and outputs are the same as RxArr’s receive function. Lines 5–10 batch packets for processing exactly as in RxArr: the completion ring is polled to find the location of ready descriptors, each such descriptor’s buffer is stored in the packet output array, and the descriptor’s buffer is replaced with a new buffer. Lines 11–13 are unique to RxList: they link dequeued descriptors one after the other, creating a linked list that will eventually be appended to the tail of the empty descriptor list. Lines 15–17 are again standard functionality. First, the case of an empty completion ring is checked, and then the core’s completion ring head (denoted *ci*, or consumer index) is updated, including a notification to the NIC via a doorbell MMIO write. Lines 18–24 are again new to RxList. They lock the shared descriptor ring to atomically (1) append the new list created in lines 11–13 after the tail of the list and (2) notify the NIC, via a doorbell

```

1 int ll_rcv(sd_ring *sdr, c_ring *cr,
2         void **pkts, int len) {
3     int idx, rcvd = 0, myhead, *iptr = NULL;
4     while (rcvd < len) {
5         c_ring_ent *cre = get_cre(cr);
6         if (cre == NULL)
7             break;
8         idx = cre->idx;
9         pkts[rcvd++] = sdr->desc[idx].buf;
10        sdr->desc[idx].buf = alloc_buf();
11        if (iptr == NULL) myhead = idx;
12        else iptr->next = idx;
13        iptr = &sdr->desc[idx];
14    }
15    if (rcvd == 0) return 0;
16    cr->ci += rcvd;
17    *cr->doorbell = cq->ci;
18    lock(sdr->lock);
19    int prevtail = sdr->hwTail;
20    sdr->desc[prevtail].next = myhead;
21    sdr->hwTail = idx;
22    sdr->ci += rcvd;
23    *sdr->doorbell = sdr->ci;
24    unlock(sdr->lock);
25    return rcvd;
26 }

```

Listing 2: RxList (linked list) shared ring receive code.

Figure 6: Although conceptually more suitable for sharing, RxList interferes with descriptors’ contiguity, hampering their prefetching and thus degrading performance. (Labels show List to Arr ratio.)

write, of the number of descriptors with empty buffers that are appended to the list. Finally, line 25 returns the number of received packets.

**Prefetching Problem** We find that RxList neutralizes descriptor prefetching, an important NIC performance optimization. Because descriptor rings are typically stored contiguously, the NIC reads sequences of contiguous descriptors in a single PCIe read transaction and caches valid descriptors in NIC memory to improve throughput and reduce latency for subsequent packets. When descriptors are linked out of array order, the NIC fails to find the next descriptor on the list in its on-NIC cache, resulting in more descriptor DMA reads being required.

Effective descriptor prefetching is critical for high PCIe-based NIC performance [70], and even more crucial for shRing. In *privRing*, a descriptor cache miss on some ring

does not stall incoming traffic destined to other rings, but with shRing there are fewer rings and so more traffic is stalled.

To demonstrate this effect, we evaluate the performance of various descriptor ring to core sharing ratios. We compare RxList to RxArr, in which the NIC follows descriptor array order when storing packets. We run the synthetic NF (from §2.3) on all cores and try to process traffic at line rate.

Figure 6a shows the throughput achieved by both designs. When there is no sharing, then RxList, RxArr, and privRing (not shown) perform similarly ( $\approx 2\%$ ). This is expected since in this case, all approaches maintain ordering within the single descriptor ring. However, as we decrease the ring to core ratio, linked list descriptors become reordered and RxList’s throughput declines sharply as sharing increases: 33% for 1:2 sharing ratio and 76% for 1:8 sharing ratio.

Figure 6b shows how costly out-of-order descriptors are, motivating RxArr. Specifically, we report the NIC’s internal packet processing time, and see that for linked lists this time grows as more cores share a descriptor ring: from 3.7  $\mu$ s at 1 core per ring to 16.3  $\mu$ s at 8. In contrast, RxArr performance remains the same regardless of the sharing ratio.

**Prefetching Solution** We propose *batched RxList*, a shRing design that obtains RxList’s resiliency against pathological core overload conditions without damaging the NIC’s performance. Batched RxList amortizes the cost of locking and descriptor reordering in RxList by batching packets to descriptors. In this design, depicted in Figure 5b, each RxList descriptor points to a buffer that can hold multiple packets. For each RxList, the NIC stores new packets destined to a core via the same descriptor used to store previous packets for that core, provided that room remains in the descriptor’s packet buffer. Only once this descriptor “fills up” will the NIC consume a new descriptor from the list and start storing incoming packets for that core in the new descriptor’s buffer. To perform this batching, the NIC caches the last Rx descriptor used for each CR associated with the RxList. The NIC thus effectively maintains per-core “mini hwHeads” pointing to each core’s current descriptor.

The benefit of the batched RxList design is twofold. From the NIC’s perspective, batching packets in descriptors and caching the descriptors reduces the importance of descriptor prefetching, as packets destined to a core experience a single cache miss per batch. From the cores’ perspective, batching reduces RxList synchronization, as locking the RxList to re-post a descriptor is now guaranteed to occur only once per batch, instead of potentially once per packet.

Although recent NICs support batching multiple packets in a single large descriptor buffer [3], batched RxList requires NIC ASIC modifications to support a list consisting of such descriptors. Therefore, we cannot evaluate batched RxList. We present this design to underscore that RxList’s tradeoffs are likely not fundamental and are caused by current NIC ASIC limitations, which can be fixed.

## 4.5 Dynamic ShRing

We propose a dynamic approach that switches between privRing and shRing during run time, depending on which architecture is more beneficial at the moment. Our goal is to disable shRing if the workload experiences pathological core overload or if it is not bottlenecked on I/O-related cache misses. We describe the heuristic we currently use to identify these conditions. We leave improving the precision and robustness of the heuristic for production use to future work.

**Pathological Overload** Pathological overloaded conditions can make overloaded cores monopolize ring descriptors. If continuous, high per-packet processing time differences are such that the packet service rate of overloaded cores is smaller than their packet arrival rate, queuing theory dictates that the Rx ring eventually becomes fully occupied with their packets. If incoming traffic is chronically imbalanced, large batches of packets destined to overloaded cores can arrive and occupy most if not all the descriptors.

In both of the above scenarios, overloaded cores invoke their ring’s receive function less frequently than underloaded cores. This is clearly the case for cores overloaded due to high per-packet processing time, but also happens if overload is due to incoming traffic imbalance. In this case, an overloaded core’s receive call produces a large batch of packets, which takes the core longer to process before returning to the ring to dequeue more packets. We detect overloaded cores based on this behavior, as explained below.

**I/O-Related Cache Miss Significance** Recall that under non-pathological conditions, a workload will benefit from shRing if (1) its I/O working set with privRing exceeds the LLC DDIO capacity and (2) the penalty of the resulting cache misses is non-negligible (§4.1). We associate (1) with high memory bandwidth utilization and (2) with high networking throughput.

**Heuristic** We measure throughput, memory bandwidth, and time between subsequent calls to the receive function and record the results in a sliding window of 16 entries. When more than half of throughput and memory bandwidth measurements exceed a predefined threshold while no core is overloaded (calls receive infrequently compared to other cores), we switch from privRing rings to shRing rings. To switch back from shRing to privRing, we wait until  $\frac{7}{8}$  of measurements are below the threshold

To switch between privRing and shRing, we pre-program two sets of RSS tables, which are NIC data structures used to steer incoming packets to descriptor and completion rings based on packet headers. Each RSS table set points to its own set of rings, i.e., privRing and shRing. Then, based on the heuristic’s decision, we update NIC steering rules to redirect packets to the appropriate RSS table set. After switching, before we begin polling the new rings for packets, we drain remaining packets from the previous ring set.

## 4.6 Implementation

Our implementation of RxArr and RxList targets 100 GbE NVIDIA NICs with unmodified ASICs. We initially relied on firmware patches to expose ring sharing mechanisms, originally aimed for InfiniBand RDMA (see §7), for Ethernet use. However, NVIDIA NIC firmware now makes these mechanisms generally available.

We implement our designs with 2039 lines of code (LOC) in the NVIDIA DPDK driver and only 137 LOC in DPDK’s core. We leverage DPDK’s command line driver options to enable the desired ring sharing mechanism and to specify how many cores share each ring. This approach enables unmodified DPDK-based applications to benefit from shRing.

Dynamic shRing is implemented in a dedicated thread that runs every 10 ms on a separate core which polls Intel PCM [39] counters for PCIe generated memory bandwidth and NIC byte and packet counters. We expose PCM counters through a library that we link with DPDK; the library is 116 LOC and the code using it in DPDK is 330 LOC. As the threshold for switching from privRing to shRing, we use throughput greater than 170 Gbps, memory bandwidth greater than 25 GiB/s, and the standard deviation between calls to Rx functions being at most 32x larger than the median (where 32 is the maximum packet batch that shRing’s Rx functions can return). We experimentally find that these values provide good results for the NFs we tested.

## 5 Evaluation

We evaluate shRing’s effectiveness using synthetic microbenchmarks as well as NAT and LB macrobenchmarks. We measure the gains obtained with shRing’s efficient I/O working set utilization in both non-pathological and pathological conditions (§4.1) under 200 GbE load.

### 5.1 Methodology

**Experimental Setup** Our setup consists of two Dell PowerEdge R640 servers, connected back-to-back via two pairs of 100 GbE NVIDIA ConnectX-5 NICs with pause frames disabled. One server is the evaluated system and the other is the load generator. Both servers have 16-core 2.1 GHz Xeon Silver 4216 CPUs, 128 GiB (=4x16 GiB) 2933 MHz DDR4 memory, and a 22 MiB LLC that consists of 11 ways. They run Ubuntu 18.04 (Linux 5.4.0) with hyperthreading and Turbo Boost disabled. The kernel is configured to isolate CPUs from the OS scheduler, use 1 GiB hugepages, disable power saving states, and disable microarchitectural side channel mitigations.

On the load generator machine, we run the stateless Cisco T-Rex packet generator [16], which we modify to improve latency measurement accuracy from 10–100 $\mu$ s to 1 $\mu$ s [81]. Unless specified otherwise, we use default application settings: 1024 descriptor Rx and Tx rings and 2 DDIO LLC

Figure 7: Normalized performance of shRing to privRing for NFs with varying memory intensity: shRing/8 improves performance in all cases. (Labels show percentage of NFs in quadrant.)

ways, and we run application logic on all 16 of the available CPU cores—8 cores per NIC. All the results presented are trimmed means of ten runs; the minimum and maximum are discarded. The standard deviation is always below 5%.

**Measurement Tools** We measure cycles per packet by modifying applications to record cycle counters, cache hit rate using Linux perf, Tx ring occupancy by comparing completion ring producer and consumer indexes, PCIe latency using NVIDIA Mellanox Neo-host [67], and memory bandwidth and PCIe hit rate using Intel PCM [39].

**Ring Mechanisms** We compare between privRing; non-dynamic array ring sharing (RxArr) between 8 cores—the maximum possible on a CPU with 16 cores and 2 NICs—which we denote “shRing/8;” and a small privRing configuration whose aggregate descriptor count equals that of shRing/8, i.e., 128 entries per ring when shRing/8 uses 1024 entries per RxArr. We remark that small privRing is impractical since it imposes loss when traffic is bursty, as shown in §3. We show it for a thorough comparison between privRing and shRing.

### 5.2 Non-Pathological Conditions

We show the benefits of using shRing under high load without pathological core overload conditions. Specifically, we evaluate (1) synthetic NFs with varying memory intensity and cache pressure; (2) NAT and LB performance; and (3) MICA key-value store performance.

For NFs, we use large 1500B UDP packets sent at 200 Gbps to stress the I/O working set, and select packet 5-tuples at random to spread the load across cores.

**Memory Intensity** To explore shRing performance with NFs of various memory intensity, we run FastClick’s synthetic WorkPackage module [8] which receives a packet, performs routing, followed by a number of random memory reads from

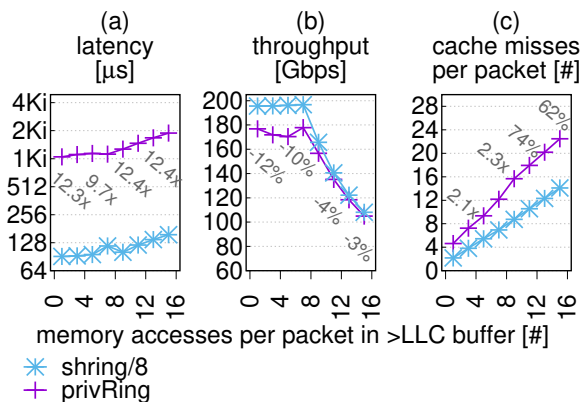

Figure 8: High cache pressure decreases performance for shRing and privRing. (Labels show privRing to shRing ratio.)

a buffer, and then sends the packet out. We modify WorkPackage to optionally read or overwrite packet payload.

We test 60 configurations: randomly reading 1, 2, 4, 8, or 12 times from a 1MiB, 10MiB, 20MiB, or 40MiB buffer (corresponding to L1, L2, LLC, and larger than LLC sizes), while packet payload is either untouched, read, or overwritten.

For each configuration, we plot shRing throughput, latency, and cycles per packet normalized to privRing; Figure 7 shows the results. We find that throughput and latency improve with descriptor sharing ratio: shRing/8 obtains the best throughput and latency followed by shRing/4 and then shRing/2. Moreover, shRing/8 always outperforms privRing (all are above the horizontal line), while shRing/4 and shRing/2 underperform privRing for 54% and 38% of the most memory intensive configurations, respectively. Exploring the configurations where shRing/2 and shRing/4 are less successful than privRing, we find that they consist of 3/16 and 11/16 NFs that read packet payload, and 5/16 and 6/16 configurations that overwrite payload, for shRing/2 and shRing/4, respectively.

**Workload Cache Footprint** We explore shRing effectiveness as the workload’s cache footprint grows. We use the aforementioned synthetic NF with 1–16 random memory accesses per packet in a 40 MiB array. Figure 8 shows the results. ShRing mitigates I/O working set induced cache misses, improving application cache hit rates by up to 2.1x, which translates to up to 13% higher throughput and up to 13.1x lower latency. As the workload’s cache footprint grows, so does CPU processing time per packet, so eventually cores exceed the CPU cycle budget needed for line rate processing. Both throughput and latency degrade as a result. As the number of processed packets thus decreases, the I/O working set induced cache stress decreases too, and so the gap between cache misses per packet in privRing and shRing shrinks.

**NAT and LB** We use two stateful FastClick NFs as macrobenchmarks: NAT and LB, which cache up to 10M flows using per-core cuckoo hash tables. NAT consistently remaps

Figure 9: LB and NAT performance at 200Gbps load.

and rewrites incoming and outgoing packet IP packet headers. LB matches each flow with one of 32 destination servers, maintaining the match for each flow and making new matches with a round-robin policy. NAT is more memory intensive than LB, as it uses two cache entries per flow (one for each direction) while LB uses only one

We show results with a load of 200 Gbps. Results with speeds greater than 170 Gbps are similar, while lower speeds show no difference in throughput and less than 5 μs in latency in favor of privRing due to the synchronization overhead of shRing. The results we show are for the default Rx ring size (i.e., 1024), results for other ring sizes are similar in nature.

Figure 9 depicts the resulting (a) throughput, (b) latency, (c) ring occupancy, (d) PCIe (DDIO) miss rate, and (e) memory bandwidth. The results show that shRing/8 outperforms privRing in throughput and latency, which is consistent with previously presented microbenchmarks. This happens because at high offered load the I/O working set starts contending with the CPU for LLC space and memory bandwidth, which slows CPU packet processing. CPU slowdown, in turn, causes ring occupancy to grow, which increases latency (as explained in §2.3).

We expect small privRing to perform similarly to shRing/8, and indeed this is the case for LB, but surprisingly small privRing NAT performance is worse than shRing. For NAT, small privRing has a notably lower DDIO hit rate and higher ring occupancy. We speculate that the root cause is that shRing reposts buffers slower as it waits for other cores to make progress, and therefore its working set is slightly smaller because less buffers are exposed to I/O.

ShRing achieves high performance because it shrinks the I/O working set size to fit in the default DDIO portion of the LLC (i.e., two LLC cache ways). When disabling DDIO, namely forbidding NIC DMA writes from allocating ways within the LLC, all ring types achieve only 150 Gbps through-

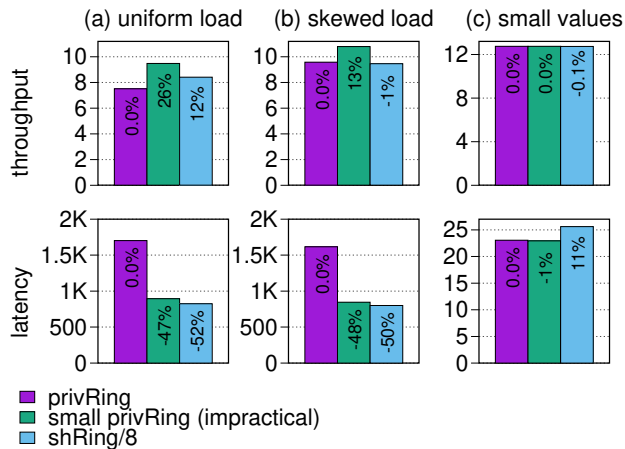

Figure 10: ShRing benefits the MICA key-value store with large I/O working sets, non-pathological load imbalance, and high load.

put and 1.3  $\mu$ s latency, which is 3% and 27% lower than privRing and shRing/8 with default DDIO (not shown in the figure). When assigning all LLC ways to DDIO, privRing performance matches shRing for LB, but it is insufficient for the more memory intensive NAT application, which uses twice as much state and whose throughput improves by less than 5% (also not shown).

**Key-Value Store** We use the MICA key-value store [62] to show that shRing is applicable beyond NFs and to highlight how workload conditions impact shRing’s effectiveness. We run MICA on 8 cores using a single 100GbE NIC, with 128 B keys and 1KiB values.

Figure 10a shows the results of a workload with 95% set operations, uniformly distributed among all cores, at the highest possible request rate. This workload satisfies the conditions that make shRing beneficial (§4.1)—i.e., (1) no pathological core overload, (2) a large I/O working set, and (3) non-negligible penalty of I/O-related cache misses. ShRing improves MICA throughput by 12% and reduces latency by 52% in this workload; small privRing shows the potential throughput gain from reducing the I/O working set, without shRing’s synchronization cost.

Figure 10b changes the workload’s traffic spread, making it imbalanced (Zipf distribution of skewness 0.99). Consequently, shRing reduces throughput by 1% over privRing but still improves latency by 50%. Figure 10c shows the initial workload but with 128B values, which makes the I/O working set small. ShRing makes no throughput improvement and increases latency by 11%. We obtain similar results when lowering the request rate of Figure 10a’s workload (not shown). In both these cases, shRing adds synchronization overhead which is not offset by I/O working set related improvements, either because the I/O working set was small to begin with (Figure 10c) or because the penalty of I/O-related cache misses is negligible (low load).

### 5.3 Pathological Conditions

This section demonstrates shRing’s sensitivity to pathological core overload, where one of the shared ring’s cores is continuously overloaded compared to the rest. We evaluate shRing/8, referred to as “shRing” here, as well as dynamic shRing/8 (denoted “dshRing”) and its ability to gracefully fall back to privRing in pathological conditions. We evaluate two causes for pathological conditions: variability in processing and variability in incoming packet distribution among cores. We also evaluate NAT and LB throughput when offered load switches from non-pathological to pathological over time.

**Processing Variability** In this experiment, we choose a target core per NIC and control its processing speed by varying the number of memory accesses it performs per packet while all other cores run the synthetic workload described in §2.3.

Figure 11a depicts the resulting throughput. When the target core’s packet processing is fast, shRing and dshRing throughput is 12% higher than privRing, but as the core’s processing slows down, shRing throughput declines to 58% lower than privRing. In contrast, dshRing notices that one core is slowing down shRing and switches to privRing, thereby avoiding performance degradation.

Figure 11b explains the observed throughput, by showing the time shRing Rx descriptors wait for co-sharing core bitmap updates before being handed back to the NIC. We present only shRing and dshRing, because privRing does not have such delays. In shRing, slow processing on the target core can delay co-sharing cores from making their processed Rx descriptors available for NIC reuse. This effect is negligible when the target core makes less than 100 memory accesses per packet, but subsequently, descriptor wait time increases dramatically (up to 257  $\mu$ s) and throughput decreases.

**Traffic Variability** Here, we choose a target core per NIC and vary the percentage of packets directed to it up to 30%. All cores run the synthetic workload. We direct 64 B packets at the target core and 1500 B packets at the others, so that even when receiving 30% of the packets, the target core’s incoming traffic is < 3% of total incoming throughput. This means that in principle, the target core’s behavior should have negligible effect on overall throughput.

Figure 12a shows the throughput in practice. When the packet load on the target core is less than 15%, shRing outperforms privRing and dshRing’s heuristic correctly enables shRing. But as load exceeds 15%, the targeted core becomes overloaded and so shRing throughput declines by up to 54%. In contrast, privRing throughput declines by only 3%, since other cores are not affected. DshRing’s heuristic identifies when the achieved throughput is too low and that it will not be improved by shRing, and thus switches to privRing.

Figure 12b shows that as with processing variability, shRing’s throughput decreases because the unloaded cores’ Rx descriptor reposting is delayed by the overloaded core.

Figure 11: When incoming packet rate is fixed, processing variability in one core (e.g., due to increased number of memory accesses) might degrade shRing’s throughput and delay descriptor reposting in peer cores. Dynamic shRing falls back on privRing when this happens.

Figure 12c presents the ratio of packets successfully processed by the target core out of all packets. While shRing maintains the target core’s ratio of outgoing to incoming packets, the cost is that as more packets target this core, shRing delays receiving on other cores. This results in drops of the 1500 B packets when the target core is overloaded, and thus throughput declines. In contrast, privRing drops excess packets that exceed the target core’s processing capacity, and as a result it has at most 17% outgoing packets on the target core.

**Handling Variability with Dynamic ShRing** We run an experiment where the incoming load switches from non-pathological to pathological after 20 seconds. Figure 13 shows NAT and LB throughput sampled every second. DshRing initially uses privRing, but as load increases, it identifies high throughput and memory bandwidth with no overloaded cores and switches to shRing. At 20 seconds, we reconfigure the load generator to send a pathological load, which overloads cores and decreases throughput. DshRing identifies the drop in throughput and switches back to privRing. Consequently, dshRing achieves good performance in both.

## 6 Kernel-Based TCP Sockets

Our implementation and evaluation focus on NFV workloads, which typically bypass the operating system (OS) networking stack and the socket abstraction. This section explores the potential benefit to socket-based TCP applications from deploying shRing in the Linux networking stack.

Concerns about the effectiveness of a shRing-based NIC OS driver are that (1) application working sets may be too large for shRing’s improved DDIO utilization to matter and (2) even if not, small private rings might not lead to packet loss in the Linux kernel, as opposed to with DPDK.

Because our shRing prototype is DPDK-based, we cannot directly evaluate shRing in the Linux kernel. We therefore use “small privRing” as a proxy, to show the benefit of

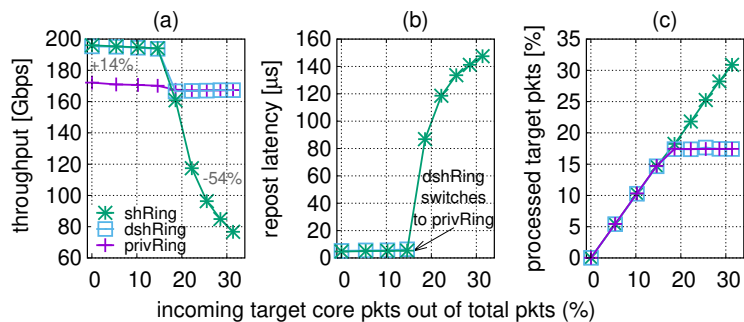

Figure 12: When variability manifests as increased rate of packets targeting one specific core (x axis), at some point, it prolongs the latency of peer core descriptor reposting (b); at this point, performance degrades (a) as the target core processing can no longer match the volume of incoming traffic (c).

reducing the I/O working set in the Linux kernel. We run Netperf [56] microbenchmarks to show that: (1) smaller I/O working sets can improve performance of a socket-based application and (2) 1Ki-sized rings are necessary to handle burstiness in the kernel.

**Pros of Smaller I/O Working Sets** We measure Netperf TCP request-response throughput (sum of Rx and Tx). We use 16 cores and two NICs with two threads per core (one per NIC). For symmetry, we use the same ring size on both sides. In all experiments, the CPU is not the bottleneck.

Figure 14a shows the throughput obtained for 64KiB requests and various response sizes. In this setting, small rings outperform large rings by up to 10%. But when the size of the request and the response are equal (Figure 14b), the results become less conclusive, e.g., for 1KiB messages throughput is almost the same for both ring sizes, and for 4KiB messages, the small ring’s throughput is 5% less than the default.

**Cons of Small Private Rings** We measure Netperf TCP stream throughput for various private ring sizes, with traffic either directed at a single core or evenly spread among 8 cores. Figure 15 (similarly to Figure 3) demonstrates that small rings work well for multicore TCP traffic, as the spread of load curbs the bursts each individual core/ring experiences. However, a single ring smaller than 1Ki overflows and causes drops, which cause TCP to back off and thus degrade throughput.

## 7 Related Work

**Efficient LLC Utilization** DDIO enabled platforms allow NICs to access data faster via the relatively small LLC. Many previous works, unrelated to ring sharing, proposed techniques to improve DDIO efficiency: (1) using small private rings to reduce the I/O working set [91]; (2) placing packets in LLC slices closest to the target processing CPU core [29]; (3) eliminating interference between applications and I/O devices when partitioning the LLC [96]; (4) placing only packet

Figure 13: NAT and LB throughput when switching from a non-pathological to a pathological workload.

Figure 14: Netperf TCP\_RR throughput with (a) 64KiB requests for various response sizes and (b) equal request and response sizes. Small rings work better as they reduce the I/O working set.

Figure 15: Netperf TCP stream throughput. Small rings work well when traffic is spread across multiple cores but cause drops otherwise.

headers in the LLC to reduce LLC contention [34, 79, 83]; and (5) modifying CPUs to prefetch DDIO-written data into mid-level caches and to invalidate data without writeback when possible to conserve memory bandwidth [1]. We show that small private rings are insufficient and propose a ring sharing mechanism that is symbiotic with the last four techniques.

**Sharing Within a Core in Software** Linux `io_uring` “automatic buffer selection” [19] lets applications pre-register buffers and later consume these via `read/recv` system calls for different file descriptors. Similarly, buffers posted to shRing are pre-registered and later assigned to cores at packet arrival time. But unlike `io_uring`, shRing operates between software and hardware.

**Sharing Within a Core in Ethernet NICs** When a single core and privilege level have multiple NIC rings, sharing their buffers and CRs to conserve resources is desirable. For example, SRIOV NICs expose a ring per VM on the hypervisor to receive packets missing hardware virtual switching rules, allowing the hypervisor to install matching rules [33, 77]. As the number of VMs exceeds the number of cores, multiple such rings must share a core. To optimize this, NVIDIA NICs

recently started sharing ring buffers and CRs within each core [61] via the same firmware changes that we used, which are now publicly available. ShRing, in contrast, shares rings between cores.

**Sharing Between Cores in RDMA** RDMA applications typically employ queue pairs (QPs) with dedicated buffers to connect between endpoints—consuming GiBs of DRAM [85, 88]. Shared Receive Queues (SRQ), like shRing, decrease memory use by sharing buffers. Whereas SRQ helps RDMA applicability by fitting I/O buffers in server DRAM, shRing improves performance by fitting I/O buffers in server LLC.

**Sharing Between Cores in Integrated NICs** Nebula [89] is an on-chip integrated NIC design optimized for RPC workloads. Nebula, like shRing, fits the I/O working set within the LLC. Whereas Nebula is applicable only for RDMA-like hardware-terminated protocols, shRing is applicable to typical general purpose Ethernet software network stacks.

## 8 Conclusions

Multicore systems with per-core Ethernet rings use too many receive rings, creating memory pressure that hampers performance. We show that shared receive rings alleviates this problem despite the associated synchronization costs.

## Abstract

Datacenter applications are often structured as many interconnected microservices, and the service mesh has become a popular approach to route RPC traffic among services. This paper presents *ServiceRouter* (SR), Meta’s global service mesh, which has been in production since 2012. SR differs from publicly known service meshes in several important ways. First, SR is designed for hyperscale and currently uses millions of L7 routers to route tens of billions of requests per second across tens of thousands of services. Second, while SR adopts the common approach of using sidecar or remote proxies to route 1% of RPC requests in our fleet, it employs a routing library that is directly linked into service executables to route the remaining 99% directly from clients to servers, without the extra hop of going through a proxy. This approach significantly reduces the hardware costs of our hyperscale service mesh, saving hundreds of thousands of machines. Third, SR provides built-in support for sharded services, which account for 68% of RPC requests in our fleet, whereas existing general-purpose service meshes do not support sharded services. Finally, SR introduces the concept of locality rings to simultaneously minimize RPC latency and balance load across geo-distributed datacenter regions, which, to our knowledge, has not been attempted before.

## 1 Introduction

The increasing need for continuous integration and deployment [25] in datacenter environments has led to the widespread adoption of the microservice architecture [?, 42], in which an application is decomposed into a collection of services that can be independently developed and deployed. To manage the traffic of remote procedure calls (RPCs) between these services, many organizations use a service mesh [30].

Figure 1 shows the most common form of layer-7 (L7, i.e., application layer) service mesh. In this architecture, each service process is accompanied by an L7 sidecar proxy running on the same machine, which routes RPC requests on behalf of the service. As an example, when service A on machine 1 sends requests to service B, the proxy on machine 1 will load-balance the requests across machines 2 and 3. If the

autoscaling system detects an increase in load and starts a new replica of service B on machine 4, the control plane’s service discovery function will notify the proxy on machine 1, which will then include machine 4 in its load-balancing targets for future requests for service B.

This paper presents Meta’s global service mesh called *ServiceRouter* (SR). SR supports a comprehensive set of features, including service discovery, load balancing, failover, authentication, encryption, observability [1], overload protection [39], distributed request tracing [32], resource attribution for capacity management [16], and duplication of traffic for shadow testing. Due to space limitations, the focus of this paper is primarily on answering the following questions: (1) how to scale a service mesh to millions of L7 routers, (2) how to minimize the hardware cost of a hyperscale service mesh, (3) how to support sharded services which are essential but often overlooked, and (4) how to simultaneously minimize RPC latency and balance load in a geo-distributed service mesh.

**Scalability.** Traditionally, a software-defined network [18] uses a centralized control plane and a decentralized data plane. Most service meshes [10,30,37] follow this approach and use a central controller to configure the routing table of each sidecar proxy. However, this approach is not sufficiently scalable for a hyperscale service mesh. The control plane has a dual function of generating global routing metadata and managing each L7 router. We advocate for keeping the former in the central control plane, but decentralizing the latter by transferring its function to L7 routers. Each L7 router should be self-configuring and self-managing so that the central control plane can scale out easily.

Figure 1: Sidecar-proxy-based service mesh.

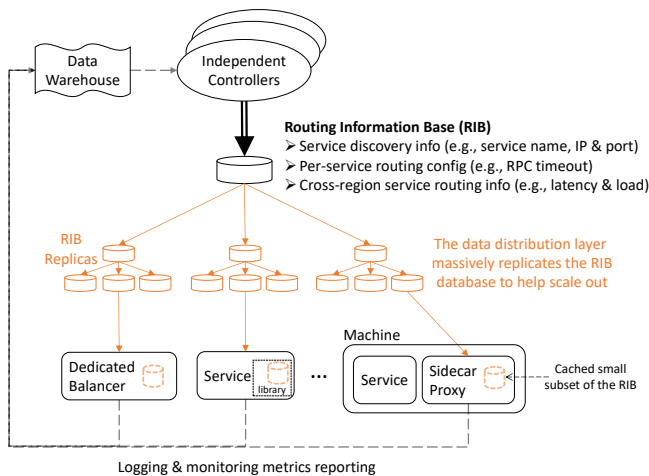

Figure 2: ServiceRouter’s scalable service-mesh architecture.

Figure 2 shows SR’s scalable architecture. On the top, different controllers independently execute functions such as registering services and generating a per-service cross-region routing table. Each controller independently updates the central *Routing Information Base* (RIB), and is not concerned with configuring or managing individual L7 routers. In the middle of Figure 2, the distribution layer replicates the RIB so that there are sufficient RIB replicas to handle read traffic from millions of L7 routers. At the bottom, guided by the RIB, each L7 router self-configures without the control plane’s direct involvement. Initially, an L7 router’s routing table is empty. When it receives an RPC request that targets a service, it fetches the routing information for the service from an RIB replica and subscribes to future RIB updates for the service.

**Hardware cost.** Existing service meshes [10, 30, 37] use sidecar proxies to forward requests (Figure 1). However, this approach incurs extra hardware costs due to the overhead of the extra routing hop, such as data serialization and deserialization in the proxy. Istio’s benchmarking [47] shows that 0.35 vCPU can handle 1,000 requests per second. Therefore, it would need the equivalent of 1,750,000 AWS `t4g.small` VMs to route 10 billion requests per second.

SR eliminates the need for a proxy and its associated hardware cost by providing the service-mesh function through a library called *SRLib*. *SRLib* is linked into service executables and routes RPC requests directly from clients to servers. However, this approach requires changes to services’ source code, which is not always possible. For example, our services written in Erlang cannot link *SRLib* into their executables.

To meet the diverse needs of services, SR enables the seamless coexistence of different types of L7 routers, including Istio-style sidecar proxies, AWS-ELB-style [5] dedicated load balancers, and gRPC-style lookaside [24] load balancers, as shown in Figure 2. The key insight that enables SR’s versatility is that the controllers at the top of Figure 2 are agnostic to the L7 routers at the bottom, allowing the L7 routers to choose their own architecture.

The embedded *SRLib* helps us achieve significant hardware savings. Currently, 99% of RPC requests at Meta are routed by *SRLib*, and the remaining 1% is routed by sidecar proxies and a group of dedicated load balancers that consume thousands of machines. If we were to completely switch from using *SRLib* to using proxies to route 100% of our traffic, we would need to add hundreds of thousands of extra machines.

**Sharded services.** Sharding [34] and replication are two key techniques for building scalable services. In our fleet, the vast majority of RPC traffic is for sharded services. Despite their importance, existing general-purpose service meshes do not directly support routing for sharded services. For example, in Figure 1, assuming that Service B’s replicas on machines 2, 3, and 4 host various data shards that can dynamically migrate across machines, it is possible for the proxy on machine 1 to route a request to machine 2 mistakenly, even if the request is meant for a shard on machine 3.

SR makes sharding support a top priority and uses a single framework to support both sharding and replication. As sharding is often tied to application logic, our key insight is to enforce separation of concerns by defining a simple and generic sharding abstraction between the service mesh and services. This allows SR to route traffic for different sharded services without needing to know their application logic.

**Cross-region routing.** Existing solutions [4, 41] are not optimized for routing across geo-distributed datacenter regions. For example, in Figure 1, should machine 1 route requests to machines 2 and 3, which have a higher load, or to machine 4, which has a longer network latency? Moreover, how to ensure that the resulting global traffic distribution for a service matches the global supply of the service’s capacity in different regions? These questions have not been well answered before.

To better support cross-region routing, we introduce the concept of locality rings for services to express their preferred tradeoff between latency and load. For example, a service can instruct SR that if and only if the load in the local region goes above 70%, SR can relax the locality constraint and route some local traffic to other regions in the same continent; if the load further increases above 80%, SR can even route some local traffic to regions in a different continent. SR collects global traffic and load information for each service, computes a cross-region routing table that conforms to the requirements specified in locality rings, and disseminates the routing table to L7 routers to guide their routing. This allows SR to provide globally optimized traffic shaping for services.

**Contributions.** We summarize our contributions below.

- SR is designed for hyperscale. While there may be proprietary systems of a similar scale, their specifics are not publicly available, and existing open-source service meshes do not scale well [57]. We hope that our experience can be helpful to those who seek to build scalable service meshes.

- SR supports the seamless coexistence of different types of L7 routers in one service mesh, including sidecar proxies [30], dedicated load balancers [5], lookaside load balancers [24], and an embedded routing library. To save on hardware costs, SR routes 99% of RPC requests in our fleet using the embedded library. This approach, along with the scale at which we utilize it, might be unique in the industry.
- While existing service meshes exclusively focus on unsharded services, which only account for 32% of our fleet’s RPC requests, SR provides built-in support for sharded services, which account for 68% of our traffic.
- Although primitive forms of locality-aware routing existed before [31], our novelty is to introduce the concept of locality rings to simultaneously minimize RPC latency and balance load across geo-distributed regions.

## 2 Comparison of Services Mesh Architectures

In this section, we compare different architectures of service mesh. The design space, shown in Table 1, is determined by the answers to two key questions: (1) which component fetches and caches the routing metadata, and (2) which component routes application RPC traffic. In Table 1, *Library*, *Kernel*, *Local*, and *Remote* mean that RPC routing or maintenance of routing metadata is performed by an embedded library, the kernel, a local proxy/daemon on the RPC client machine, or a remote proxy/service outside the client machine, respectively.

### 2.1 Different Types of L7 Routers in SR

SR allows different L7 router setups to coexist in one service mesh in order to support diverse use cases. These setups are shown in Figure 4 and explained below. Different types of L7 routers interoperate well and can send RPC requests to the same server at the same time.

**SRLib.** This setup is shown in Figure 4(a) and corresponds to solution (9) in Table 1. It provides the service-mesh function through a library, which is directly linked into the RPC client’s executable. The library can route requests directly to servers without the need for a proxy, eliminating the extra hardware cost and routing latency of a proxy. The client only needs to fetch and cache a small part of RIB (called the *miniRIB*) that is actively used by the client.

We run a separate *RIBDaemon* on the client machine to cache *miniRIB*, instead of relying on SRLib to do so. This

		Which component manages and caches <i>miniRIB</i> ?			
		Lib	Kernel	Local	Remote
Which component forwards application RPC traffic?	Lib	(1) ✗	(5) ✗	(9) SRLib	(13) SRLookaside
	Kernel	(2) ✗	(6) eBPF	(10) ✗	(14) ✗
	Local	(3) ✗	(7) ✗	(11) SRSidecarProxy	(15) SRSidecarProxy plus SRLookaside
	Remote	(4) ✗	(8) ✗	(12) ✗	(16) SRRemoteProxy

Table 1: The complete solution space for service mesh. The symbol ✗ indicates undesirable solutions.

separation allows for the use of *cgroup* to provide strong isolation between a) *RIBDaemon*’s less urgent background work that keeps *miniRIB* up-to-date and b) *SRLib*’s latency-sensitive foreground work that routes RPC requests and is on the critical path of application performance. Updates to RIB can be very spiky and when those updates are pushed to *miniRIB*, they can cause a spike in CPU usage to process the updates. Figure 3 shows the spiky CPU usage of a production machine’s *RIBDaemon*. When *cgroup* throttles *RIBDaemon*, it has little impact on *SRLib* because *SRLib* consults *RIBDaemon* only once on its first RPC for a service and all subsequent RPCs for the service go directly from *SRLib* to servers without involving *RIBDaemon*. In contrast, if *miniRIB* is managed by *SRLib*, *cgroup* cannot isolate the resource usage for maintaining *miniRIB* from the application’s own resource consumption because *SRLib* is linked into the application.

**SRLookaside.** This setup, shown in Figure 4(b) and corresponding to solution (13) in Table 1, addresses the issue of *RIBDaemon* running on every RPC client machine and consuming resources, particularly memory. It eliminates *RIBDaemon* by moving the function of *miniRIB* management and server selection to a remote and shared *SRLookasideService*, while still routing RPCs directly from clients to servers without going through an intermediate proxy.

Historically, Meta used a large fleet of small machines with as little as 16GB memory because of their advantages in power efficiency. Accordingly, *SRLookaside* was developed to save memory on those small machines. Now even our small machines have at least 64GB memory and hence the usage of *SRLookaside* was deprecated, because the limited memory savings no longer justify the burden of maintaining the *SRLookaside* service.

**SRSidecarProxy.** This setup, shown in Figure 4(c) and corresponding to solution (11) in Table 1, incurs extra hardware costs and routing latency like Istio [30], but its implementation is much more scalable than Istio, because each *SRProxy* self-manages without the control plane’s involvement and only caches *miniRIB* instead of the entire RIB. At Meta, the usage of *SRSidecarProxy* is mostly limited to services written in Erlang because *SRLib* does not directly support Erlang.

Figure 3: Spiky CPU usage of a machine’s *RIBDaemon*.

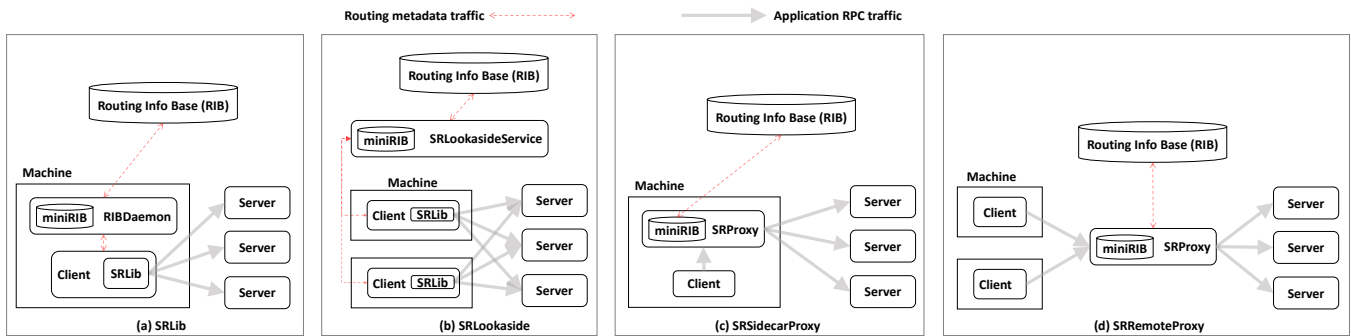

Figure 4: Service mesh design alternatives. The diagrams show how RPC clients send requests to RPC servers.

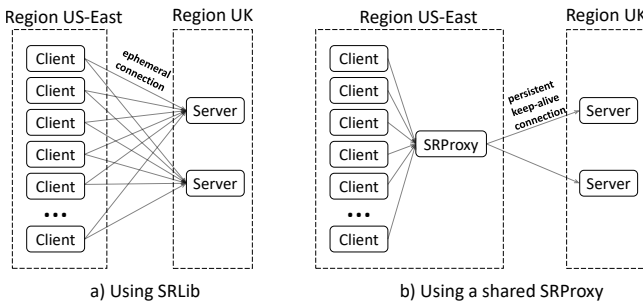

Figure 5: A shared SRProxy is better at dealing with many clients sending infrequent cross-region RPC requests.

**SRRemoteProxy.** This setup, shown in Figure 4(d) and corresponding to solution (16) in Table 1, is similar to AWS ELB [5]. SRRemoteProxy functions as a dedicated load balancer shared by multiple clients, reducing the number of RPC connections and increasing the reuse of keep-alive connections, as illustrated in Figure 5. Suppose there are a large number of clients and each client sends a request to a server in a remote datacenter region occasionally. Each RPC would experience a long delay due to the three rounds of cross-region round-trip time needed to establish a new TLS/TCP connection. A shared proxy eliminates this overhead by keeping a small number of cross-region connections alive and reusing them to send requests on behalf of many clients.

## 2.2 Comparison of L7 Routers

Next, we compare solutions in Table 1. Solutions (1)–(4) are undesirable because managing miniRIB in the library would impact the application’s performance due to lack of isolation. Solutions (5), (7), and (8) are undesirable because there is no system call to access miniRIB cached in the kernel. Although solution (6) exists in the form of eBPF-based service mesh [35], its function is limited by what can be done by an eBPF program in the kernel. For example, Cilium [29]’s eBPF program can only handle L3/L4 protocols and it still has to use a sidecar proxy to handle L7 protocols. Similar to solution (6), solutions (10) and (14) are undesirable because of the difficulty of implementing advanced L7 routing features in the kernel.

Service Mesh Alternatives	A1: HW cost	A2: direct RPC	A3: fast RIB	A4: save mem	A5: unchg code	A6: share conn
SRLib	✓	✓	✓	≈	✗	✗
Sidecar Proxy	✗	✗	✓	≈	✓	✗
Remote Proxy	✗	✗	✓	✓	✓	✓
Lookaside	≈	✓	✗	✓	✗	✗

Attributes	Description
A1: HW cost	No extra hardware cost for proxy or lookaside service.
A2: direct RPC	Application RPC traffic goes from clients to servers without the overhead of going through an intermediate proxy.
A3: fast RIB	No overhead to access Routing Information Base (RIB) outside the client machine thanks to local RIB caching.
A4: save mem	No extra memory usage on the client machine thanks to the elimination of the local RIB cache.
A5: unchg code	No need for application source code modification.
A6: share conn	Benefits of multiple clients sharing a proxy, e.g., better load balancing or connection reuse (Figure 5).

Alter-natives	When to use a particular service-mesh setup	Usage at Meta
SRLib	Use SRLib for large-scale deployments where hardware costs and routing latency are most important.	99% of traffic
Remote Proxy	Use remote proxies if it benefits from multiple clients sharing a proxy, e.g., to improve connection reuse when there are many low-traffic clients (Figure 5).	Some limited use
Sidecar Proxy	Use sidecar proxies if you cannot modify application source code to use SRLib, or SRLib does not support the app’s programming language (e.g., Erlang).	Only one-off use
Lookaside	Use a remote lookaside service to reduce the memory used on every client machine for caching miniRIB.	Depreciated

Table 2: Comparison of service mesh design alternatives.

Solution (12) is undesirable because it is strictly worse than (16), i.e., if routing is performed by a remote proxy, it is better to move miniRIB to the remote proxy as well. Theoretically, solution (15) uses less memory on the client machine than (11) does. However, (15) is not used at Meta since even (11) is not widely used and the added benefit of (15) is limited.

Finally, for ease of access, we summarize in Table 2 the comparison of the design alternatives.

Figure 6: ServiceRouter’s control-plane components.

### 3 ServiceRouter Design

In this section, we first present an overview of ServiceRouter and then elaborate on its key design ideas.

#### 3.1 Overview

SR supports all four types of L7 routers depicted in Figure 4. For the sidecar or remote proxy setup, we add a wrapper layer atop SRLib code to run it as a standalone proxy. SR’s control-plane components are depicted in Figure 6 and further explained below.

**Routing Information Base (RIB).** RIB is a Paxos-based key-value store with nine Paxos acceptors distributed across five geographic regions to ensure high availability. It centrally stores routing metadata for all services running in all regions. It uses thousands of Paxos learners to create many local RIB replicas in every region to ensure high read throughput and availability even if a region is disconnected from other regions. We discuss how to scale RIB in §4.1.

**Global Registry Service (GRS).** GRS maintains service and shard discovery information in RIB. Figure 7 shows two example services registered at GRS. *Service A* is replicated but not sharded. When the cluster manager [53] starts or stops a container for *service A*, it informs GRS to update the list of *service A*’s replicas. We will explain SR’s built-in support for sharded services in §3.3.

**Configuration Management System (CMS).** CMS [52] allows customization of the routing policy for each service, including RPC timeout, connection reuse, locality routing preference, etc. Services owners follow the configuration as code paradigm to author, review, and commit routing configurations. It also supports automated configuration updates. For example, the latency monitoring service (LMS) periodically aggregates and commits configuration updates related to cross-region latency to guide SRLib’s routing decisions.

**Cross-region Routing Service (xRS).** Compared with a centralized load balancer, SRLib only has a local view of the traffic from one client and might not make globally optimal routing decisions. xRS addresses this problem by aggregating global traffic information for each service and computing a cross-region routing table, which is disseminated via RIB and consumed by SRLib to guide its routing decisions.

Figure 7: Examples of GRS’ service registry records.

#### 3.2 Service Discovery

A RIBDaemon runs on each machine and maintains a so-called miniRIB that caches the specific parts of RIB that are needed by the RPC clients running on the machine. Initially, miniRIB is empty. When SRLib wants to send an RPC request to a particular service, such as *service X*, it requests *service X*’s routing metadata from RIBDaemon. RIBDaemon fetches the metadata from a RIB replica, caches it on disk so that it can survive machine reboots, subscribes to future updates related to *service X*, and finally returns the metadata to SRLib. SRLib also subscribes to RIBDaemon for future updates and caches the metadata in memory (but not on disk) for later reuse so that it won’t contact RIBDaemon on every RPC request.

When the deployment of *service X* is changed in the future, the cluster manager informs GRS to update RIB. The update is immediately pushed to all RIB replicas, which further push the update to every RIBDaemon that subscribes to *service X*’s routing metadata. Finally, RIBDaemon pushes the update to SRLib. *Service X* may be deployed in multiple datacenter regions, and its replicas in each region are managed by a different regional cluster manager. All of these cluster managers inform GRS to update the same service-registry record for *service X* so that a client’s RPC request can potentially be routed to a replica in any region (§3.4.1). The RPC client of a service can choose to send requests only to servers located in the same region as the client. In this scenario, to reduce overhead, RIBDaemon subscribes only to routing updates originating from the local region.

With the help of the cluster manager, clients do not need to independently discover a server’s failure through timeouts. When a server is brought down for planned maintenance, such as code deployment, the cluster manager first updates RIB to inform the clients and then stops the server. For unplanned failures, the cluster manager detects all kinds of failures, such as process crashes/hangs and machine failures, and updates RIB to inform the clients.

#### 3.3 Support for Sharded Services

SR provides built-in support for sharded services. In Figure 7, *service B* is both sharded and replicated. We define a sim-

ple sharding abstraction between SR and services to enforce separation of concerns, so that SR can route traffic without needing to know a sharded service’s internal application logic. Specifically, a service specifies how a 128-bit key space is partitioned into shards. Each shard can be independently replicated and migrated across containers. Each shard replica is associated with an abstract role, e.g., *primary* or *secondary*. In this example, *shard5* corresponds to the key range [500, 900) and its replica on *IP4:port4* serves the *secondary* role. SR is not concerned with the real semantics of the shard key or role, and merely routes requests according to a client’s request.

```
SRClient *cln = SR_get_client("ServiceB", 618/*key*/, SECONDARY);
cln->foo(); // Invoke RPC for foo().
```

In this example, SR discovers that *shard5* contains key 618 and *shard5*’s *secondary* role is served by its replicas on *IP3:port3* and *IP4:port4*. SR picks one of them to serve the request according to the load balancing policy. In the service’s implementation, the *primary* and *secondary* roles could be mapped to the leader and follower replicas of a database, respectively.

SR’s shard-map abstraction is generic and currently supports hundreds of sharded services. Most but not all of them are managed by a common shard manager [34], which notifies GRS to update the shard registry when new shards are added or removed, or existing shards are migrated across containers.

With SR, sharded and unsharded services share and reuse all the sophisticated components in SR (Figures 2 and 6). Moreover, routing for sharded services works out-of-the-box without any additional effort. In contrast, existing general-purpose service meshes do not support sharded services, and applications have to develop their own solutions.

**Design alternatives.** One alternative to SR’s shard-map approach is *consistent hashing* [33]. Given a list of servers, it deterministically determines the server responsible for a given key based on hashing. As a result, it does not need to store the *shard map* in Figure 7. Despite its advantage in simplicity, consistent hashing is insufficient for advanced sharding use cases, as its deterministic key assignment does not support dynamic migration of shards in response to shard load changes [2, 34]. SR provides built-in support for both consistent hashing and the shard-map approach. As shown in our previous work [34], out of the hundreds of sharded services at Meta, the number of services that choose to use a flexible shard map is 5.4 times higher than the number of services that choose to use consistent hashing, which confirms the importance and effectiveness of the shard-map approach.

Another alternative to SR’s shard-map approach is to allow a service to provide its own custom lookaside-service implementation. This approach can provide maximum flexibility and separate the service’s custom shard discovery and selection logic from the service mesh. Both gRPC [24] and SR’s lookaside interfaces can support this approach. At Meta, some service owners were initially interested in this approach

because of its flexibility. However, they ultimately did not use it because of the burden of maintaining a custom lookaside service, and also because it turns out that the shard-map approach and consistent hashing together are sufficient for nearly all sharded services.

### 3.4 Load Balancing

SR’s load-balancing solution is based on the `Pick-2` [41] algorithm. `Pick-2` randomly samples two servers from a candidate pool and chooses the server with less load as the RPC target. However, using `Pick-2` alone is not sufficient for a geo-distributed service mesh. Therefore, we have developed three novel techniques to complement `Pick-2`: 1) Consider regional locality when sampling two random servers (§3.4.1). 2) Sample two random servers from a stable subset of servers, rather than all servers, to maximize connection reuse (§3.4.2). 3) Take an adaptive approach to load estimation based on the workload characteristics (§3.4.3). Further details on these techniques are provided in the following sections.

#### 3.4.1 Locality Awareness

In a geo-distributed service mesh, a faithful implementation of `Pick-2` would cause long RPC latencies because it does not take regional locality into account. Our measurements show that the P50 of within-region RTT is only 116 $\mu$ s, while the P50 of cross-region RTT is 35ms and the P99 is as high as 163ms. These data emphasize the importance of considering regional locality when routing RPC requests.

Instead of `Pick-2`’s approach of randomly sampling two servers from the candidate pool, SR uses the so-called *locality rings* to filter out long-latency servers that are far from the client, and then sample from the remaining nearby servers. Each service can define a set of rings with increasing latencies, e.g., [ring<sub>1</sub>: 5ms | ring<sub>2</sub>: 35ms | ring<sub>3</sub>: 80ms | ring<sub>4</sub>:  $\infty$ ]. The Latency Monitoring Service (LMS) periodically updates RTTs between regions, and RPC clients obtain them via CMS.

An RPC client uses cross-region RTTs to estimate its latency to different servers. Starting from ring<sub>1</sub>, if the client finds any RPC server whose latency is within the latency bound for ring<sub>*i*</sub>, it filters out all servers in ring<sub>*i*+1</sub> and above, and randomly samples two servers from ring<sub>*i*</sub>. If the service has no servers in ring<sub>*i*</sub>, it considers servers in ring<sub>*i*+1</sub>, and so forth. SR’s default setting maps [ring<sub>1</sub>|ring<sub>2</sub>|ring<sub>3</sub>|ring<sub>4</sub>] to [same region | neighboring regions | same continent | global].

Filtering by locality rings reduces routing latencies but still has limitations due to lack of a global view. First, servers in ring<sub>*i*</sub> might be overloaded while servers in ring<sub>*i*+1</sub> are underutilized. Second, clients’ local routing decisions might not lead to an optimal global traffic distribution that matches the global supply of server capacity. In particular, when a region *X* fails, if all clients independently decide to reroute their requests initially going to *X*, to *X*’s nearest region *Y*, they may overload *Y*, bring it down, and together move onto the next region *Z*, and so forth, causing a domino effect.

The Cross-region Routing Service (xRS) solves these problems by using global information to compute a per-service cross-region routing table whose entry  $[P_{ij}]$  means that  $P_{ij}$  fraction of the service's RPC requests originated from region  $R_i$  should be routed to region  $R_j$ . The cross-region routing table is stored in RIB and disseminated to all clients. When an RPC client wants to send a request, it follows the traffic distribution  $P_{ij}$  to randomly choose a destination region, and then applies the normal routing algorithm to select a server in the destination region.

xRS can purposely update the routing table to shift traffic out of a region in preparation for an upcoming maintenance event or in response to a disaster. While doing so, it tries to avoid overloading other regions. Guided by a PID controller [50], it gracefully shifts traffic across regions to prevent over-reaction. If there is insufficient capacity globally, it creates so-called black holes in the routing table to instruct clients to drop certain traffic instead of overloading servers.

Next, we describe how xRS computes the cross-region routing table. xRS collects traffic and load information globally, and simulates how a region's load would change if more or less traffic is routed to the region. For each service, xRS periodically fetches load information from its servers and aggregates it by region. It also collects requests per second (RPS) served by servers in each region, which is used to calculate the *RPS cost* as the ratio of a region's load to its RPS. *RPS cost* is the estimated load increase due to a unit of RPS increase. For example, the load for a region with a 60% load serving 100 RPS, would increase by 0.6% if 1 RPS is added to the region.

xRS strives to simultaneously minimize RPC latency and balance load across regions. It expands the locality rings with load thresholds, e.g.,  $[\text{ring}_1: 5ms : 55\% \mid \text{ring}_2: 35ms : 65\% \mid \text{ring}_3: 80ms : 80\% \mid \text{ring}_4: \infty : \infty]$ . Intuitively, it means that, for example, when  $\text{ring}_1$ 's load goes beyond 55%, xRS will relax its latency restriction and start to consider routing traffic to servers in  $\text{ring}_2$ , and so forth. This load-enriched locality ring information is not directly consumed by SRLib, but instead is fed to xRS to compute a per-service cross-region routing table as follows. xRS first tries to serve all requests in the source region locally, by setting  $\forall i P_{ii} = 1$  and  $\forall i \forall j \neq i P_{ij} = 0$ . Then assisted by each region's *RPS cost*, it identifies the most loaded region and tries to follow the preference in the locality rings to move some of the region's traffic to nearby regions. This process repeats until either no regions are overloaded or all regions are equally loaded.

Currently, 46% of our services are routed using xRS' cross-region routing tables, while the rest are routed using the baseline locality rings without the routing tables. Some services choose not to use xRS due to the overhead of collecting global traffic and load information. Moreover, some services generate high traffic and require low latency, and as a result, they prefer to fail a request instead of routing it across regions.

In total, about 16% of RPC requests in our fleet are routed across regions. This emphasizes the importance for global

service meshes to optimize cross-region routing, an area that is largely overlooked by existing service meshes.

**Design alternative.** With xRS, service owners need to apply their domain knowledge to set the thresholds for network RTT and server utilization in locality rings. To avoid the burden of setting these thresholds, an alternative approach is to use end-to-end RPC latency as the sole metric, which, in theory, would automatically consider both network RTT and server utilization. The load-balancing goal of this latency-focused approach would be to minimize the average RPC latency. Pacifici et al. [45] used a similar approach in a local cluster setting. However, SR does not follow this approach because, based on both queuing theory [11] and our production experience, modeling latency at high utilization is not robust. This implies that xRS would not be able to accurately predict how traffic shifts would affect RPC latency.

Moreover, minimizing RPC latency by trading long queuing delay at the RPC server for long cross-region network RTT is not a robust method, as it can lead to overloading of nearby servers and a high RPC error rate. We explain this through an example. Suppose a client sends requests to two servers  $X$  and  $Y$ , where  $X$  is in the same region with a  $100\mu s$  RTT and  $Y$  is in a different region with a  $100ms$  RTT. Further assume that it takes  $1ms$  to process a request. To minimize the RPC latency, the latency-focused approach would send all requests to  $X$ , which is in the local region, until its queuing delay reaches  $100ms$ , and only then it would start to send requests to  $Y$ , which is in a remote region. However, with a processing time of  $1ms$ , when the queuing delay at  $X$  reaches  $100ms$ ,  $X$  would be severely overloaded and might experience a high error rate. Overall, in a geo-distributed environment where network RTT may vary by three orders of magnitude, from  $100\mu s$  to  $100ms$ , the latency-focused approach is not robust.

### 3.4.2 RPC Connection Reuse

Our measurements show that setting up a new TLS/TCP connection takes  $1.6ms$  and consumes  $14KB$  of memory on each side. To reduce this overhead, SR keeps the TLS/TCP connections and reuses them across different RPC requests. However, the randomization used by `Pick-2` makes connection reuse ineffective. As `Pick-2` randomly samples two servers out of all  $n$  servers for each request, over time, an RPC client communicates with all  $n$  servers. However, it is impractical to maintain keep-alive connections with all  $n$  servers when  $n$  is large because of the memory and CPU overhead required to maintain the connections.

To improve connection reuse, an RPC client chooses a stable subset of  $k$  servers out of all  $n$  servers (often  $k \ll n$ ), and keeps reusing these  $k$  stable servers. Upon each RPC request, `Pick-2` samples two servers out of the  $k$  stable servers instead of all  $n$  servers. Over time, the client maintains keep-alive connections with the  $k$  stable servers.

One challenge is for each RPC client to independently choose their  $k$  stable servers while globally the load spreads

evenly across all  $n$  servers. Suppose a server on average maintains keep-alive connections with  $M$  clients. When a new server is added to the existing  $n$  servers, an ideal and stable solution should require only  $M$  clients to drop one existing server out of their list of  $k$  stable servers and add the new server to their list, so that the new server also serves  $M$  clients like other servers.

With SR, each RPC client uses Rendezvous Hashing [9,54] to select  $k$  stable servers, which achieves the ideal properties described above. Specifically, a client uses its unique client ID as hashing salt, computes the hashcodes of all servers, and chooses the  $k$  servers with the largest hashcode. Stable servers and Rendezvous Hashing together help SR maximize connection reuse. In production, over 99% of our RPC requests reuse existing connections.

**Design alternative.** We prefer Rendezvous Hashing over Consistent Hashing [33] because it allows SR to use weighted hashing to assign client connections proportional to a server’s compute power. This in combination with a weighting mechanism to bias the `Pick-2` probability proportional to a server’s compute power, solves the problem that our large fleet runs multiple generations of hardware that have very different performance characteristics. Moreover, Rendezvous Hashing achieves better load balancing. For example, when a server dies, its load is evenly redistributed to other servers even without using Consistent Hashing’s virtual servers.

### 3.4.3 Adaptive Load Estimation

In order for `Pick-2` to choose a routing target between two candidates, it needs to know the load information. By default, SR uses the number of outstanding requests at an RPC server to represent its load. In addition, SR allows custom load metrics such as CPU, memory, disk, or any application-level metric. Currently, 77% and 18% of the RPC requests in our fleet use the number of outstanding requests and CPU usage as the load metric, respectively, while the rest use other metrics.

To determine a server’s load, a client has two options: 1) Poll the server for its load right before deciding whether to send a request to the server, which incurs additional overhead and latency. 2) Have the server include its load information on its responses and then cache it at the client for later reuse, which is efficient but may result in the client using stale load information and causing load imbalance.

To strike a balance between these two approaches, SR employs an adaptive mechanism. An RPC response is always piggybacked with the server’s current load information. When evaluating a server’s load before sending a new request, the client uses the cached load information only if it is sufficiently fresh (method 1). Otherwise, it polls the server for its realtime load if the network RTT to the server is low compared with the server’s average request-processing time (method 2). In the worst case that the cached load information is stale and the polling overhead is high, it chooses one of the two candidate servers at random. (method 3).

**Design alternative.** LI [13] attempts to solve the load-estimation problem by using methods 1 and 3 alone, without method 2 (polling). Data from our production system show that, with SR’s adaptive mechanism, about 50%, 25%, and 25% of RPC requests end up using methods 1, 2, and 3, respectively. This confirms the usefulness of introducing the just-in-time polling method.

## 4 Evaluation

Our evaluation attempts to answer the following questions:

1. Does SR scale well? (§ 4.1)
2. To what extent does SRLib save hardware costs, and when should one use SRProxy versus SRLib? (§ 4.2)
3. Can SR balance load within and across regions? (§ 4.3)
4. Are sharded services important, and can SR effectively support both sharded and unsharded services? (§ 4.4)

### 4.1 Scalability

Hyperscale is a key design goal that distinguishes SR from most of the existing service meshes. SR currently operates in tens of datacenter regions and runs millions of L7 routers to serve tens of thousands of services. GRS globally distributes service discovery information for millions of containers and hundreds of millions of shards.

To understand the scale of individual services, we plot the number of servers used by services in Figure 8. A small fraction of services are very large while most are very small. Specifically, while 90% of services each use less than 200 servers, 2% of services each use more than 2,000 servers and the largest service uses about 90K servers. Figure 9 shows the RPS of services. Similarly, while most services have a low RPS, some hyperscale services process billions of RPS. These hyperscale services often demand the highest performance and most sophisticated features from SR. Overall, Figures 8 and 9 show that SR scales well for both a small number of hyperscale services and a large number of small services.

In SR’s overall architecture (Figure 6), the central RIB enables separation of concerns for different components in the

Figure 8: Number of servers used by services. Each dot represents one service. Note that both axes are in log scale.

Figure 9: Requests per second by services. Each dot represents one service. Note that both axes are in log scale.

data plane and the control plane so that each component can scale out independently. However, RIB itself might become a bottleneck, primarily due to the large amount of service-discovery data stored in RIB and the associated write rate. Currently, RIB’s total size is about 12GB, processing about 335 writes/second at a total data rate of about 39MB/second. The write rate is low because writes are heavily batched; in particular, sometimes thousands of updates for the service-discovery registry are batched into a single write. In the past, we used ZooKeeper as the data store for RIB, which could not scale beyond a few GB, and hence we sharded RIB. Now we use an in-house data store [6] that scales well and there is no urgency to shard RIB further. Overall, currently RIB is not a bottleneck and it can be further sharded to scale out if needed.

The distribution of RIB is fast, far from reaching any scaling bottleneck. We operate about 2,000 RIB replicas globally, which form a 2-layer data distribution tree among themselves. In our production environment, the distribution latency of an RIB update to reach clients in geo-distributed datacenter regions is 400ms/900ms/1300ms at P50/P95/P99, respectively.

Due to the propagation delay of service discovery information, any system that does service discovery and routing, not just SR, will encounter the problem of stale routing information on some clients. In the face of stale routing information, SR guarantees correctness and strives to minimize performance impact. For example, if an SR client sends a request for a specific shard to a server that no longer holds the shard, the client will receive an error and automatically retry a different server. To improve performance, SR minimizes the chance of this scenario by implementing graceful shard migration. When migrating a shard from server  $X$  to server  $Y$ , as described in our previous work [34], the shard manager first starts the shard on  $Y$ , then updates RIB to redirect clients to send traffic to  $Y$ , and finally stops the shard on  $X$ .

As long as RIB scales well, xRS, CMS, LMS, GRS, and the L7 routers can all scale out horizontally. xRS is sharded by service and can scale out horizontally. Computing the routing table for one service only takes about one second. CMS processes about 10,000 routing-configuration changes per day for about 2,500 services, and 99% of those changes

are driven by automation tools. Overall, the rate of writes to CMS is far from reaching any bottleneck.

To understand the nature of routing-configuration changes, we list the types of the most frequent changes on an average day. A data pair ( $X\%/Y$ ) below means that every day  $X\%$  of the total changes are for a specific type, which are applied to  $Y$  number of services. The top types of changes are 1) *processing timeout* (27%/1700), the server-side RPC processing timeout; 2) *locality ring* (30%/700); 3) *traffic shedding* (11%/3), the percentage of traffic to be shed for a given client ID in an overload situation; and 4) *shadow traffic* (6%/100), the percentage of production traffic to be replicated to a test service. These data demonstrate that it is easy to dynamically reconfigure the routing policies for thousands of services at the central CMS. Moreover, it shows that locality ring is an important feature that is frequently tuned for services to achieve the best cross-region routing performance.

## 4.2 Hardware Cost

We compare the CPU overhead of SRLib and SRProxy, and use case studies to illustrate when to use SRProxy.

### 4.2.1 SRLib versus SRProxy

To quantify the hardware cost, we conduct an experiment to compare three RPC setups: 1) *SRLib*, where a client uses SRLib to route requests to a simple service running on 10 machines; 2) *SRProxy*, where a client sends requests to a remote SRProxy, which forwards requests to the servers; and 3) *Thrift*, where a barebone client hard-codes a most efficient way to randomly select one of the 10 servers and invokes it using the Thrift [51] RPC protocol. SRLib and SRProxy’s internal implementation also use Thrift but add extra logic atop it. Therefore, Thrift represents the lower-bound baseline.

In all three setups, the RPC connections are 100% reused to avoid the connection establishment overhead. All servers used in the experiment are located in the same region to minimize the impact of network latency. We use three RPC payload sizes. The *Production* size uses requests and responses of 5.4KB and 6KB, respectively, which are the average sizes of payloads in production. The *Large* and *Small* sizes use payloads that are  $10x$  or  $\frac{1}{10}x$  of the production payload size, respectively. We report in Figure 10 the end-to-end RPC latency and the total CPU instructions executed across the client, proxy (if used), and server when processing one RPC.

Using production-sized payloads, compared with Thrift, SRLib and SRProxy consume 80% and 273% additional CPU cycles, respectively. The overhead is high because this experiment is set up to measure almost the worst case of SRLib and SRProxy. Since the payload’s data type is a trivial string, serialization and deserialization in Thrift take little time. Moreover, both the RPC client and server do not do any processing. Overall, this setup minimizes all other overhead in order to show the worst-case setup for SRLib and SRProxy. In our production environment, when aggregated across all workloads

Figure 10: Comparison of latency and CPU overhead across three setups: the Thrift baseline, SRLib, and SRProxy.

running on all servers, SRLib consumes 36% additional CPU cycles compared to Thrift. This is much lower than the 80% overhead observed in this worst-case experiment.

For the SRProxy setup using production-sized payloads, the CPU consumption is evenly split between the client and proxy. Thrift and SRLib have almost identical latency, whereas SRProxy’s latency is 107% higher. Using large-size payloads, the relative overhead of SRLib and SRProxy becomes smaller. Compared with Thrift, SRLib and SRProxy consume additional 25% and 190% CPU cycles, respectively.

This experiment shows that, across the RPC client and proxy, the SRProxy setup in total consumes more than twice the amount of CPU cycles as the SRLib setup. In our production environment, we use thousands of SRProxy machines to route 1.1% of the total RPC requests, which generate only 0.1% of the total RPC data transferred. The remaining RPC requests are routed by SRLib. If we were to completely switch from SRLib to SRProxy and route 100% of the RPC traffic by SRProxy, we would need hundreds of thousands of additional machines for SRProxy.

In the SRProxy setup with production-sized payloads, the split between CPU instructions executed in the kernel and

user space is 26% versus 74%. This indicates that even if the kernel overhead could be entirely eliminated through methods like zero-copy data forwarding, it would still be insufficient to significantly reduce the proxy’s overhead. Moreover, the proxy cannot perform zero-copy data forwarding because it needs to manage encryption and identity.

Using small and production-sized payloads, SRLib’s latency appears to be slightly better than Thrift, but since the standard deviation is high, the small difference is mostly caused by measurement noises in our production network that serves many other production services. Lastly, we would expect to see less CPU cycles consumed by the client side of the SRProxy setup compared with the client side of the SRLib setup, as the former does less routing work. However, the difference is insignificant in this experiment because the SRLib code path is slightly better optimized by our years of investments in it.

#### 4.2.2 Case Study of When to Use SRProxy

As shown in Figure 5, a shared SRProxy improves connection reuse, which potentially can reduce the latency of cross-region RPCs at the expense of extra hardware to host SRProxy. The tradeoff depends on the business value of the reduced latency and the cost of the extra hardware. In practice, we always carefully evaluate our customer’s request of using SRProxy case by case. We present several case studies below.

**E-Comm.** E-Comm is a sharded ranking service used in e-commerce. Due to its tight service-level objective (SLO) for latency, all of its shards were replicated to every region to enable local access. We analyzed its traffic pattern and found that by allowing only 5% of its traffic to go across regions, we could avoid replicating 33% of its shards in every region. This would lead to significant hardware savings but at the expense of increased latency. In Figure 11, we compared E-Comm with and without SRProxy and found that SRProxy improved cross-region connection reuse and reduced the P90 latency from about 325ms to about 150ms. E-Comm’s maximum per-region RPS is about 300K, which can be handled by 4 SRProxy machines since each SRProxy machine can handle about 87K RPS. In practice, about 10 SRProxy machines are needed to provide sufficient buffers for failure and unexpected

Figure 11: E-Comm’s P90 latency with and without SRProxy.

load spikes. After the evaluation, we decided to enable SRProxy for E-Comm because the 10 SRProxy machines per region would allow us to save 33% of E-Comm’s hardware capacity by routing 5% of its traffic across regions while still keeping its latency within its SLO.

**Key-value store.** This distributed key-value store has 1.5 million data shards. Accordingly, its service-discovery information includes a large shard map for these 1.5 million shards (see an example in Figure 7). It takes a lot of memory on the key-value store’s clients to cache this large service’s full service-discovery information. We evaluated enabling SRProxy to offload the service-discovery cache from the client machines to SRProxy, and noted that it saved on the client machines 250MB memory at P99. Moreover, SRProxy helped with connection reuse and thus latency. The clients have poor connection reuse due to the huge fanout of requests to many different shards hosted by different servers. Shared SRProxies could drastically improve connection reuse and reduce latency by 27% on average. However, due to the key-value store’s high RPS, it would need 1,500 SRProxy machines. Eventually, we decided that the cost would not sufficiently justify the benefits and hence did not use SRProxy to route its traffic.

### 4.3 Load Balancing

SR performs load balancing both within a region and across regions. We evaluate both scenarios in this section.

#### 4.3.1 Same-Region Load Balancing

To evaluate same-region load balancing, we selected 15 representative services that produce significant traffic within a region. 10 of these services are unsharded and 5 are sharded. We measured each service’s average production load (pending requests for unsharded services and CPU usage for sharded services) across its servers and normalized the load by its mean. To evaluate whether the load evenly spreads across

Figure 12: Load balancing within a region for unsharded (U) and sharded (S) services. The top group shows the normalized average load and the bottom two groups show the load’s coefficient of variation (CV) across servers.

a service’s different servers, we calculated the coefficient of variation (CV) for each service. Figure 12 summarizes the results. We observe that the load is concentrated within a narrow band for all services. Across all 15 services, the median CV is low  $P50_{CV} = 0.18$  and  $P95_{CV} = 0.6$ . In particular, the CV for unsharded services is always low ( $P50_{CV}^u = 0.13$  and  $P95_{CV}^u = 0.20$ ), indicating that SR effectively balances the load across their servers.

The CV for sharded services is higher ( $P50_{CV}^s = 0.44$  and  $P95_{CV}^s = 0.61$ ), indicating that the load is less balanced. This is because some shards are hot (receiving a lot of traffic) while others are cold (receiving little traffic), due to the nature of data stored in the shards. As a result, even if SR perfectly routes RPC requests to different replicas of the shards, the load on the servers that host different shards may still be unbalanced. To further balance the load, it may be necessary to migrate shard replicas across containers and/or create additional replicas of the hot shards. However, these operations may have a high overhead, so our shard manager [34] performs these operations only enough to prevent server overload without attempting to perfectly balance the load. Overall, these data show that SR can use a single service mesh to balance load for both sharded and unsharded services.

#### 4.3.2 Cross-Region Load Balancing

**Locality ring.** A service’s locality-ring configuration (§ 3.4.1) guides SR to route requests to nearby servers when appropriate. To assess its effectiveness, we measure P90 latencies for requests that fall into different locality rings. Most services (63.8%) use SR’s default locality-ring configuration: `[same region | neighboring regions | same continent | global]`. Interestingly, 15.4% of services simply set their locality ring as `[global]`, meaning that they have no locality preference. Most of these services are not user facing and not sensitive to latency, but instead care more about availability. 9.7% of services set their locality ring as `[same region | global]`, meaning that they prefer a request being served in the local region, but if that’s impossible, they prefer the request being served by a more lightly loaded server in any region, as opposed to a more heavily loaded server in a nearby region. The remaining 11.1% of services use their own custom locality-ring configuration.

We found that the P90 latency is 12/83/201/262 ms for requests that are served by servers in the *Region / NeighboringRegions / Continent / Global* rings, respectively. This confirms the correct behavior that the inner rings exhibit lower latencies than the outer rings. Moreover, the latency jump at each expanded ring level is significant, indicating that fine-grained locality management is helpful. Initially, our default ring configuration was `[same region | same continent | global]`. As more datacenter regions were added to our infrastructure, the latency difference between regions in the same continent became more significant. Then we were able to easily introduce a new ring level, *neighboring regions*, thanks to the flexibility offered by locality rings.

Figure 13: xRS shapes a service’s traffic across several regions to prevent overloads.

**Cross-region load spillover.** xRS computes a cross-region routing table per service to guide L7 routers’ routing decisions (§3.4.1). To evaluate its effectiveness, we choose a service that does newsfeed fetching and ranking for one of our main products. The service uses the following locality-routing thresholds,  $[\text{ring}_1:75\% \mid \text{ring}_2:80\% \mid \text{ring}_3:85\% \mid \text{ring}_4:90\%]$ , where the second number (e.g., 75%) in the pairs is a load threshold. It means that if the measured load in an inner ring exceeds the threshold, xRS should compute a new routing table to shift some traffic from the inner ring to the next-level outer ring in order to reduce load in the inner ring. The load metric for the service is CPU utilization averaged across the service’s all servers in a region.

In Figure 13, we report a real incident that happened to the service in production, which was not conducted by us just for the sake of experiment. The figure shows the average load across several regions for the service in the span of 40 minutes. We observe that xRS was able to shift traffic to maintain the load well below the  $\text{ring}_1$  load threshold of 75% for most regions except Region 0 during a short spike.

At 09:53 AM, Region 0 exhibited high load (81.2%), which exceeded its  $\text{ring}_2$  load threshold (80%). xRS evaluated shifting some traffic to Region 0’s  $\text{ring}_2$  regions (i.e., Regions 2, 8, and 10) and chose Region 2 as the target because it had the lowest load. xRS calculated that by shifting some traffic from Region 0 to Region 2, the load of Region 0 would fall below the load threshold. This resulted in a new routing table which reduced  $P_{0,0}$  traffic by 5.35% and set  $P_{0,2} = 5.35\%$ , meaning that 5.35% of requests originating from Region 0 should be routed to Region 2. Then, the load of Region 0 fell to 70.9% and subsequently to 65.47% at 09:54 AM. The corresponding load increase in Region 2 was insignificant because the service had a large capacity footprint in Region 2.

At 09:55 AM, the load of Region 0 spiked again to 92.83% and then to 96.69% at 09:56 AM, which was above the service’s  $\text{ring}_4$  threshold (90%). In response, xRS reduced  $P_{0,0}$

(a) Data plane (i.e., application RPCs).

(b) Control plane (i.e., service-discovery updates).

Figure 14: Traffic for unsharded and sharded services, excluding memcache.

by 12% at first (99.24%  $\rightarrow$  86.92%) and then by another 13% (86.92%  $\rightarrow$  74.38%). The removed traffic was again added to Region 2 alone as it was the least loaded region among all regions in Region 0’s  $\text{ring}_4$ .  $P_{0,2}$  increased first from 0.76% to 13.08% and then from 13.08% to 25.62%. These adjustments helped the load in Region 0 to drop to 64.34% and the region became healthy again at 09:57 AM.

Overall, the whole process above was fully automated by xRS without any manual intervention. It demonstrates that xRS is effective in dynamically managing cross-region traffic.

## 4.4 Sharded Services

Currently, our fleet runs hundreds of sharded services [34]. Although they only account for about 3% of our tens of thousands of services, they generate more traffic than the other 97% unsharded services, because many sharded services are among our largest and highest traffic services. Specifically, most of the largest services in Figures 8 and 9 are sharded, and the two services studied in §4.2.2 are both sharded. To give a sense of scale, our fleet has millions of containers for unsharded services, and hundreds of millions of shard replicas.

Figure 14(a) shows that the aggregate RPS for all sharded services is 212% of the aggregate RPS for all unsharded services. Our memcache [38] is sharded and has the highest RPS among all our services, but it is excluded from the comparison in Figure 14(a) to avoid overshadowing other services. The RPS for memcache alone is 975% of the aggregate RPS for all unsharded services. Although memcache has a high RPS, each of its requests is very lightweight and hence memcache servers do not account for a large fraction of our fleet capacity. Figure 14(b) shows that the aggregate control-plane traffic to

update service-discovery information for all sharded services is 240% of the aggregate traffic for all unsharded services. This is because sharded services more frequently migrate shards across servers to balance load.

Overall, the traffic for sharded services overwhelmingly dominates both the data plane and the control plane of our service mesh, which highlights the importance of providing first-class built-in support for sharded service in a service mesh. Excluding memcache, RPCs for sharded services account for 68% of all RPCs, rising to 92% when memcache is included (as our memcache is sharded). Despite the importance of sharded services, all existing general-purpose service meshes ignore sharded services and exclusively focus on unsharded services. Our key insight in supporting sharded and unsharded services in a single framework is to define a sharding abstraction between SR and services to enforce separation of concerns so that SR can route traffic without knowing a service's internal application logic.

## 5 Limitations of SRLib and Our Solutions

In this section, we discuss several limitations of SRLib and how we address them.

**Dynamic policy updates.** In addition to load balancing, SR offers a large set of service-mesh features such as overload protection [39], observability [1], distributed tracing [32], and encryption. These features are managed through dynamic policy updates, which need to be executed by L7 routers in near-real-time. Without good tooling support, deploying policy updates for a library embedded in applications could be harder than for standalone sidecar proxies. At Meta, this problem is solved by a powerful configuration management system called Configurator [52]. The policies for both SRProxy and SRLib are managed in the same way. When a policy changes, Configurator propagates the change and sends an upcall to SRLib embedded in applications. SRLib then applies the new policy immediately, without restarting the application.

**Source code modification.** One disadvantage of SRLib is that it requires code changes to services. Traditional RPCs use an IP address and a port number to obtain an RPC client, whereas SRLib obtains an RPC client using a service name. The code example below shows that it is straightforward to modify a traditional RPC framework to use SRLib.

```
TraditionalRPCClient *cln = get_client(IP, port);
cln->foo(); // Invoke RPC for foo().
SRClient *cln2 = SR_get_client("service_name");
cln2->foo(); // Invoke RPC for foo().
```

Moreover, source-code modification related to RPC is not unique to SRLib, and is widely adopted by hyperscalers. Regardless of how routing is done, as long as a hyperscaler's RPC framework does not entirely rely on the standard but slow DNS for service discovery, they have to modify their application code to integrate with their custom service-discovery

system. Examples of this include Google's Borg Name Service [55], Netflix's Eureka [17], LinkedIn's Rest.li Dynamic Discovery [49], Twitter's Finagle [19], Uber's Hyperbahn [27], and Airbnb's Synapse [3]. The prevalence of custom service-discovery systems, which often require source-code modifications to use, suggests that this approach is practical as long as the changes are simple and limited to RPC's narrow interface.

**Library code deployment.** Deploying a new version of SRLib is more difficult than deploying a new version of a sidecar proxy. This is because SRLib is compiled into tens of thousands of services, each with its own deployment schedule. Furthermore, in theory, it is possible that some services may not be updated for a long time, resulting in their continued use of an outdated version of SRLib. At Meta, this problem is solved by a powerful continuous software deployment tool called Conveyor [25]. With the help of Conveyor, 97% of the services at Meta are configured to deploy automatically without manual intervention, whether it is on a daily or weekly basis, or whenever a code update successfully passes all tests. Moreover, due to reasons beyond SR, it is a company mandate for all services to be deployed regularly, which ensures that services run with a recent version of SRLib.

**Bugs in SRLib.** If SRLib's new code has a bug, it can be difficult to instantly roll back all services. To mitigate this risk, every major code change or new feature in SRLib is gated by a configuration parameter that can be toggled live in production via Configurator [52], as shown in the example below, without requiring a software deployment or process restart.

```
// Introduce a new FEATURE_X in the SRLib code.
if (check_gate(FEATURE_X)) {
    // New code path...
} else {
    // Old code path...
}
```

In the example above, when `FEATURE_X` is updated on a central server via Configurator, the new parameter value is propagated to all SRLib instances within seconds. SRLib's next invocation to `check_gate(FEATURE_X)` returns the updated parameter value and switches the code path accordingly, without requiring a restart of the application process.

After the above new code is released into production, `check_gate(FEATURE_X)` defaults to false, as if the new code path does not exist. Configurator then manages a canary testing process where it selectively enables the new code path for a small number of replicas of a few services by setting `check_gate(FEATURE_X)` to true. If the test is successful, the new code path is gradually enabled for more services. If a bug is encountered, `FEATURE_X` can be instantly disabled for all services via a configuration change. Overall, incremental rollouts of new SRLib code gated by configuration changes allow us to mitigate the risk of SRLib bugs.

**Summary.** At Meta, managing widely deployed libraries (WDL) such as SRLib is largely a solved problem thanks to the help of Configurator [52] and Conveyor [25]. These tools also help manage about a dozen other WDLs, so the problem is not unique to SRLib. However, we acknowledge that, even with the help of Configurator and Conveyor, it is still more challenging to develop, deploy, and manage SRLib than sidecar or remote proxies because SRLib is linked into every service. Although SR supports both SRProxy and SRLib, we prioritize the cost savings of hundreds of thousands of machines that come with the routing-library approach, over the simplicity that comes with the proxy approach. Our experience in production demonstrates that the routing-library approach is not only cost-effective but also practical, even in highly complex environments, despite its challenges.

## 6 Related Work

There is an array of works from both academia and industry discussing routing and load balancing in datacenter environments, at either layer-3/4 [5, 8, 12, 14, 18, 21, 40, 44, 46] or layer 7 [3, 5, 15, 19, 20, 23, 26, 30, 36, 37, 43, 48]. Layer-3/4 load balancers can be implemented either in hardware [8, 21, 40] or in software [5, 14, 22, 28, 44, 46, 48]. As a layer-3 solution, anycast [56] can route requests to nearby servers, but it does not consider the servers' dynamic load. As shown in Figure 14, the majority of our traffic is for sharded services, which cannot be handled by these layer-3/4 solutions as they do not understand application shards.

More relevant to SR are layer-7 (L7) service-mesh solutions that route requests across microservices. L7 routing can inspect application-level information, enabling more advanced load balancing. L7 routing can be performed by a group of dedicated proxies [3, 5, 15, 20]. However, using remote proxies comes with significant latency and hardware costs, so SR limits the use of SRProxy to around 1% of its traffic, only for services that can benefit the most from connection reuse.

More related to SRLib, which routes 99% of our traffic, are service meshes that distribute L7 decisions closer to the clients. eBPF [35] is efficient but is limited in its L7 capabilities. For example, Cilium [29]'s eBPF program can only handle L3/L4 protocols, and it still needs to use a sidecar proxy to handle L7 protocols. RPC frameworks such as Thrift [51], gRPC [23], and Finagle [19] are the foundations of service meshes, but they do not offer the complete capabilities needed for a geo-distributed service mesh, such as global-traffic-aware routing.

To address these limitations, more complex service meshes [15, 30, 36, 37] have been proposed. Envoy [15] is typically deployed as a sidecar proxy, and Istio [30] provides a control plane to manage Envoy proxies. We compare different service meshes in Table 2 and show that the sidecar approach is easy to deploy, but increases latency and incurs significant hardware costs. Zhu et al. [57] show that Istio adds 92% extra CPU usage and increases the latency by 185% [57]. mRPC [7] confirms that a sidecar increases the P99 RPC la-

tency by 180% and decreases throughput by 44%. SR takes the routing-library approach to avoid the overhead of a proxy.

mRPC [7] eliminates the double marshaling overhead of the sidecar approach, by using shared memory to communicate between the application and the sidecar and by not performing marshaling in the application. However, this approach requires modifying applications to allocate memory for RPC arguments from a heap in shared memory. This can be difficult since memory allocations tend to scatter throughout an application and sometimes occur in system libraries such as `strdup()` that cannot be easily modified.

While Istio offers locality-aware routing based on static rules [31], SR dynamically computes a per-service global routing table based on global traffic. Google Slicer [2] supports service discovery for sharded services, but this function is not offered by the underlying service mesh out of the box.

## 7 Conclusion

We presented Meta's global service mesh, called *ServiceRouter* (SR). SR differs from other publicly known service meshes in several significant ways. First, SR scales significantly beyond previously published work, currently processing tens of billions of requests per second. This is achieved by massively replicating the routing information base (RIB) to guide L7 routers to self-configure and self-manage in a decentralized manner. Second, SR minimizes hardware costs by providing the service-mesh function out of an embedded routing library for 99% of its traffic, in contrast to the common approach of using sidecar or remote proxies alone. Third, SR introduces the concept of locality rings to simultaneously minimize RPC latency and balance load across geo-distributed datacenter regions. Finally, SR supports both sharded and replicated services through a common underlying routing framework.

Our ongoing work is focused on improving global routing in accordance with global capacity management [16] and enhancing overload protection to ensure services gracefully degrade in the event of large-scale disasters [39].

## Acknowledgments

This paper presents 11 years of work by past and current members of several teams at Meta, including ServiceRouter, CSLB, SMC, and Falcon. In particular, we would like to call out the current members of the ServiceRouter team who are not on the author list: Akrama Baig Mirza, Bo Huang, Emanuele Altieri, Kenny Lau, Lijie Tang, Mikhail Shatalov, Nan Su, Nitesh Kant, Scott Diao, Tao Chen, Wei Song, and Weilun Wang. We thank all reviewers for their insightful comments, Shie Erlich for the support, as well as Andrii Grynenko, Rahul Gokul, and Stepan Palamarchuk for their contributions to some ideas presented in the paper.

## Abstract

SmartNICs have recently emerged as an appealing device for accelerating distributed systems. However, there has not been a comprehensive characterization of SmartNICs, and existing designs typically only leverage a single communication path for workload offloading. This paper presents the first holistic study of a representative off-path SmartNIC, specifically the Bluefield-2, from a communication-path perspective. Our experimental study systematically explores the key performance characteristics of communication among the client, on-board SoC, and host, and offers insightful findings and advice for designers. Moreover, we propose the concurrent use of multiple communication paths of a SmartNIC and present a pioneering guideline to expose new optimization opportunities for various distributed systems. To demonstrate the effectiveness of our approach, we conducted case studies on a SmartNIC-based distributed file system (LineFS) and an RDMA-based disaggregated key-value store (DrTM-KV). Our experimental results show improvements of up to 30% and 25% for LineFS and DrTM-KV, respectively.

## 1 Introduction

Remote Direct Memory Access (RDMA) has been widely adopted in modern data centers [23, 71, 20], pushing network bandwidth (towards 400 Gbps [44]) and distributed system performance [17, 76, 75, 64, 80, 82, 77] to the next level. However, the high-speed network requires more CPU resources to saturate a fast RDMA-capable NIC (RNIC) [38], which places a significant CPU burden on distributed systems [32]. One-sided RDMA can alleviate CPU pressures by enabling the RNIC to directly read and write host memory in a CPU-bypass way. However, the limited offloading capabilities may cause network amplifications and thus degrade system performance [61, 28].

The continuous improvements in RDMA [67] and the essential power and memory walls of CPUs have led to the emergence of SmartNICs—the RNICs with programmable capabilities. These NICs offer systems the opportunity to offload more complex computations to the NIC. Currently, there are two main types of SmartNICs. The first one is the *on-path* SmartNIC [42], which directly exposes the processing units (NIC cores) for handling RDMA packets to the systems. Unfortunately, programming low-level NIC cores with firmware [38, 61] and isolating the offloaded program

from normal RDMA requests pose significant burdens on developers. To simplify system development, the *off-path* SmartNIC [52, 53, 9, 51] attaches a programmable multicore SoC (with DRAM) next to the RNIC cores, which is off the critical path of RDMA. Thanks to this separation, the SoC is independent of normal RDMA requests and can further deploy a full-fledged OS to make the developments easier [32]. Specifically, developers can treat the SoC as a separate server. In this paper, we focus on off-path SmartNIC<sup>1</sup> due to its generality and programmability.

There have been valuable studies on characterizing off-path SmartNICs [38, 37, 32, 68, 2], with a focus on their ability to offload computation. A key finding is that the computing power of off-path SmartNICs is weaker than that of the host [38, 37, 32]. This means that off-path SmartNICs do not improve the speed of a single network path, such as that between NIC and the host. For example, iPipe [38] found that the path between the host and SoC has a relatively high latency due to the support for more developer-friendly RDMA.

Although prior work has been valuable in utilizing SmartNICs for distributed systems, it has primarily focused on offloading computation to the SmartNIC’s SoC. However, it is surprising that the fundamental function of SmartNICs, namely networking, has been overlooked despite its significant impact on overall performance. In fact, networking on the SmartNIC is intricate, because it provides multiple communication paths. For example, SmartNICs support using RDMA to access the memory of the host or SoC, as well as exchanging data between the host and the SoC.

To this end, this paper conducts the first systematic study on characterizing the performance of communication paths of SmartNIC. Unlike previous studies that simply report basic performance numbers [37, 32, 68], we systematically analyze the performance implications of SmartNIC architecture on different paths. Specifically, we investigate why and when one path may be faster than another, identify the bottlenecks for each path, examine how the heterogeneity of the SoC brings performance anomalies in paths related to the SoC, and finally explore how paths interact with each other. The main highlights of our results are:

- *Different paths exhibit diverse performance characteristics.* The RDMA path from the NIC to the SoC is up to 1.48× faster than the path to the host.

<sup>1</sup>This paper will use “SmartNIC” (or “SNIC” for brevity) to specifically refer to off-path SmartNICs.

- *The SoC introduces new performance anomalies to paths related to it.* The low-level hardware details of the SoC, including the memory access path and PCIe MTU, differ from those of the more powerful host CPU. Without considering such factors, RDMA requests involving the SoC suffer from up to 48% bandwidth degradation.
- *The paths between the SoC and the host may underutilize the PCIe.* RDMA from the SoC to the host (and vice versa) crosses the NIC internal PCIe twice. It can only utilize half of the PCIe bandwidth and requires processing up to 6× more PCIe packets than the others. DMA only passes the PCIe once, but it is not always faster than RDMA due to the weaker SoC DMA engine (compared to the one on the RNIC) and also suffers from packet amplifications.

Based on our performance characterization, we found that prior approaches, which mainly optimize a single path for a specific functionality of distributed systems, failed to fully exploit SmartNICs. This is because a single path cannot utilize the computing and networking capability of SmartNICs. Further, only considering a single path may ignore resource interference between different paths (e.g., the PCIe and PCIe switches). As a result, LineFS can only utilize up to 117 Gbps of bandwidth on a 200 Gbps SmartNIC. A similar issue exists in SmartNIC-based disaggregated key-value store: while choosing a path to offload all key-value (KV) store operations to the SmartNIC SoC can eliminate the network amplification in existing RDMA-based key-value stores, the wimpier computing power of SmartNIC SoC limits its overall throughput.

Based on the observations from our study, we further propose an optimization guideline to help designers smartly exploiting multiple paths of SmartNICs. Instead of optimizing distributed systems along a single path, it holistically exploits multiple paths for functionalities with different characteristics and carefully considers cross-path interference. To demonstrate the efficacy of our guideline, we conduct two case studies by optimizing two state-of-the-art systems, namely LineFS [32] and DrTM-KV [11, 76]. Due to the exposed new optimization spaces, following our guideline can improve the performance of LineFS and DrTM-KV by up to 30% and 25% accordingly.

**Contributions.** We summarize our contributions as follows:

- A comprehensive performance characterization of representative off-path SmartNICs, with a particular focus on various communication paths.
- The first optimization guideline for smartly exploiting the multiple paths of SmartNICs with managed cross-path resource interference.
- Two case studies on SmartNIC-accelerated distributed systems (i.e., file system and key-value store) with notable performance improvements, demonstrating the efficacy of our guideline.

**Assumptions and generalizability of our work.** We assume an off-path SmartNIC with the following architecture: the SoC is linked with NIC cores via a PCIe switch, and there is heterogeneity between SoC and host CPUs. We believe this is a representative architecture, as many older (e.g., NVIDIA Bluefield-1 [55], Broadcom Stingray [9]), current (e.g., NVIDIA InnoVA2 [51], Bluefield-2 [52]), and upcoming SmartNICs (e.g., Bluefield-3 [53], Marvell OCTEON 10 DPU [43]) use a similar setup. We conducted experiments on Bluefield-2 [52]—the state-of-the-art SmartNIC with this architecture. Meanwhile, we also confirmed that our results hold for Bluefield-1.

However, we acknowledge that significant architectural changes (e.g., on-path SmartNICs) may affect our findings. Nevertheless, we argue that our methodology—first studying the performance implications of each communication path and then smartly exploiting multiple paths of SmartNICs—can be generalized to other SmartNICs. Our benchmarking code, tools, and systems are available at <https://github.com/smarnickit-project>.

## 2 Background and Context

### 2.1 RDMA-capable NICs (RNICs)

RDMA (Remote Direct Memory Access) is a low-latency (2  $\mu$ s) and high-bandwidth (200 Gbps) network widely adopted in modern data centers [23]. One intuitive way to utilize RDMA is to accelerate message passing with its *two-sided* primitives (SEND/REC<sup>2</sup>), such as RDMA-based RPC [27, 17, 12, 47, 30]. Alternatively, the one-sided primitives (READ/WRITE<sup>2</sup>) allow the RNIC to access the host memory bypassing the host CPU. Specifically, the NIC core internally uses the direct memory access (DMA) feature of the PCIe link to access the host memory (see Figure 1(a)).

Though RDMA has boosted the performance of many distributed systems [18, 76, 62, 29], usually by orders of magnitude, it still has the following two problems especially when the RNICs scale up to higher performance.

**Issue #1: Host CPU occupation.** For two-sided primitives, distributed systems need non-trivial CPUs to saturate a powerful NIC. Our measurements show that a 24-core server can only saturate 87 million packets per second (Mpps) on a 200 Gbps RNIC (ConnectX-6), while NIC cores can process more than 195 Mpps.<sup>3</sup> A recent work further shows that a distributed file system requires 2.27× CPU cores to handle network packets, when the network bandwidth scales from 25 Gbps to 100 Gbps [32]. Although deploying more powerful CPUs can alleviate this issue, RNIC bandwidth is also rapidly growing, currently reaching up to 400 Gbps [44].

**Issue #2: Network amplification.** Using one-sided RDMA primitives alleviates the host CPU pressure by allowing sys-

<sup>2</sup>We use READ/WRITE to indicate RDMA READ/WRITE in this paper.

<sup>3</sup>Detailed hardware setups can be found in §2.4.

**Figure 1:** Architecture of different NICs: (a) RDMA-capable NIC (RNIC), (b) on-path SmartNIC, and (c) off-path SmartNIC (our focus).

**Figure 2:** An illustration of a get request in a distributed in-memory key-value store that is accelerated by using either (a) RNICs (w/ network amplification) or (b) SNICs (w/o network amplification).

tems to offload memory accesses to the RNIC. However, the limited offloading capability constraints system performance, as a single request may involve multiple round trips of READs/WRITEs to complete (usually termed *network amplification*). Figure 2(a) exemplifies the execution of a *get* request on a distributed in-memory key-value store with one-sided RDMA READs. The client first uses one (or multiple) READ(s) to query the index for a given key. Based on the index returned by the previous READs, an additional READ is issued to retrieve the value.

## 2.2 From RNICs to SmartNICs

To address the limitations of RNICs, SmartNIC adds an on-board memory (4–64 GB) together with various computation units (e.g., SoC) to the NIC. By exposing them to the developers, SmartNIC enables offloading customized computations onto it. Specifically, SmartNICs can be categorized as follows.

**On-path SmartNIC.** As shown in Figure 1(b), the on-path SmartNIC exposes the NIC cores to the systems with low-level programmable interfaces, allowing them to directly manipulate the raw packets. As the name implies, the offloaded code is *on* the critical path of the network processing pipeline. Example NICs include Marvell LiquidIO [42] and Netronome Agilio [48]. The benefit is that the offloaded code is closer to the network packets. Therefore, inline requests that only interact with the NIC, such as writing to the on-board memory (②), are extremely efficient [38, 61].

However, on-path SmartNIC has two limitations. First, the offloaded code (④) competes NIC cores with the network requests sent to the host (①). If offloading too much computation onto it, the normal networking requests sent to the host

**Table 1:** Hardware description of Bluefield-2 [52].

Component	Hardware description
NIC cores	ConnectX-6 (2× 100 Gbps RDMA ports)
SoC cores	ARM Cortex-A72 processor (8 cores, 2.75 GHz)
SoC memory	1× 16 GB of DDR4-1600 DRAM
PCIe1	PCIe 4.0 × 16 (256 Gbps bandwidth)

would suffer a significant degradation [38]. Second, programming on-path NICs is difficult due to its low-level interface.

**Off-path SmartNIC.** As shown in Figure 1(c), the off-path SmartNIC offers an alternative: it packages additional compute cores and memory in a separate SoC next to the NIC cores. Therefore, the offloaded code is *off* the critical path of the network processing pipeline. From the NIC perspective, the SoC can be viewed as a second full-fledged host with an exclusive network interface. To bridge the NIC cores, SoC and host together, a PCIe switch is integrated inside the SmartNIC to properly dispatch network packets. Example NICs include NVIDIA Bluefield [52, 53] and Broadcom Stingray [9].

Compared to the on-path counterparts, the offloaded code does not affect the network performance of the host as long as it does not involve network communications (②). Thanks to this clear separation, the SoC can run a full-fledged kernel (e.g., Linux) with a full network stack (i.e., RDMA), simplifying system development and allowing for offloading complex tasks [32]. However, accelerating distributed systems with off-path SmartNICs is typically more challenging than using the on-path counterparts. This is because the PCIe switch prolongs all communication paths (i.e., ①, ②, and ③), causing potential performance degradation.

## 2.3 Target SmartNIC: NVIDIA Bluefield-2

We conduct our study on Bluefield-2, a typical off-path SmartNIC optimized for offloading general-purpose computations. Figure 1(c) illustrates its overall hardware architecture, with detailed hardware configuration shown in Table 1.

**Hardware.** Bluefield-2 equips a mature RNIC (ConnectX-6) as its NIC cores for high-speed networking. These cores support all RDMA operations. Its programmability comes from an integrated on-board SoC, which has 16 GB DRAM and an ARM Cortex-A72 (8 cores, 2.75 GHz). A PCIe 4.0 switch bridges the NIC cores, SoC and host together, enabling

**Table 2:** Machine configurations in our two rack-scale RDMA-capable clusters.

Name	Nodes	RDMA-capable NIC	Host PCIe (PCIe0)	Host CPU	Host Memory
SRV	3	1 × ConnectX-6 (200 Gbps) 1 × Bluefield-2 (200 Gbps)	PCIe 4.0 × 16 (256 Gbps)	2 × Gold 5317 v4 (12 cores, 3.6 GHz)	128 GB DDR4-2933
CLI	20	1 × ConnectX-4 (100 Gbps)	PCIe 3.0 × 16 (128 Gbps)	2 × E5-2650 v4 (12 cores, 2.2 GHz)	96 GB DDR4-1600

bi-direction data transfer of up to 256 Gbps. Note that the SoC is linked to the PCIe switch via an internal link, rather than through PCIe.<sup>4</sup> Specifically, the hardware counters provided by Bluefield [54] also imply that it has only two PCIe links: one linking RNIC with the switch (PCIe1) and the other linking the switch with the host (PCIe0).

**Software.** The SoC runs a full-fledged Linux, allowing developers to treat it as a normal ARM server. The kernel also hosts a full RDMA stack, making it convenient for enabling RDMA-based communication. In addition, Bluefield provides DOCA [57] SDK for advanced usage, such as DMA.

**Communication primitives: RDMA and DMA.** All communication paths related to the SoC are conducted using RDMA to simplify system development. As shown in Figure 1(c), clients can issue one-sided or two-sided RDMA requests to the SoC (②), similar to a twin server on the host. Meanwhile, the SoC can also interact with the host via RDMA, and vice versa (③). However, exchanging data between the SoC and the host must pass through the RNIC (PCIe1 and NIC cores) for RDMA support, which adds a hidden bottleneck to this path. Fortunately, we found that Bluefield further provides DMA support (③\*) with DOCA [57], allowing the SoC to use DMA to access the host memory (and vice versa), bypassing the RNIC.

**Existing state of exploring Bluefield.** Previous studies [38, 37, 32, 68] have mainly focused on the computing power of Bluefield (④ in Figure 1), revealing the relative weakness of the SoC cores in terms of performing offloaded tasks and sending network requests. This is because the frequency and number of cores are inferior to those of the host CPU. Due to the power constraints of SmartNICs, it is unlikely that the relative performance comparison between the NIC and host CPU will change. Hence, we take this as a premise during our investigation.

In contrast, few studies have considered various communication patterns in Bluefield (i.e., ①, ②, and ③), which are the main focus of our work. Thostrup *et al.* [68] found that accessing the SoC memory (②) using READ is faster than accessing the host memory (①) in the same way. iPipe [38] shows that using RDMA to communicate between the host and SoC (③) has high latency due to the software overhead of supporting RDMA. This paper systematically explores the performance characteristics of Bluefield and summarizes insightful lessons and advice for future system developers.

<sup>4</sup>This has been confirmed by the NIC vendor.

## 2.4 Notation and testbed

**Notations.** This paper follows Bluefield’s hardware specification when describing low-level hardware details related to Bluefield-2. As shown in Figure 1(c), “PCIe1” refers to the PCIe link connecting the NIC cores to the PCIe switch, and “PCIe0” refers to the link connecting the switch and the host’s PCIe controller. The ARM cores, along with the on-chip memory of Bluefield-2, are collectively referred to as “SoC.” The machine hosting Bluefield-2 is referred as the “host.” Furthermore, we use the terms “requester” and “responder” to refer to the machine issuing the RDMA requests and the destination hardware component, respectively. For example, in Figure 1(c), the requesters of paths ① and ② are any RDMA-capable machines (also called clients), and the responders are the host and SoC, respectively. For path ③, the requester and responder are the host and SoC, respectively, and vice versa.

**Testbed.** Table 2 presents the machine configurations in our testbed. To best utilize SmartNIC, we deploy Bluefield-2 on the servers (SRV) with matching PCIe link (PCIe 4.0) by default. These machines can replace Bluefield-2 with 200 Gbps ConnectX-6 (RNIC) for comparisons. Other machines (CLIs) serve as clients that issue RDMA requests to the servers. All machines in SRV and CLIs are connected through a Mellanox SB7890 100 Gbps InfiniBand Switch. Note that the network performance of the evaluated 200 Gbps NIC is not limited since they connect to the switch with two 100 Gbps ports.

**Table 3:** The findings and advice from our study. Claims supported by sufficient evidence are denoted by **E**, while those supported by hypotheses are denoted by **H**.

SNIC Paths	Findings/Advice	E/H
① (§3.1)	Throughput of RDMA is lower than RNIC	H
	Latency of RDMA is higher than RNIC	E
② (§3.2)	One-sided RDMA performance is better	H
	Avoid memory accesses to close addresses	E
	Avoid large READ requests	H
③/③* (§3.3)	RDMA overuses the PCIe bandwidth	E
	Avoid large READ/WRTIE requests	H
	Enable doorbell batching carefully for RDMA	E
	Use DMA (③*) to improve PCIe utilization	E
①+② (§4.1)	Improve throughput by using paths ① and ② concurrently (esp. in opposite directions)	H
①/②+③ (§4.1)	Selectively offload traffic to ③	E

**Figure 3:** The end-to-end latency (upper) and peak throughput (lower) of random inbound RDMA requests on different NICs. The symbols ①, ②, and ③ in the legend correspond to the communication paths listed in Figure 1.

### 3 Characterizing SmartNIC Performance

As mentioned in §2.3, it is well-known that the *computing power* of NIC is wimpier than that of the host CPU. Therefore, we focus on analyzing the *communication efficiency* of SmartNIC. Figure 3 shows the end-to-end latency and peak throughput of sending different RDMA requests (e.g., READ, WRITE, and SEND/RECV) using either RNIC or SmartNIC through different communication paths.

**Evaluation setup.** We conducted our experiments on the clusters described in Table 2, using a state-of-the-art RDMA communication framework [76]. For one-sided operations (READ and WRITE), the requester communicates with one responder using RDMA’s reliable connection (RC) queue pairs (QPs). The responder addresses are randomly chosen from a 10 GB address space by default. For two-sided operations (SEND/RECV), the responder implements an echo server that utilizes all available cores for handling messages, and the requester communicates with it via unreliable datagram (UD) QPs for better performance [29, 76, 30]. For end-to-end latency, we deploy one requester machine to prevent interferences from queuing effects. For peak throughput, we use up to eleven requester machines to saturate the responder. Finally, we enable all well-known optimizations, including address alignment [81], unsignaled requests [27] and huge pages [17] to prevent side effects from misusing RDMA.

#### 3.1 Communication from Client to Host (path ①)

**Latency.** To compare communication with the host, we conduct an apple-to-apple comparison between Bluefield-2 (SNIC ①) with ConnectX-6 (RNIC ①), as they share the same NIC cores [52]. Their performance gap best illustrates the “performance tax” paid by the SmartNIC architecture. As shown in Figure 3, SNIC ① has 15–30%, 15–21%, and

**Figure 4:** The exec. flow of READ/WRITE on SNIC and RNIC.

6–9% higher latency than RNIC ① for READ, WRITE, and SEND/RECV, respectively. The increased latency on SNIC comes mainly from the PCIe switch and PCIe1 between the host and NIC cores. The one-way PCIe latency is approximately 300 ns, which is non-trivial for small RDMA requests (1–2 μs). Note that the result is measured indirectly. Specifically, the end-to-end read latency on SNIC and RNIC is 2.6 μs and 2.0 μs, respectively. Compared to RNIC, READ on SNIC passes through the PCIe switch twice (see Figure 4). Thus, the cost of each pass is around 300 ns, which matches the number reported in recent literature [69]. Furthermore, the increased latency of WRITE on SNIC is lower than that of READ, because it omits one pass through PCIe switch for completion [49]. The latency of SEND/RECV on SNIC also increases, but mainly due to the larger CPU costs at the responder; the latency to post a request (via MMIO) on SNIC is higher than RNIC (399 cycles vs. 279 cycles).

**Throughput.** As shown in Figure 3, for READ, WRITE, and SEND/RECV, SNIC ① has 19–26%, 15–22%, and 3–36% lower throughput than RNIC ① for payloads less than 512 bytes, respectively. We suspect the lower throughput is due to the longer latency in processing RDMA requests caused by PCIe switch. However, for larger requests, the results are similar to using RNIC as both are bottlenecked by the network bandwidth.

**Figure 5:** (a) An illustration of three examples of different combinations of data flows on different paths, and (b) the peak throughput of different combinations of data flows on different communications paths.

**Bottleneck.** The lowest bandwidth limit of NIC, PCIe1, and PCIe0 will first become the bottleneck for communication from client to host. On our testbed, the bottleneck is the network: 200 Gbps. On the other hand, we find an interesting phenomenon: the total inbound bandwidth of the requester can approach *twice* the limit—400 Gbps—because the links are *bi-directional* [58]. Specifically, if packets flow in opposite directions, e.g., the READ and WRITE packets in Figure 5(a), they can be multiplexed on the same link. To illustrate this, we dedicate two requesters (each with 12 threads to saturate the one-way bandwidth) to issue 4 KB packets. As shown in Figure 5(b), if two clients send READ and WRITE requests separately, a total of 364 Gbps bandwidth is measured on a 200 Gbps NIC (see READ+WRITE of SNIC ①). In contrast, if both clients send the same type of requests (either READ or WRITE), only about 190 Gbps is measured. Note that though this phenomenon is widely known in traditional networking (i.e., messaging), where the messages are typically two-sided, it is largely ignored by many RDMA-based systems, because RDMA request can be one-sided.

**Takeaways.** Being “smart” incurs performance degradation for communicating with the host for small requests. For small requests, we demonstrate that extending RNIC (ConnectX-6) to SNIC (Bluefield-2) causes performance degradation by up to 36% and 30% in throughput and latency, respectively. In general, for distributed systems that only use the path ①, it is recommended to use RNIC. Although the overhead may be negligible for large requests or for networking with longer latency, RNIC is cheaper and more energy-efficient than SNIC.

### 3.2 Communication from Client to SoC (path ②)

**Latency.** For sending requests from the client to SoC (SNIC ② in Figure 3), the latency of READ decreases by up to 14% compared to the host (SNIC ①). The *reason* is that it skips PCIe0. Yet, it is still 4–15% higher than RNIC, because requests still must go through the PCIe switch at PCIe1. For WRITE, SNIC ② provides similar performance as SNIC ① due to the asynchronous completion of cores (see Figure 4). For SEND/RECV, SNIC ② has 21–30% higher latency than SNIC ① due to the weaker computing power of SoC.

**Figure 6:** Different paths to access host and SoC memories.

**Throughput.** SNIC ② has better throughput than SNIC ①, reaching  $1.08\text{--}1.48\times$  for payloads less than 512 bytes. Interestingly, the READ of SNIC ② is even higher than that of RNIC ① before reaching the peak network bandwidth. For this undocumented results, we suspect that it is due to the closer packaging of SoC memory and the PCIe switch. Specifically, the SoC is linked to the PCIe switch via an internal link, rather than through PCIe. Note that a confident analysis relies on the hardware details of Bluefield, which unfortunately are not available now. For WRITE, SNIC ② is still lower than that of the RNIC ①. Our *hypotheses* are twofolds. First, SoC has fewer DRAM channels compared to the host (1 vs. 4), limiting the concurrency of write accesses. Nevertheless, READ is not affected because read accesses on DRAM are faster than write accesses [25, 73]. Second, SoC can only utilize a portion of NIC cores (see §4.1). Finally, SEND/RECV has a poor performance on ②: it just achieves up to 64% of the host (SNIC ①). This is due to the wimpy computing power of SoC, since the throughput of SEND/RECV is bottlenecked by the responder CPU to send the reply.

**Bottleneck.** As shown in Figure 1(c), since SNIC ② only flows through NIC and PCIe1, the bottleneck is their lower bandwidth limit, which is still Bluefield-2’s 200 Gbps NIC. Therefore, as shown in Figure 5(b), the performance of SNIC ② is the same as that of SNIC ①, namely the total of 400 Gbps and 200 Gbps bandwidth for opposite direction and same direction communication, respectively.

In addition to the basic RDMA performance of the SNIC, we found several factors that could also prevent distributed systems from achieving the aforementioned performance.

**Advice #1: Avoid memory accesses to close addresses.** The

**Figure 7:** The peak throughput of accessing host memory and SoC memory via SNIC, READ (a) and WRITE (b).

**Figure 8:** The bandwidth (a) and PCIe packet throughput (b) for accessing (READ and WRITE) the host (SNIC ①) and SoC (SNIC ②) via SmartNIC. For brevity, we omit the result of SEND/RECV since it is the same as WRITE for large payloads [27].

wimpy SoC cores may impact the memory access behavior of one-sided RDMA primitives, because it usually supports fewer features compared to the more powerful host CPU cores. Specifically, Data Direct I/O (DDIO) [26] is widely supported by the host CPUs, which allows the NIC to directly read/write data from/to its last level cache (LLC), as shown in Figure 6. SoC cores may also equip with similar features (e.g., ARM CCI [5]), but whether to do so is vendor-specific. The SoC cores of our hardware (ARM Cortex-A72 in Bluefield-2) do not support DDIO. We find that one-sided RDMA without DDIO suffers performance drop if the requested memory addresses fall into a small range (i.e., they are close together). This is *because* DRAM requires a (not-too-small range) to utilize all memory modules concurrently. LLC is faster than DRAM, so we suspect the impact is smaller.

Figure 7 shows the peak throughput of accessing host memory and SoC memory via SNIC with the increase of address ranges.<sup>5</sup> For WRITE, the throughput of SNIC ② using SoC drops to 22.7 M reqs/s (from 77.9 M reqs/s) when address range decreases to 1.5 KB (from 48 KB). In contrast, the performance of SNIC ① using Host CPU is hardly affected when DDIO is enabled. For READ, the degradation is relatively smaller. The throughput of SNIC ② drops from 85 M reqs/s to 50 M reqs/s when decreasing the range from 48 KB to 1.5 KB. This is because DRAM can serve reads faster than writes [25, 73]. Finally, we also plot the RNIC results as a reference. When requests addresses are close, we can see that ① also suffers a significant performance drop on WRITE when DDIO is disabled.

<sup>5</sup>Note that we attach Bluefield to CLI machines for the evaluation because we are unable to disable DDIO on the SRV machines.

**Table 4:** PCIe Maximum Transfer Unit (MTU) on our testbed, and the number of PCIe packets required to transfer  $N$  bytes via different communication paths of Bluefield-2. Our simplified model omits control-path packets (e.g., two-sided message arrival notification).

	Host CPU cores ( $H_{MTU}$ )		SoC cores ( $S_{MTU}$ )
PCIe MTU	512 B		128 B
	SNIC ①	SNIC ②	SNIC ③
PCIe1	$\lceil N/H_{MTU} \rceil$	$\lceil N/S_{MTU} \rceil$	$\lceil N/H_{MTU} \rceil + \lceil N/S_{MTU} \rceil$
PCIe0	$\lceil N/H_{MTU} \rceil$	–	$\lceil N/H_{MTU} \rceil$

**Advice #2: Avoid large READ requests.** It is common practice to use requests with large payloads to fully exploit network bandwidth. For example, using requests with payloads larger than 16 KB is enough to saturate a 200 Gbps RNIC even using a few threads. Unfortunately, we observed that the READ performance of SNIC ② collapses with request payload larger than 9 MB, as shown in Figure 8(a). We *suspect* that NIC cores suffer from head-of-line blocking when processing large READ requests. For a READ request, the NIC issues a PCIe read transaction to fetch the data, which is further segmented into multiple PCIe packets. The maximum size of a PCIe packet is determined by the PCIe Maximum Transfer Unit (MTU), negotiated by the linked hardware devices during bootstrap [49]. Table 4 lists the PCIe MTU on our testbed. SoC cores (the endpoint of SNIC ②) use a smaller PCIe MTU (128 B) due to its weaker CPU. As a result, NIC core that processes a large DMA read sent to SoC memory (SNIC ②) must wait for more PCIe packets to arrive, resulting in lengthy processing stalls. Since the overall NIC packet processing power is not the bottleneck: as shown in Figure 8(b), the requests with payloads smaller than 9 MB still can achieve a high processing rate while it collapses for the others, so we suspect some blocking happens at the NIC core. Note that WRITE requests are not affected since DMA does not wait for the completion [83, 49].

On the contrary, the host uses a larger PCIe MTU (512 B), so it does not suffer from bandwidth degradation (SNIC ①). As shown in Figure 8(b), the NIC can issue 46.7 million PCIe packets per second to the host (SNIC ①). The aggregated bandwidth reaches 191 Gbps, bottlenecked by the network.

**Takeaways.** For READ and WRITE, sending requests to SoC is typically faster than that to the host (or even faster than via RNIC) because SoC is “closer” to the NIC (without PCIe0). In contrast, using SEND/RECV to communicate with SoC is slower due to weak SoC cores. Furthermore, designers still need to carefully consider the heterogeneity between host CPU cores and SoC cores to avoid performance anomalies. Specifically, memory accesses to a small address range may suffer performance degradation due to the lack of DDIO support on SoC cores. In addition, sending large READ requests to SoC may underutilize the bandwidth so the request should be proactively segmented into smaller ones.

**Figure 9:** The bandwidth (a) and PCIe packets throughput (b) for sending (R)EAD/(W)RITE requests between the host and SoC.

### 3.3 Communication between SoC and Host (path ③)

We first describe our measurements and findings of RDMA and then compare RDMA (③) with DMA (③\*).

**Latency.** As shown in Figure 3, the latency of sending requests from SoC to the host (SNIC ③ S2H) is very high, especially for READ, since the requester (SoC) takes longer to issue an RDMA request to the NIC. The latency in the opposite direction (from the host to SoC, SNIC ③ H2S) is reduced but still 4–17% higher than SNIC ②. Although the intra-machine communication saves one network round-trip, it adds additional PCIe transfers. Specifically, the request on SNIC ② flows the requester-side PCIe (not shown in Figure 1(c)), the network, PCIe1, and the PCIe switch, while the request on SNIC ③ (H2S) flows PCIe0, the PCIe switch, PCIe1 twice (in and out), and the PCI switch (again).

**Throughput.** For requests with payloads less than 512 bytes, the throughput of SNIC ③ (both S2H and H2S) is dominated by the requester’s capability to post networking requests. This is because a single requester machine (either SoC or the host) cannot saturate the NIC with small requests<sup>6</sup>, the READ throughput of SNIC ③ only reaches 29 M reqs/s and 51.2 M reqs/s for S2H and H2S, respectively, still far from its limit. For WRITE and SEND/RECV, the results are similar. For larger requests, they are bottlenecked by the PCIe bandwidth, which will be discussed in more detail next.

**Bottleneck.** As shown in Figure 5(b), for packets flowing in a single direction, communication between host and SoC is bottlenecked by PCIe bandwidth (256 Gbps) rather than the uninvolved NIC (200 Gbps). Therefore, the peak bandwidth of SNIC ③ is slightly higher than SNIC ① and ② (204 Gbps vs. 191 Gbps). Readers might be interested in why the results of SNIC ③ cannot be close to 256 Gbps. We suspect that it requires much more PCIe packets than the others. For packets flowing in opposite directions, SNIC ③ can not utilize twice the limit as the other paths (i.e., SNIC ① and ②). This is because RDMA overuses the PCIe: each request passes through PCIe1 twice (in and out), exhausting the bi-directional link.

**Advice #3: Avoid large READ/WRTIE requests.** Communications between the host and SoC (SNIC ③) also suffers from bandwidth degradation for large READ requests like SNIC ②,

<sup>6</sup>We use up to eleven requester machines for SNIC ① and SNIC ②.

**Figure 10:** The latency of posting requests to NICs (a) and the impact of doorbell batching (DB) on the requester.

possibly due to the head of line blocking as we have discussed before. Moreover, this issue appears with large WRITE requests because the SmartNIC must first read data from the requester and then write it to the responder. As shown in Figure 9(a), the READ/WRITE performance of SNIC ③ collapses to about 100 Gbps for large requests. Table 4 shows the number of PCIe packets required to transfer  $N$  bytes via different communication paths. For SNIC ③, the NIC generates more packets due to passing through PCIe1 twice. Further, the performance of S2H collapses earlier than H2S as it will pass through PCIe1 first. Suppose we transfer data at 200 Gbps from SoC to the host. The SoC cores first transfer 195 M PCIe packets per second (pps) to the NIC (PCIe1), then the NIC forwards data back to the PCIe switch via PCIe1 again with 49 Mpps (the host supports 512 B MTU), and finally, the switch forwards 49 Mpps through PCIe0. Therefore, SmartNIC should process at least 293 Mpps for transferring data at 200 Gbps, which is  $3\times$  and  $1.5\times$  higher than SNIC ① and SNIC ②, respectively. This is further confirmed by our measurements of the hardware counters. As shown in Figure 9(b), for sending 256 KB READ requests from SoC to the host, the bandwidth reaches 204 Gbps, and the NIC transfers about 320 M PCIe packets per second.

**Advice #4: Enable doorbell batching carefully.** The time of posting each request to the NIC is dominated by Memory-Mapped IO (MMIO) [76, 28]. The SoC suffers a high MMIO latency when communicating with the host (see Figure 10(a)). A known optimization is doorbell batching (DB) [28]: to send a batch of  $B$  requests, the requester first chains them together in memory, then use one MMIO to ask the NIC to read these requests with DMA in a CPU-bypass way. DB reduces the number of MMIOs required from  $B$  to 1. Thus, for RNIC ① and SNIC ②, DB is always helpful and can bring 2–30% performance improvement (see Figure 10(b)). For the communication between host and SoC (SNIC ③), DB is still helpful at the SoC-side. As shown in Figure 10(b), when sending a batch of READs to the host, DB improves the SoC performance by 2.7–4.6 $\times$  for batch sizes 16–80. The huge improvement is partly due to the CPU-bypass feature of DMA, and also because the NIC is faster in using DMA to read requests stored on SoC memory (see §3.2). However, DB is not always helpful at the host-side, because it is slower to

**Figure 11:** The throughput and bandwidth comparisons of using RDMA (③) and DMA (③\*) when communicating from SoC to the host, the only supported primitive of DMA of our SNIC.

read host memory using NIC DMA (see §3.1). For batch sizes of 16, 32, and 48, DB decreases the throughput of host-SoC communication by 9%, 7%, and 6%, respectively.

**RDMA (③) vs. DMA (③\*).** Besides RDMA, SoC can use DMA (③\*) to read/write data from the host (and vice versa) via the DMA engine inside the SoC. It has the benefits of reducing two PCIe passes (PCIe1) and bypassing RNIC compared to RDMA (see Figure 1), resulting in a lower latency, e.g.,  $1.9 \mu$  vs.  $2.6 \mu$  for 64 B SoC to host READ. However, we find the SoC DMA engine has a weaker processing power than RNIC (RDMA). For brevity, we only present results on SoC to host. The results of host to SoC is the same as SoC to host since host DMAs are offloaded to SoC for execution [56]. As shown in Figure 11, for WRITE, the peak throughput of DMA is only 47–59% of that of RDMA for requests with payload less than 4 KB. The results of READ is similar. DMA WRITE even fails to saturate the PCIe limit (256 Gbps) for payloads between 16 KB and 1 MB. We suspect it is due to the poor processing capability of the SoC’s DMA engine, yet we cannot confirm this without knowing the confidential internal design of the SoC. Another observation from the bandwidth results is that DMA also suffers from the anomalies of RDMA (see Advice #3): For payloads larger than 1 MB, there is a significant performance drop for both READ and WRITE.

For bandwidth, ③\* has a higher theoretical upper bound than ③: it is bottlenecked by the bidirectional bandwidth of PCIe, as it bypasses the PCIe1. However, Figure 5 shows that it fails to achieve so (only 178 Gbps for READ + WRITE). This suggests that the slow DMA engine will first become the bottleneck. Nevertheless, bypassing PCIe1 still has the benefits of reducing interferences to other paths. We will discuss them in §4 in detail.

**Takeaways.** First, enabling doorbell batching is critical for SNIC ③ at the SoC side, because SoC has wimpy computation power. Yet, it is negatively impacted at the host side for small batch sizes. Second, SNIC ③ has a different bottleneck than SNIC ① and SNIC ②. It is always bottlenecked by the uni-directional bandwidth of PCIe, while others are limited by the minimal bi-directional bandwidth of network and PCIe.

**Figure 12:** Throughput for (a) READ and (b) WRITE with the increases of requester machines.

If this factor is not adequately considered, distributed systems will underutilize the NIC bandwidth (see §5.1). Third, though DMA utilizes PCIe better than RDMA for SoC to communicate with the host, it has a lower throughput due to the weaker DMA engine at the SoC. Finally, we should avoid transferring large requests between the host and SoC, for both RDMA and DMA and for both READ and WRITE.

## 4 A Guideline for Smartly Exploiting Multiple Paths of SmartNIC

Previous approaches mainly leverage a single path of SmartNIC to optimize a specific functionality of distributed systems. However, this cannot fully exploit the computing and networking capabilities of SmartNICs. Furthermore, only considering a single path may ignore interference on resources (e.g., PCIe and PCIe switch) between different paths. Therefore, we first holistically study the performance characteristics of concurrently using multiple paths, and then lay out an optimization guideline for designers to smartly use SmartNICs.

### 4.1 Characterizing concurrent communication paths

**Concurrent communication with the host and the SoC (①+②).** We focus on the throughput results (see the lower part of Figure 3) since the latency results are roughly the average of the two paths. We evaluate the peak throughput by assigning half of the clients to send requests to the host while the others to send to the SoC. We can see that the total peak throughput of concurrently using ① and ② (SNIC ①+②) is typically faster than each of them. For READ, WRITE, and SEND/RECV, SNIC ①+② outperforms the lower of them by up to  $1.45\times$ ,  $1.50\times$ , and  $3.3\times$ , respectively.

For SEND/RECV, a concurrent path utilize both of the host and SoC to process the requests, so the performance improvement is clear. However, the READ/WRITE performance improvement is non-intuitive and undocumented, since two paths should compete for NIC cores. Our *suspicion* is that the SmartNIC internally reserves some NIC cores for each endpoint. Therefore, sending requests to the host and the SoC concurrently can further increase *peak* throughput by enabling more NIC cores. To quantify this, we design a microbenchmark that first increases the requester machines to saturate the NIC and then changes the responder, as shown in Figure 12. All requests use 0 B payload to avoid interference of DMA, i.e., the request will return before passing PCIe1 [6].

For READ, five requester machines are sufficient to saturate NIC cores when using SNIC ① or SNIC ② alone. Therefore, for concurrently using SNIC ① and SNIC ②, we first dedicate five requester machines for one responder, and then add requesters for the other responder. Both cases (SNIC ①+② and SNIC ②+①) offer similar performance, with 4–13% and 5–10% higher throughput than using SNIC ① or SNIC ② alone. For WRITE, all results are almost the same.

Finally, as expected, the aggregated throughput of the two paths (SNIC ① and SNIC ②) is much higher than concurrently using them (352 Mpps vs. 195 Mpps), indicating that most NIC cores are still shared, i.e., each can communicate with two endpoints, and only a few is dedicated. This also implies that concurrently using multiple resources of SmartNIC is non-trivial.

**Concurrent inter- and intra-machine communication (①/②+③).** There exist four concurrent combinations of inter- and intra-machine communication. For brevity, we focus on the results of SNIC ①+③/H2S, other combinations are similar. To study the concurrent usage of the two paths, we first deploy sufficient clients (five requester machines) to saturate the network for SNIC ①. Afterward, we start the requester on the host (one machine with 24 threads) sending RDMA requests to the SoC (SNIC ③/H2S). Our measurements reveal that concurrently enabling intra-machine communication degrades the performance of inter-machine communication. As shown in Figure 3, for READ, WRITE, and SEND/RECV, the throughput of small requests (less than 512 bytes) drops 7–15%, 4–27%, and 9–14%, by comparing SNIC ① and SNIC ①+③(H2S). For large requests, the performance is always bottlenecked by the network bandwidth, so the degradation is negligible.

The SNIC ③ affects other communication paths of SmartNIC, because it relies on the NIC (PCIe1 and the PCIe switch) for RDMA support. In comparison, SNIC ③\* communication can leverage DMA to reduce such interferences. For example, for READ with payloads 16–64 B, we only observe a 5–6% throughput drop, after adding SNIC ③\* to ①.

**Bottleneck.** Assuming each path has only one type of request, e.g., either READ or WRITE. For SNIC ①+②, each part has the same bottleneck (the NIC), so the bandwidth limit is 400 Gbps (bi-directional). For SNIC ①+③, it is bottlenecked by SNIC ③, which is limited on the uni-direction of PCIe (256 Gbps) since it occupies both directions of PCIe1 (see Figure 5(b)). Nevertheless, if SNIC ① is used in opposite directions (i.e., READ and WRITE), SNIC ①+③ can reach a higher limit. For example, the aggregated bandwidth can achieve 456 Gbps (in theory) if we restrict the bandwidth of data transfer on SNIC ③ to 56 Gbps. This suggests that selectively offloading small portion of data to SoC may be optimal. Finally, if possible, it is usually better to combine SNIC ① or ② with DMA (①/②+③\*) despite DMA being slower than RDMA (see §3.3). This is because DMA has

better PCIe utilization (without passing PCIe) and RNIC utilization (without using RNIC).

**Takeaways.** Sending requests from clients to the host and the SoC concurrently (SNIC ①+②) can better utilize NIC cores to handle small RDMA requests, especially when used in opposition directions (e.g., one for READ and one for WRITE). On the contrary, uncontrolled use of intra-machine (host-SoC) communications (SNIC ③) may harm inter-machine communications, which is the intrinsic purpose of using SmartNIC. Specifically, if the uni-directional bandwidth of PCIe is smaller than the bi-directional bandwidth of the NIC, using SNIC ③ can introduce a hidden bottleneck. Therefore, we should always consider using SNIC ③ only when spare resources are made available. Specifically, if the inter-machine communication saturates the NIC, the bandwidth used by SNIC ③ should no larger than  $P - N$ , where  $P$  and  $N$  are the limit of the PCIe and the network, respectively. For example, it should be 56 Gbps on our testbed. Using SNIC ③\* can reduce the interference between paths, but SNIC ③\* also has limitations: it is slower than SNIC ③.

Finally, in real-world distributed systems, it is common that a single communication path cannot fully saturate all resources of SmartNIC. For example, SNIC ② is the fastest but limited by small memory and wimpy cores on the SoC. On the other hand, only using SNIC ① as RNIC would waste all resources on the SoC. Therefore, we should concurrently use multiple paths provided by the SmartNIC, but carefully avoid interference between them.

## 4.2 An optimization guideline

This section presents our optimization guideline for smartly utilizing multiple communication paths of SmartNIC to improve the performance of distributed systems. Specifically, given the functionality (e.g., file replication in a distributed file system) of a target distributed system that needs to be accelerated by SmartNIC, we recommend designers consider the following steps:

1. Devise potential alternatives for SmartNIC to support the given functionality, and optimize them based on performance characteristics uncovered by our study.
2. Evaluate and rank alternatives based on system-specific criteria.
3. Select and combine alternatives in turn until the resource of SmartNIC is saturated.

**System-specific criteria.** The criteria can be the desirable properties that the system designer aims to achieve, or the restrictions of the systems. For replication in a distributed file system, the properties include low host CPU overhead and high network bandwidth utilization [32]. For a disaggregated key-value store, the properties include less network amplification, low latency and high throughput. The restriction the host has little or no CPU that we can use [86].

**Figure 13:** The host CPU usage breakdown of different alternatives when replicate 8 MB data (a). Write bandwidth when the host is idle (b) and busy (c) for A1, A2 and A2 + A3.

**Discussion.** We currently only consider the combination of alternatives in a greedy way, which is sufficient for most networked functions in real-world distributed systems. Further, SmartNIC usually offers a limited number of available options. Note that efficiently combining alternatives is challenging. For different systems, different alternatives may consume different resources on the SmartNIC, while a combination of them may involve different levels of resource contentions. Our previous analysis—including the bottleneck of different communication paths and concurrently utilizing multiple paths on the SmartNIC—will guide designers to avoid most performance contention. Nevertheless, how to systematically choose and combine different paths is our future work.

## 5 Case Studies

To demonstrate the efficacy of our study and the optimization guideline, this section presents two detailed case studies.

### 5.1 Distributed file system

**Overview.** File replication is a key pillar in distributed file systems for fault tolerance. With the emergence of RDMA and non-volatile memory (NVM), an appealing trend is to use RDMA to directly replicate file updates on remote NVM for better performance [32, 3, 40, 4], i.e., RDMA primitives can directly write NVM just like DRAM, with network and NVM bandwidth fully utilized [81].

**Devise alternatives.** The desirable properties of file replication are high performance, high network utilization and low host CPU overhead. There are three alternatives to implement file replications on our SmartNIC, as illustrated in Figure 14.

1. **Alternative (A1).** It comes from the state-of-the-art distributed file system on SmartNIC, LineFS [32], which completely offloads the file replication to SoC. The SoC will compress and replicate the file to reduce data transferred through the network with low host CPU usage. After receiving a replication request, the primary SoC reads the file from host (③), compresses it (④), and writes the file to remote backups with chain replication [72] (②). Specifically, if there are multiple backups, the second backup will further re-replicate the log to the next backup on the chain and so on.
2. **Alternative (A2).** Guided by our study, we can replace

the ③ in A1 with ③\* to reduce interference on the PCIe bandwidth, specifically, PCIe1 on the SmartNIC.

3. **Alternative (A3).** The host can directly write the file from the host to the remote backup with WRITE (①) [40]. Note that this approach typically skips file compression to prevent non-trivial host CPU overhead (see Figure 13 (a)).

**Baseline.** LineFS [32] is a state-of-the-art distributed file system based on NVM and SmartNIC. It adopts A1 to replicate the files. We further implement A2 and A3 on its open-source codebase<sup>7</sup>, and rewrite its backend with more efficient RDMA implementation to scale to 200 Gbps networking, e.g., with asynchronous and batched RDMA operations.

**Optimization on each alternative.** By default, LineFS adopts a chunk size of 16 MB in its open-source codebase for A1. Based on our Advice #3 described in §3.3, we shrink it to 256 KB for a better performance over ③. This optimization further applies to A2 and A3.

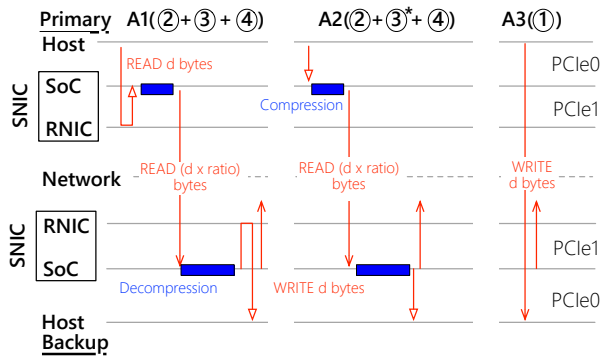

**Analyse alternatives.** A1 is the most straightforward way to offload file replication, reducing the data transferred through the network ( $d$  vs.  $d \times ratio$ ). Thus, the ideal peak bandwidth is  $N/ratio$ , where  $N$  is the bandwidth limit of SmartNIC. However, A1 does not consider the costly PCIe occupation of ③ (§3.3), which even fails to saturate the network bandwidth for file transfer. Denote the primary’s PCIe limit (uni) as  $P$ . A1’s file transfer bandwidth  $d$  is limited by  $\frac{P}{1+ratio}$ , because each data packet must pass the *PCIe1 out link* twice. As shown in Figure 14, one is from SoC to RNIC ( $d$  bytes) and another from SoC to the remote ( $d \times ratio$  bytes). On our platform ( $p = 256 Gbps$ ), so A1 is only better than file is not compressed (whose performance is bottlenecked by the network  $N = 200 Gbps$ ) when the compression ratio is lower than 28%. Worse even, A1 cannot saturate the network bandwidth of SmartNIC when encountering a bad compression ratio ( $\geq 28\%$ ). For example, without compression ( $ratio = 1$ ), the peak of A1 is only 128 Gbps.

Figure 13 (b) presents the results of A1 on the file write benchmark of LineFS. This benchmark does not compress the file. We can see that A1 only achieves 117 Gbps with 8 clients when the host is idle.

A2 addresses the poor PCIe utilization of A1 by replacing ③ with ③\*. As shown in Figure 13 (b), A2 is 1.01–1.13 ×

<sup>7</sup><https://github.com/casys-kaist/LineFS>

**Figure 14:** Overview of alternatives for file replication with SmartNIC. *ratio* is defined as `compressed size / uncompressed size`. We omit the control path messages as they are trivial.

faster than A1 under different number of clients. However, A2 fails to achieve a close to 200 Gbps result (peak at 133 Gbps) due to the following two reasons. First, the WRITE of ③\* cannot fully utilize the full PCIe bandwidth on our platform (see Figure 11). Second, the poor computation power of SoC may also become the performance bottleneck of file replication.

A3 bypasses the PCIe occupation problem of A1, and the slow DMA WRITE and weak SoC issues of A2. Meanwhile, its data path is shorter (see Figure 14). As shown in Figure 13(a), it takes 40% shorter time to wait for the log acknowledgment compared to A2. As a result, A3’s replication bandwidth is 5–41% faster than A2 under different client setups. The drawback is that A3 takes more CPU cycles even without considering compression (Filesystem), see Figure 13(a). This is because A1 and A2 can digest the file log on the SoC. Thus, the overall process time reduction of A3 is 8% (decreased from 40%) compared to A2.

**Select and combine alternatives.** Since A2 is always better than A1, we will only consider combining A2 with A3. As we have analyzed before, A3 is faster than A2. Therefore, increasing the ratio of A3 in a combined path (A2 + A3) always improves the performance, as shown in Figure 15. However, if file compression for high network utilization is enabled, it has high host CPU utilization, as shown in Figure 13 (a). Disabling compression for A3 will lower the network utilization, also illustrated in Figure 15. Specifically, when increasing the percentage of path A3 in clients, the network utilization is reduced from 50% to 0% considering a fixed 50% compression ratio.

Considering A2 has better network utilization, we follow a greedy approach that first saturate the SoC with A2 for better network utilization. Afterward, clients use A3 to do the file replication. This approach can achieve the best of both worlds: the combined path is faster than A2 with network better utilized than A3.

**Evaluation results.** Figure 13 (b) and (c) further present the file replication benchmark results of A2 + A3 when the host CPU is idle and busy, respectively. We follow the same setup as LineFS [32]’s benchmark and add a CPU-intensive

**Figure 15:** Analysis of the network utilization and performance when combining A2 and A3.

workload (streamcluster [7]) to the host CPU to emulate a busy experimental setup. A2 + A3 is 7–30% and 4–21% faster than original LineFS when CPU is idle and busy, respectively, thanks to the more efficient usage of SmartNIC and a smart utilization of multiple execution paths.

## 5.2 Disaggregated key-value store

**Overview.** RDMA-based disaggregated key-value stores (R-KVS) are prevalent in modern data centers [75, 70, 17, 86]. In R-KVS, one or more memory servers store both indexes (usually hash table) and values. Clients on other machines use READs to traverse the index and retrieve the corresponding value to handle requests (i.e., get), see A1 in Figure 16.

**Devise alternatives.** The desired properties are high throughput, low latency and minimal network amplification. The restriction is that we can barely use the host CPU (i.e., disable SEND/RECV for path ①). SmartNIC enables five alternatives for R-KVS, as illustrated in Figure 16.

1. **Alternative (A1).** The client treats SmartNIC as a normal RNIC and uses READs to handle the get request (①). This approach suffers from network amplification.
2. **Alternative (A2).** One intuitive approach for offloading is to send the get request to the SoC using SEND/RECV (②). The SoC can then traverse the index and read the value on the host via RDMA or DMA READ. This approach effectively eliminates network amplification.
3. **Alternative (A3).** One drawback of A2 is that reading data from SoC to the host is slower reading from the host’s local memory. An optimization is to offload the indexes to the SoC memory (④). This approach is similar to index caching at the clients [11, 62, 75], but caching the indexes at the SmartNIC is more effective. Each client has a small memory that can only cache hundreds of entries in a disaggregated setting [86], while SmartNIC has a relatively large SoC memory (e.g., 16 GB on Bluefield-2) that can cache all the indexes.
4. **Alternative (A4).** Accessing the index on the SoC using SEND/RECV (②) cannot fully utilize the NIC cores of SmartNIC, because the peak throughput of SEND/RECV is only 21.6 M reqs/s. Therefore, we can use READs to traverse the index on the SoC (②), and another READ to retrieve the value on the host (①).

**Figure 16:** Alternatives (A1–A5) for offloading a get request of RDMA-based disaggregated key-value store to off-path SmartNIC.

**Figure 17:** (a) Latency and (b) throughput comparisons between different alternatives on YCSB C. For A5, we restricted the selection of clients keys to always hit the cached values on SmartNIC.

This approach still has network amplification, but can utilize the fast path (②) to improve performance (see §3.2).

- Alternative (A5).** Similar to index caching, SoC memory can further cache a portion of values (e.g., the values of hot keys). This approach avoids using the costly communication path (③) of the previous alternatives.

**Baseline.** DrTM-KV [11] is a state-of-the-art KV store optimized for RDMA: it adopts cluster-chaining hash index such that the client typically finds the value position of a given key in one READ. Specifically, for a get request, the client first READs a 64 B bucket (based on the hash of the key), finds the remote address of the corresponding value in it, and then fetches the value with another READ. DrTM-KV supports index caching at the client to skip the first READ [80], but it may not be always feasible in a disaggregated environment due to memory constraints [86], so we disable it.

**Optimization on each alternative.** We implement A1–A5 on DrTM-KV guided by our study (§3). Specifically, we carefully enabled doorbell batching for alternatives related to the SoC CPU (A2, A3 and A5). Besides, we apply Advice #1 for A4 and A5, which replicate a few hot keys to multiple replications to avoid sending requests to a small range of memory. We use DMA (③\*) instead of RDMA (③) to implement A2 and A3 as it is always faster due to lower latency. For example, A2 throughput is improved by up to 79% with ③\*. A2 and A3 does not suffer from the low DMA throughput discovered in §3.3 because the SoC will first become the bottleneck.

**Analyse alternatives.** We use YCSB C [16] (100% get) with default Zipfian request distribution ( $\theta = 0.99$ ) for all the experiments. The payload sizes of keys and values are 8 B

and 64 B, respectively, similar to prior work [41, 45, 30, 66, 75]. Following the microbenchmark setup, we use one client machine to measure the latency and deploy up to eleven client machines to measure the peak throughput.

Figure 17 demonstrates that none of the path can achieve both high throughput and low latency. A5 (SEND/RCV) achieves the lowest latency ( $4.6 \mu s$ ) because it completely eliminates the network amplifications problem and costly host-SoC communications (③). However, its peak throughput (17.6 M reqs/s) is significantly lower than some other alternatives. Specifically, the peak throughput of A5 (READ) and A4 reach 70 M reqs/s and 58.3 M reqs/s, respectively. They have a higher throughput because the RDMA path to SoC (①) is faster (§3.2). Note that A5 is not always achievable, which requires caching all the key-values at the SoC memory. Therefore, A4 is a suitable design if the SoC cores become the bottleneck (④). A1 has a higher latency and lower throughput than A4, since RDMA to the host (①) is relatively slow. A2 and A3 are bottlenecked by the slow host-SoC communication (③, see §3.3), which is not suitable for offloading KV store requests.

**Select and combine alternatives.** Our analysis suggests that the optimal combination is A4 and A5. Initially, the first few clients use A5, whereas the later clients use A4. The exact switch point can be estimated by using queuing theory [24] to model the capacity of SoC and the capability of RNIC, as in prior work [46].

In addition, using A5 presents a challenge as clients are unaware of which values are cached at SoC. Although A3 can be used as a fallback path for cache misses, it will result in significant performance degradation (see Figure 17). To tackle this issue, we provide a simple solution: when a cache miss occurs, the SoC returns the address of the value to the client, which then issues a READ to retrieve the value accordingly, similar to A4. In real-world skewed workloads (e.g., YCSB [16]), cache misses are rare.

**Evaluation results.** Figure 18 shows the latency and throughput results on YCSB C. We plotted the graph by increasing the number of client machines. The combination of A4 + A5 achieves a peak throughput of 68 M reqs/s, which is 25%, 36%, and 12% higher than RNIC, A1, and A4, respectively. Note that we omit A2 and A3 as they are bottlenecked by SoC cores and have extremely low peak throughput. The benefits

**Figure 18:** Performance of YCSB C using different alternatives. Note that A5 cannot run a full workload alone, since SoC memory is not large enough to cache all values. For A4 + A5, one client uses A5, and the rest use A4.

of A4 + A5 mainly come from utilizing faster SoC RDMA and SoC cores for reducing network amplifications.

## 6 Discussion

**Generalizability.** Although our study primarily focuses on one particular SmartNIC, Bluefield-2 [52], we believe that our findings and advice can be applied to other off-path SmartNICs that share a similar hardware architecture. These SmartNICs extend RDMA-capable NICs, such as Stingray PS225 [9] (which extends NetXtreme 100 Gbps RNIC [8]), by attaching a heterogeneous SoC and bridging SoC and RNIC together with a PCIe switch. We have confirmed that all our results hold on Bluefield-1 [55]. Moreover, the next generation of Bluefield (Bluefield-3) still follows the same architecture, except for using faster RNIC (400 Gbps ConnectX-7), PCIe (5.0), and SoC (ARMv8.2+ A78). Even though other SmartNICs may have different parameters than Bluefield-2, our methodology, analysis tools (open-sourced), and performance models (e.g., Table 4) also apply to them.

Furthermore, DPDK [1] is another popular communication primitive over SmartNIC. From a NIC’s perspective, DPDK is similar to SEND/RECV over UD. Therefore, we believe that most of our findings are still applicable to DPDK as well. Unfortunately, we do not have an Ethernet-based testbed to confirm this further.

**Suggestions for hardware vendors.** Our study has uncovered several anomalies that can be mitigated through hardware improvements, which we suggest vendors consider. For example, current host to SoC DMA must offload to SoC for execution [56], while supporting CXL [15] can utilize the more powerful host CPU DMA engine for it. However, doing so in a programmer-friendly way [21] will require strong cooperation between the SoC OS and host OS. To the best of our knowledge, no SmartNIC supports CXL yet. Moreover, supporting CCI [5] can mitigate the performance degradation problem described in Advice #1. Furthermore, aligning the SoC PCIe MTU with the host is likely to improve PCIe performance when transferring large payloads. Finally, we encourage vendors to disclose more hardware details of SmartNICs to help explain and confirm the findings of our study.

## 7 Other Related Work

**SmartNIC offloading.** Offloading computation to SmartNICs has attracted significant attention in academia and industry. The offloaded tasks include network functions [59, 34, 19], microservices [14, 39], and others [33, 36, 22, 35, 61, 74, 65]. We share the same vision—improving the performance of distributed systems by offloading computation and communication to SmartNICs, but further exploit the multiple communication paths of SmartNICs. In addition, most prior work has focused on leveraging a single path of on-path SmartNICs, so our work can inspire future research on multi-path offloading for on-path SmartNICs.

**RDMA offloading.** Before the emergence of SmartNICs, many distributed systems offloaded remote memory accesses to one-sided RDMA primitives [75, 64, 17, 63, 46, 50, 13, 76, 82, 79, 84, 40, 85, 86]. However, prior work has observed the poor semantics of one-sided RDMA and has therefore leveraged advanced RDMA features (e.g., WAIT [60, 31], DCT [77, 78]) or introduced new RDMA primitives [65, 10]. These efforts are orthogonal to our work and could also benefit from our findings when using SmartNICs in the future.

## 8 Conclusion

Designing high-performance distributed systems with SmartNICs requires an in-depth understanding of low-level hardware details. This paper presents a comprehensive study of off-path SmartNIC. Unlike prior work, we explore how the SmartNIC architecture and the heterogeneity of its computation units can impact communication performance related to its components. We further propose the first optimization guideline for designers to smartly exploit multiple communication paths of SmartNICs for distributed systems, and demonstrate our guideline by improving two distributed systems. In general, our study can help system designers develop a better understanding of SmartNICs before applying them in high-performance distributed systems.

## Acknowledgment

We sincerely thank our shepherd, Rachit Agarwal, and the anonymous reviewers for their comments and suggestions to improve the paper. We also thank Zhuobin Huang for discussing DPDK on SmartNIC, Jun Lu and Dong Du for providing the Bluefield-1 hardware, Dingji Li, Erhu Feng, Jinyu Gu, and Fangming Lu for their valuable feedback on earlier versions of the paper. This work was supported in part by the National Key Research & Development Program of China (No. 2022YFB4500700), the Fundamental Research Funds for the Central Universities, the National Natural Science Foundation of China (No. 62202291, 62272291, 61925206), as well as research grants from Huawei Technologies and Shanghai AI Laboratory. ## Abstract

Today, most communication between the NIC and software involves exchanging fixed-size packet buffers. This packetized interface was designed for an era when NICs implemented few offloads and software implemented the logic for translating between application data and packets. However, both NICs and networked software have evolved: modern NICs implement hardware offloads, e.g., TSO, LRO, and serialization offloads that can more efficiently translate between application data and packets. Furthermore, modern software increasingly batches network I/O to reduce overheads. These changes have led to a mismatch between the packetized interface, which assumes that the NIC and software exchange fixed-size buffers, and the features provided by modern NICs and used by modern software. This incongruence between interface and data adds software complexity and I/O overheads, which in turn limits communication performance.

This paper proposes Ensō, a new streaming NIC-to-software interface designed to better support how NICs and software interact today. At its core, Ensō eschews fixed-size buffers, and instead structures communication as a stream that can be used to send arbitrary data sizes. We show that this change reduces software overheads, reduces PCIe bandwidth requirements, and leads to fewer cache misses. These improvements allow an Ensō-based NIC to saturate a 100 Gbps link with minimum-sized packets (forwarding at 148.8 Mpps) using a single core, improve throughput for high-performance network applications by 1.5–6×, and reduce latency by up to 43%.

## 1 Introduction

Network performance dictates application performance for many of today’s distributed and cloud computing applications [48]. While growing application demands have led to a rapid increase in link speeds from 100 Mbps links [31] in 2003 to 100 Gbps in 2020 [89] and 200 Gbps in 2022 [58], a slowdown in CPU scaling has meant that applications often cannot fully utilize these links. Consequently, recent changes to NICs and networked software have focused on reducing the number of CPU cycles required for communication: NIC offloads allow the NIC to perform common tasks (e.g., segmentation) previously implemented in software; and more efficient network I/O libraries and interfaces, including DPDK and XDP, allow applications to reduce processing in the network stack. We begin with the observation that despite these changes, utilizing 100 Gbps or 400 Gbps links

remains challenging. We demonstrate that this is because of inefficiencies in how software communicates with the NIC. While NICs and the software that communicate with them have themselves changed significantly in the last decade, the NIC-to-software interface has remained unchanged for decades.<sup>1</sup>

Most NICs currently provide an interface where all communication between software and the NIC requires sending (and receiving) a sequence of fixed-size buffers, which we call *packet buffers* in this paper. Packet buffer size is dictated by software, and is usually chosen to be large enough to fit MTU-sized packets, e.g., Linux uses 1536 byte packet buffers (sk\_bufs) and DPDK [19] uses 2kB packet buffers (mbufs) by default. We use the term *packetized NIC interface* to refer to any NIC-to-software interface that uses packet buffers for communication. We observe that two changes in how NICs are used today have led to an impedance mismatch with packetized interfaces.

First, many NIC offloads such as TCP Segmentation Offloading (TSO) [20, 39], Large Receive Offloading (LRO) [14], serialization offloads [44, 71, 86], and transport offloads [3, 14, 27, 77] take inputs (and produce outputs) that can span multiple packets and vary in size. In using these offloads with a packetized interface, software must needlessly split (and recombine) data into multiple packet buffers when communicating with the NIC.

Second, software logic for sending (and receiving) packets uses batches of multiple packets to reduce I/O overheads. In the common case, NICs and software process packets in a batch sequentially. However, packetized interfaces cannot ensure that packets in a batch are in contiguous and sequential memory locations, reducing the effectiveness of several CPU and IO optimizations.

This mismatch between how modern NICs are used and what the packetized interface provides causes three problems that affect application performance:

**Packetized abstraction:** While imposing fixed-size buffers works reasonably well when software *always* needs to exchange MTU-sized packets, it becomes clumsy when used with higher-level abstractions such as application-level messages (e.g., RPCs), bytestreams, or even simpler offloads such as LRO. When using this interface, the NIC (or software) must split messages that are larger than the packet buffer into multiple packet buffers. Applications then need to deal

<sup>1</sup>Osiris [22], published in 1994, describes an interface that is nearly identical to the one adopted by many modern NICs.

with input that is split across multiple packet buffers. Doing so either requires that they first copy data to a separate buffer, or that the application logic itself be designed to deal with packetized data. Indeed, implementing any offload or abstraction that deals with more than a single packet’s worth of data (e.g., transport protocols, such as TCP, that provide a bytestream abstraction) in a NIC that implements the packetized interface requires copying data from packet buffers to a stream. This additional copy can add significant overhead, negating some of the benefits of such offloads [72, 88].

**Poor cache interaction:** Because the packetized interface forces incoming and outgoing data to be scattered across memory, it limits the effectiveness of prefetchers and other CPU optimizations that require predicting the next memory address that software will access—a phenomenon that we refer to as *chaotic memory access*. As we show in §7, chaotic memory accesses can significantly degrade application performance, particularly those that deal with small requests such as object caches [9, 57] and key-value stores [4, 52].

**Metadata overhead:** Since the packetized interface relies on per-packet metadata, it spends a significant portion of the PCIe bandwidth transferring metadata—as much as 39% of the available bandwidth when using small messages. This causes applications that deal with small requests to be bottlenecked by PCIe, which prevents them from scaling beyond a certain number of cores. The use of per-packet metadata also contributes to an increase in the number of memory accesses required for software to send and receive data, further reducing the cycles available for the application. We observed scalability issues due to PCIe bottleneck in our implementation of Google’s Maglev Load Balancer [23].

In this paper, we propose Ensō, a new interface for NIC-application communication that breaks from the lower-level concept of packets. Instead, Ensō provides a streaming abstraction that the NIC and applications can use to communicate arbitrary-sized chunks of data. Doing so not only frees the NIC and application to use arbitrary data formats that are more suitable for the functionality implemented by each one but also moves away from the performance issues present in the packetized interface. Because Ensō makes no assumption about the data format itself, it can be repurposed depending on the application and the offloads enabled on the NIC. For instance, if the NIC is only responsible for multiplexing/demultiplexing, it can use Ensō to deliver raw packets; if the NIC is also aware of application-level messages, it can use Ensō to deliver entire messages and RPCs to the application; and if the NIC implements a transport protocol, such as TCP, it can use Ensō to communicate with the application using bytestreams.

To provide a streaming abstraction, Ensō replaces ring buffers containing *descriptors*, used by the current NIC interface, with a ring buffer containing *data*. The NIC and the software communicate by appending data to these ring

buffers. Ensō treats buffers as *opaque* data, and does not impose any requirements on their content, structure or size, thus allowing them to be used to transfer arbitrary data, whose size can be as large as the ring buffer itself. Ensō also significantly reduces PCIe bandwidth overhead due to metadata, because it is able to aggregate notifications for multiple chunks of data written to the same buffer. Finally, it enables better use of the CPU prefetcher to mask memory latency, thus further improving application performance.

Although the insight behind this design is simple, it is challenging to implement in practice. For example, CPU-NIC synchronization can easily lead to poor cache performance: any approach where the NIC and CPU poll for changes at a particular memory location will lead to frequent cache invalidation. Ensō avoids this obstacle by relying on explicit notifications for CPU-NIC synchronization. Unfortunately, explicit notifications require additional metadata to be sent over the CPU-NIC interconnect, which can negate any benefits for interconnect bandwidth utilization. Ensō mitigates this overhead by sending notifications *reactively*. We discuss our synchronization strategy in detail, as well as other challenges to the Ensō design in §4.

To understand its performance, we fully implement Ensō using an FPGA-based SmartNIC. We describe our hardware and software implementations in §5 and how Ensō can be used depending on the functionality offered by the NIC in §6. In §7 we present our evaluation of Ensō, including its use in four applications: the Maglev load balancer [23], a network telemetry application based on NitroSketch [54], the MICA key-value store [52], and a log monitor inspired by AWS CloudWatch Logs [6]. We also implemented a software packet generator that we use in most of the experiments.<sup>2</sup> We observe speedups of up to 6× relative to a DPDK implementation for Maglev, and up to 1.47× for MICA with no hardware offloads.

Finally, while Ensō is optimized for applications that process data in order, we show that Ensō also outperforms the existing packetized interface when used by applications that process packets out of order (e.g., virtual switches), despite requiring an additional memory copy (§7.2.2).

Ensō is fully open source, with our hardware and software implementations available at <https://enso.cs.cmu.edu/>.

## 2 Background and Motivation

The way software (either the kernel or applications using a kernel-bypass API) and the NIC exchange data is defined by the interface that the NIC hardware exposes. Today, most NICs expose a *packetized* NIC interface. This includes NICs from several companies including Amazon [2], Broadcom [12], Intel [39], Marvell [56], and others. Indeed, prior

<sup>2</sup>Developing this software packet generator was a necessary first step in evaluating Ensō because no existing software packet generators could scale to the link rates we needed to stress test Ensō!

**Figure 1:** Data structures used to receive packets in a packetized NIC interface. Each packet is placed in a separate buffer that can be arranged arbitrarily in memory.

work [68] found that of the 44 NIC drivers included in DPDK, 40 use this interface. Due to its ubiquity, the packetized NIC interface has dictated the API provided by nearly all high-performance network libraries, including `io_uring` [15], DPDK [19] and `netmap` [73]. In this section, we describe the packetized NIC interface and highlight some of the issues that it brings to high-performance applications.

## 2.1 Packetized NIC Interface

A core design choice in the packetized NIC interface is to place every packet in a dedicated packet buffer. The NIC and the software communicate by exchanging packet *descriptors*. Descriptors hold metadata, including packet size, what processing the NIC should perform (e.g., update the checksum or segment the packet), a flag bit, and a pointer to a separate *packet buffer* which holds the actual packet data. Most packet processing software pre-allocate a fixed number of buffers for packets; new packets (either generated by an application or incoming from the network) are assigned to the next available buffer in the pool, which may not reside in memory anywhere near the preceding or following packet. Because software does not know the size of incoming packets beforehand, buffers are often sized so that they can accommodate MTU-sized packets (e.g., 1536B in Linux and 2kB in DPDK).

Figure 1 shows an example of a packetized NIC interface being used to receive four packets from a particular hardware queue on the NIC. The NIC queue is associated with a set of NIC registers that can be used to control a receive (RX) descriptor ring buffer and a transmit (TX) descriptor ring buffer. Before being able to receive packets, the software informs the NIC of the addresses of multiple available buffers in its pool by enqueueing descriptors pointing to each one in the RX descriptor ring buffer. The NIC can then use DMA to write the incoming packet data into the next available packet buffer and enqueue updated descriptors containing metadata such as the packet size. Importantly, the NIC also sets a ‘flag’ bit in the descriptor to signal to the software that packets have arrived for this buffer. Observing a notification bit for the descriptor under the head pointer, the software can then increment the head pointer.

A similar process takes place for transmission: the sending software assembles a set of descriptors for packet buffers that are ready to be transmitted and copies the descriptors—but not the packets themselves—into the TX ring buffer; the flag bit in the descriptor is now used to signal that the NIC has

transmitted (rather than received) a packet.

One of the major benefits of dedicating buffers for each packet is that multiplexing/demultiplexing can be done efficiently in software. If the software transmitting packets is the kernel, this might mean associating each descriptor/packet pair with an appropriate socket; if the software in use is a software switch [32, 67] this might mean steering the right packet to an appropriate virtual machine. Either way, the cleverness of the packetized NIC interface in using dedicated packet buffers shines here: rather than copying individual packets in the process of sorting through inbound packets, the switching logic can deliver packet pointers to the appropriate endpoints. These packets can then be processed and freed in arbitrary order.

The usage model for a modern high-performance software stack, however, looks very different. Instead of *one* software entity (e.g., kernel, software switch) mediating access to the NIC, there may be many threads or processes with *direct NIC access* (i.e., kernel bypass). High-performance NIC ASICs expose *multiple hardware queues* (as many as thousands [39]) so that each thread or process can transmit and receive data directly to the NIC without coordination between them. The NIC then takes on all of the responsibilities of demultiplexing, using, e.g., RSS [82], Intel’s Flow Director [39], or (for a very rich switching model) Microsoft’s AccelNet [28]. In this setting, the multiplexing/demultiplexing capabilities of the packetized NIC interface offer no additional value.

## 2.2 Issues with a Packetized Interface

While many high-performance applications today gain little from a packetized interface, they still need to pay for the overheads accompanying it. Shoehorning data communication between the NIC and applications into fixed-sized chunks leads to inefficient use of CPU caches and PCIe bandwidth for small requests, as well as additional data copies due to fragmentation for applications that rely on large messages or bytestreams.

In this section, we conduct microbenchmarks that isolate these issues, and in §7, we also show the impact that these issues have on real applications.

**Chaotic Memory Access:** We experiment with a simple DPDK-based ping/pong program (a description of our testbed is in §7) which receives a packet, increments a byte in the packet payload, and re-transmits it. For this program, we observed maximum throughput of 40 Gbps using a 100 Gb NIC (Intel E810) and a single 3.1 GHz CPU core. When we conduct a top-down analysis [43], we see that the application is backend-bound, primarily due to L1 and L2 cache misses. Figure 2a shows around 6% miss ratio for the L1d and a 55% miss ratio for the L2 cache. This high cache miss ratio is a direct consequence of using per-packet buffers in the packetized NIC interface. First, because *packet buffers themselves are scattered in memory, reads and writes to packet data evade*

(a) Miss ratio for L1d and L2 caches. (b) PCIe bandwidth utilization. Up to 39% of the read bandwidth is consumed with metadata.

**Figure 2:** PCIe bandwidth and cache misses for an application forwarding small packets with a packetized NIC interface (E810).

any potential benefit from shared cache lines or prefetching.<sup>3</sup> Applications like key-value stores [4, 52] or packet processors [18] exhibit very high *spatio-temporal* locality in their data access: they are designed to run to completion (i.e., they continue working on a packet or batch until the work for that item is completed, leading to repeated accesses to the same data), and they operate over incoming packets or batches in the order in which they arrive (i.e., the current item being processed serves as an excellent predictor of the next one). However, this structure is not realized in the memory layout of packetized buffers, and hence to any cache optimizations, reads and writes appear unpredictable. Second, because every packet is paired with a descriptor, the total amount of memory required to store all of the data required for I/O increases, exacerbating last-level cache contention simply because more data needs to be accessed. Indeed, prior work [55, 81] has repeatedly demonstrated that the size of the working set for packet processing applications often outgrows the amount of cache space dedicated to DDIO [35], negating the benefits of this hardware optimization to bring I/O data directly into the cache. As we discuss in detail in §7.2.3, using a different NIC interface that facilitates sequential memory accesses can drop the miss ratio from 6% to 0.2% for the L1d cache, and from 55% to 9% for the L2 cache.

**Metadata Bandwidth Overhead:** We observe that the packetized NIC interface requires the CPU and the NIC to exchange *both* descriptors and packet buffers. This leads to the second problem with the packetized interface: *up to 39% of the CPU to NIC interconnect bandwidth is spent transferring descriptors* (Figure 2b). While NIC-CPU interconnect line rates are typically higher than network line rates, the gap between them is relatively narrow. This is particularly problematic for small transfers as the PCIe theoretical limit drops to only 85 Gbps with 64-byte transfers [62]. We also expect this gap to remain small in the future as a state-of-the-art next generation server with a 400 Gbps Ethernet connection and 512 Gbps of PCIe 5.0 bandwidth would still bottleneck with 39% of bandwidth wasted on metadata. This observation complements recent studies that also point to the PCIe as a source of congestion for transport protocols [1].

<sup>3</sup>We note here that the aforementioned performance penalty arises in spite of the fact that DPDK performs mbuf-level software prefetching.

**Figure 3:** Steps to receive batches of messages in two Ensō Pipes.

**In summary:** By pairing every packet with a separate descriptor, the packetized NIC interface was well designed for a previous generation of high-throughput networked applications which needed to implement multiplexing in software. However, for today’s high-performance applications, it introduces unnecessary performance overheads.

### 3 Ensō Overview

Ensō is a new streaming interface for NIC-application communication. Ensō’s design has three primary goals: (1) *flexibility*, allowing it to be used for different classes of offloads operating at different network layers and with different data sizes; (2) *low software overhead*, reducing the number of cycles that applications need to spend on communication; and (3) *hardware simplicity*, enabling practical implementations on commodity NICs.

Ensō is designed around the *Ensō Pipe*, a new buffer abstraction that allows applications and the NIC to exchange arbitrary chunks of data as if reading and writing to an unbounded memory buffer. Different from the ring buffers employed by the packetized interface (which hold descriptors to scattered packet buffers), an Ensō Pipe is implemented as a *data ring buffer* that contains the actual packet data.

**High-level operation:** In Figure 3 we show how an application, with two Ensō Pipes, receives messages. Initially, the Ensō Pipes are empty, and the HeadSW and TailNIC point to the same location in the buffer ①. When the NIC receives messages, it uses DMA to enqueue them in contiguous memory owned by the Ensō Pipes ②. In the figure, the NIC enqueues two messages in Ensō Pipe A’s memory, and three in Ensō Pipe B’s memory. The NIC informs the software about this by also enqueueing two notifications (one for each Ensō Pipe) in the notification buffer. The software uses these notifications to advance TailNIC and process the messages. Once the messages have been processed, the software writes to a Memory-Mapped I/O (MMIO) register (advancing HeadSW) to notify the NIC—allowing the memory to be reused by later messages ③. Sending messages is symmetric, except for the last step: the NIC notifies the software that messages have been transmitted by overwriting the notification that the CPU used to inform the NIC that a message was available to be transmitted.

**Ensō Pipe’s flexibility:** Although Figure 3 shows the steps to send *messages*, because Ensō Pipes are opaque, they can be used to transmit arbitrary chunks of data. These can be raw packets, messages composed of multiple MTU-sized packets, or even an unbounded bytestream. The format of the data is dictated by the application and the offloads running on the NIC. Moreover, Ensō Pipes’ opaqueness means that they can be mapped to any pinned memory within the application’s memory space. Thus, by mapping both the RX and TX Ensō Pipes to the same region, network functions and other forwarding applications can avoid copying packets. In our evaluation (§7) we use this approach when implementing Maglev and a Network Telemetry application.

**Performance advantages of an Ensō Pipe:** The fact that data can be placed back-to-back inside an Ensō Pipe addresses both of the performance challenges we listed previously: First, Ensō Pipes allow applications to read and write I/O data *sequentially*, thus avoiding chaotic memory accesses. Second, as shown in Figure 3, inlining data in an Ensō Pipe removes the need for per-packet descriptors, thus reducing the amount of metadata exchanged over the PCIe bus, and reducing cycles spent managing (i.e., allocating and freeing) packet buffers.

**Challenges:** Although implementing a ring buffer for data transfer is, on its own, a simple idea, coordinating the notifications between the CPU and the NIC to update head and tail pointers turns out to be challenging.

*Efficient coordination:* The packetized interface coordinates incoming and outgoing packets by ‘piggybacking’ notifications in the descriptor queue itself. Each descriptor includes a ‘flag bit’ that can be used to signal when the descriptor is valid. Software polls the next descriptor’s flag bit to check if a new packet arrived. We cannot use the same strategy for Ensō Pipes as they do not assume a format for the data in the buffer, and hence cannot embed control signals in it.

In §4.1, we discuss how naïve approaches to notification can stress worst-case performance of MMIO and DMA. In particular, concurrent accesses to the same memory address can create cache contention between the CPU and the NIC. Ensō uses dedicated *notification buffers* to synchronize updates to head and tail pointers; when combined with batching and multiqueue processing, the notification buffer approach reduces the threat of cache contention.

*Notification pacing:* Ensō Pipes are designed so that notifications for multiple packets can be combined, reducing the amount of metadata transferred between the CPU and the NIC. However, it is still important to decide *when* to send notifications: when sent too frequently they waste PCIe bandwidth and add software overheads, but if sent too infrequently the core might be idle waiting for notification, thus reducing throughput. Ensō includes two mechanisms, *reactive notifications* and *notification prefetching* (§4.2), that

control when notifications are sent. These mechanisms are naturally adaptive, i.e., they minimize the number of notifications sent without limiting throughput, and can be implemented without adding hardware complexity.

*Low hardware complexity and state:* Because the design of Ensō involves both hardware and software, we must be careful to not pay for software simplicity with hardware complexity. Ensō favors coordination mechanisms that require little NIC state. We aim for a design that is simple and easily parallelized. We present Ensō’s hardware design in §5.

**Target applications:** Ensō implements a streaming interface that is optimized for cases where software processes received data in order. Our evaluation (§7) shows that this covers a wide range of network-intensive applications.

One might expect that the resulting design is ill-suited for applications that need to multiplex and demultiplex packets (e.g., virtual switches like Open vSwitch [67] and BESS [32]), as such applications require additional copies with Ensō.<sup>4</sup> However, perhaps surprisingly, Ensō outperforms the packetized interface *even when it requires such additional copies*. As we show in §7.2.2, when comparing the performance of an application that uses Ensō and copies each packet, to a similar DPDK-based application that does not copy packets, using a CAIDA trace [13] (average packet size of 462 B), we find that Ensō’s throughput is still 28% higher than DPDK’s (92.6 Gbps vs. 72.6 Gbps). We discuss how Ensō can be used depending on the applications and the functionality offered by the NIC in §6.

## 4 Efficient Notifications

The key challenges in Ensō arise from efficiently coordinating Ensō Pipes between the CPU and the NIC. In this section, we describe how Ensō efficiently coordinates pipes using notifications (§4.1) and how it paces such notifications (§4.2).

### 4.1 Efficient Ensō Pipe Coordination

Recall from Figure 3 that the software and the NIC coordinate access to RX Ensō Pipes using  $\text{Head}_{\text{SW}}$  and  $\text{Tail}_{\text{NIC}}$  and to TX Ensō Pipes using  $\text{Head}_{\text{NIC}}$  and  $\text{Tail}_{\text{SW}}$ . How should software and the NIC communicate pointer updates?

In the descriptor ring buffers employed by the packetized NIC interface, software communicates pointer updates to the NIC using MMIO writes, and the NIC communicates pointer updates via inline signaling in the descriptor buffer itself [25, 39], avoiding the overheads of MMIO reads. Because the descriptor’s format is defined by the NIC, the NIC

<sup>4</sup>Note that this overhead only affects applications that multiplex/demultiplex packets, and does not apply to software, e.g., TCP stacks, that processes packet data but might need to reorder packets. This is because reordering packet data (rather than whole packets) requires a memory copy when using either interface.

**Figure 4:** Notification buffer being used to notify the arrival of three chunks of data in an RX Ensō Pipe. Notifications contain the latest Tail<sub>NIC</sub> for a given Ensō Pipe as well as a flag signal.

can dedicate a ‘flag signal’ in every descriptor to signal that the descriptor is valid. Software can then poll the next descriptor until its flag becomes valid. This way, there is no need for the NIC to explicitly tell software of pointer updates. Unfortunately, we cannot use this approach for Ensō. While Ensō Pipes can still use MMIO writes for pointer updates from software, we cannot embed inline signaling in the Ensō Pipe itself since we do not impose any structure on the data.

We considered several design options to communicate pointer updates. We focus on one illuminating rejected design here: sharing an address in main memory between the NIC and software. With each Ensō Pipe, we might have a dedicated address in memory where the NIC writes the latest Tail<sub>NIC</sub>. The software can then poll this address to determine the latest value. Unfortunately, this approach leads to contention because every time the NIC writes to memory, the cache entry on the CPU is invalidated. If software continues to poll the same cache line, the resulting contention reduces throughput by orders of magnitude: we measured a throughput below 5 Gbps when using small transfers with this approach. We discuss other rejected approaches in Appendix A.

#### 4.1.1 Notification Buffer

Ensō uses a *notification buffer* to communicate pointer updates. Although the structure of the notification buffer on its own does not solve the cache contention challenge, when combined with *batched notifications* and when it is used to aggregate notification updates to/from *multiple* Ensō Pipes, this approach prevents the CPU from busy waiting on the shared cache line and hence avoids contention-induced slowdowns.

Figure 4 shows an RX Ensō Pipe with its corresponding notification buffer. It shows how a single notification indicates the presence of multiple sequential chunks of data at the same time; we discuss how notifications are ‘batched’ or coalesced in §4.2. Notifications contain the latest Tail<sub>NIC</sub> for a given RX Ensō Pipe as well as a flag signal that software can use to check if the next notification is ready to be consumed. As is done typically with descriptor ring buffers, software advances the NotificationHead<sub>SW</sub> using an MMIO write after consuming a notification. Like an RX Ensō Pipe, a TX Ensō Pipe also uses a separate notification buffer to synchronize pointer updates. But software enqueues new notifications when it wants to transmit a chunk of data and the NIC overwrites the transmission notification with a completion noti-

fication once it is done transmitting the corresponding batch. Completions flip a flag signal, so that software can check if the following cache line corresponds to a completion or a pending TX notification.

#### 4.1.2 Multiplexing and Scaling

**Within a single thread:** To let a single thread efficiently access multiple Ensō Pipes, we associate multiple Ensō Pipes with the same notification buffer. To accomplish this, notifications include an *Ensō Pipe ID* alongside the Tail<sub>NIC</sub> and the flag signal that we discussed before. As a result, software can probe a *single* notification buffer to retrieve updates from *multiple* Ensō Pipes. This avoids the known scalability issues from needing to poll multiple queues [59, 76].

**Among multiple threads:** To let multiple threads send and receive data independently, Ensō supports multiple notification buffers. Each thread can use a *dedicated* notification buffer, avoiding costly synchronization primitives. When setting up a new Ensō Pipe, software tells the NIC which notification buffer is associated with it. Therefore, the NIC knows to which notification buffer to send a notification.

**Among multiple applications:** In addition to using independent notification buffers, Ensō ensures that applications only have access to their own subset of Ensō Pipes and notification buffers. Each queue’s MMIO pointer register pair is kept in its own dedicated page-aligned block of memory [22]. This lets the kernel map the pointer registers at a per-queue granularity to the address space of the application that requested it.

#### 4.1.3 Notifications: Contention and Overhead

Allowing multiple Ensō Pipes to share the same notification queue (§4.1.2), and having notifications arrive only for larger batches of data (§4.2) naturally prevents contention by keeping the NIC ‘ahead’ of the CPU in updating the notification buffer, and also reduces the PCIe overhead of communicating these notifications. As the CPU reads in data for one Ensō Pipe, the NIC is writing new entries for subsequent Ensō Pipes. Because the CPU is processing larger batches of data, it is busier for longer before it needs to check the notification buffer. Hence, as line rates go up, the two are unlikely to be accessing the same cache line simultaneously.

### 4.2 Pacing Notifications

As mentioned above, Ensō batches notifications aiming to reduce metadata bandwidth consumption and to keep CPUs busy processing data, rather than waiting for notifications. Using the wrong batch size, however, is problematic: a system that uses batch sizes that are too small would unnecessarily transmit extra metadata, and a system that uses batch

```

func onPktArrival()      func onRxUpdate(HeadSW)
if status = 0 then      if HeadSW = TailNIC then
    notify(TailNIC)      status ← 0
    status ← 1           else
                        notify(TailNIC)

```

**Figure 5:** Reactive notification mechanism for an Ensō Pipe. It only sends notifications when new data arrives and status = 0, or if software updates Head<sub>SW</sub> and it is different from Tail<sub>NIC</sub>.

sizes that are too large might unnecessarily inflate latency. Ideally, the NIC could keep track of how frequently software is consuming notifications and try to send a notification right before software needs the next one, with all the data that have arrived since the last software read. Ensō approximates this ideal approach but without the impossibility of perfectly predicting when the next read is coming.

Instead of trying to predict when to send the next notification, Ensō lets software dictate the pace of notifications by sending notifications *reactively*. It leverages the fact that the NIC is already aware of when the software is consuming data, as the NIC is notified whenever software updates Head<sub>SW</sub> through MMIO writes. Therefore, the NIC can send notifications in response to these updates. Specifically, we allow the actual NIC tail pointer (Tail<sub>NIC</sub>) to diverge temporarily from what is observed from software via the notification buffer. Ensō suppresses updates to Tail<sub>NIC</sub> until the NIC sees an update to Head<sub>SW</sub>. Our implementation uses a single status bit for every Ensō Pipe, initialized to ‘0’, which indicates if the buffer has data.

**Operation:** Figure 5 summarizes the reactive notification mechanism. Whenever data arrive at an RX Ensō Pipe (onPktArrival), we check the status bit, only sending a notification if status = 0 (indicating that the buffer is empty). We also potentially send notifications whenever software updates Head<sub>SW</sub> (onRxUpdate). If the new Head<sub>SW</sub> is the same as Tail<sub>NIC</sub>, it means that the buffer is now empty and we can reset the status back to ‘0’ without sending a new notification. Otherwise, it indicates that software is unaware of some of the latest data in the buffer, which triggers a new notification.

**Discussion:** Reactive notifications cause the notification rate to naturally adapt to the rate at which software is consuming data, as well as how fast incoming data is arriving. When software is slow to consume data from a particular Ensō Pipe, bytes accumulate and the NIC sends fewer notifications for that Ensō Pipe. When software is fast to consume data, it advances the Head<sub>SW</sub> pointer more often, causing the NIC to send frequent notifications.

Reactive notifications ensure that every piece of data is notified, but as we will see in §7.2.5, they can impose a small latency overhead. This overhead occurs if packet arrivals are known to the NIC but have not yet been communicated in the notification buffer. In this case, when Head<sub>SW</sub> reaches Tail<sub>NIC</sub>, software has to wait for a PCIe RTT before it is notified of the waiting packets. While an extra PCIe RTT

is unlikely to be an issue for Internet-facing applications, it might be an issue for some latency-sensitive applications [7].

**Notification prefetching:** To improve latency for latency-sensitive applications, Ensō also implements a notification prefetching mechanism. Notification prefetching allows software to explicitly request a new notification to the NIC. Applications can use notification prefetching either explicitly, by calling a function to prefetch notifications for a given Ensō Pipe, or transparently, by compiling the Ensō library in low-latency mode. When compiled in low-latency mode, the library always prefetches notifications for the next Ensō Pipe before returning data for the current one. We evaluate the impact of using notification prefetching in §7.2.5.

## 5 Ensō Implementation

Our Ensō implementation consists of three pieces: a userspace library, a kernel module, and a NIC hardware that implements Ensō. We implement the library and kernel module on Linux in about 9k lines of C and C++17. Our hardware implementation uses about 10k lines of SystemVerilog, excluding tests and auto-generated IPs. Our hardware implementation targets an FPGA SmartNIC but the same design could also be implemented in an ASIC.

### 5.1 Software Implementation

Applications use a library call to request notification buffers and Ensō Pipes. Typically, applications will request a notification buffer for each thread but may use multiple Ensō Pipes per thread, depending on their needs. The library sends requests for new Ensō Pipes and notification buffers to the kernel, which checks permissions, allocates them on the NIC, and then maps them into application space. Ensō Pipes are typically allocated in pairs of RX and TX Ensō Pipe but may also be allocated as unified RX/TX Ensō Pipes. Unified RX/TX Ensō Pipes map the RX and TX buffer to the same memory region, which is useful for applications that modify data in place and send them back, e.g., network functions. In contrast, separate Ensō Pipes map the RX and TX buffers to the different memory regions and are useful for typical request-response applications.

To ensure a consistent abstraction of unbounded Ensō Pipes we must also deal with corner cases that arise when data wrap around the buffer limit. To prevent breaking received data that wrap around, we map the same Ensō Pipe’s physical address twice in the application’s virtual memory address space. This means that, to the application, the buffer appears to be twice its actual size, with the second half always mirroring the first one. The application can then consume up to the full size of the buffer of data at once, regardless of where in the buffer the current Head<sub>SW</sub> is. To transmit data that wrap around the buffer limit, the library checks if

Figure 6: NIC RX Datapath.

the transfer goes around the Ensō Pipe boundary and automatically partitions it into several transfers, each of which is smaller than the overall buffer size.

## 5.2 Hardware Implementation

We now describe key RX and TX hardware modules.

### 5.2.1 RX Datapath

Figure 6 illustrates the RX datapath. It receives as input data and metadata, which includes the Ensō Pipe ID and the size of the corresponding data that is being enqueued. Metadata is handled separately from the data, which allows for smaller queues between modules. The RX datapath is composed of the following modules:

**RX Ensō Pipe Managers:** The Ensō Pipe managers are responsible for keeping Ensō Pipe state such as the buffer’s physical address,  $Head_{SW}$ ,  $Tail_{NIC}$ , notification buffer ID, and notification status bit. When metadata arrive for Ensō Pipe  $i$ , the manager checks for sufficient space in  $i$  and advances  $i$ ’s  $Tail_{NIC}$ . The manager also determines whether to trigger a notification according to the reactive notification strategy (§4.2). To trigger a notification, the manager includes the notification buffer ID and sets a bit in the metadata that is sent to the Notification Buffer Manager.

We use multiple Ensō Pipe Managers for two reasons. First, it enables flow-level parallelism. Each manager requires two cycles to process each metadata, achieving a request rate of 125 Mpps at a 250 MHz clock. To achieve 100 Gbps line rate (148.8 Mpps) we thus need at least two managers. Second, multiple managers enable scaling to high Ensō Pipe counts. We split the state for different Ensō Pipes among different managers, allowing the logic to be closer to the memory that it needs to access. We configure the number of Ensō Pipe Managers at synthesis time with a default of 16, which allows the design to meet timing for up to 16k Ensō Pipes.

**RX Notification Buffer Manager:** This module issues notifications when needed. It spends one cycle for every request and an extra cycle for those that require a notification. If we can suppress notifications for at least 20% of requests, we only need a single notification manager at a 250 MHz clock. A single notification manager is also sufficient since we use fewer notification buffers than Ensō Pipes, e.g., one notification buffer per CPU core. Our implementation defaults to 128 notification buffers but also meets timing with 1024.

Figure 7: NIC TX Datapath.

**DMA Engine:** This module uses DMA to write data and notifications to the correct address in host memory based on the metadata computed by the upstream modules.

### 5.2.2 TX Datapath and Configuration Path

The TX datapath (Figure 7) is composed of:

**TX Notification Buffer Manager:** This module keeps state for all TX notification buffers. When software enqueues a new TX notification and advances  $NotificationTail_{SW}$  using an MMIO write, the manager requests a DMA read to fetch the notification from memory. The read request is sent to the DMA Engine, which enqueues the DMA read response to the Notification FIFO. The manager can then consume the notifications, allowing it to request DMA reads for the actual data inside an Ensō Pipe. It also sends information about each data request to the Completion Monitor module.

**Completion Monitor:** When the data requested by the TX Notification Buffer Manager arrive, the DMA Engine enqueues them to the Data FIFO. The Completion Monitor consumes the data and keeps track of the number of bytes pending in each request using information that it received from the TX Notification Buffer Manager. When the request completes, the Completion Monitor sends a TX completion notification to the DMA Engine that writes it to host memory. It can then output the data and the metadata, containing the Ensō Pipe ID and size, to downstream modules on the NIC.

**Configurator:** Configuration notifications are enqueued to the Configuration FIFO instead of the Notification FIFO. These are consumed by the Configurator, which directs the configuration to the appropriate module on the NIC. For instance, when the kernel sets a new Ensō Pipe, it inserts an entry in the NIC Flow Table to direct a set of packets to it.

## 6 Using Ensō

Ensō provides a zero-copy streaming abstraction that the NIC and applications can use to exchange data. Thus far, we have shown how this abstraction can be efficiently *implemented*. We now discuss how Ensō should be *used*.

How one uses Ensō depends on how features are split between hardware and software. We consider three settings: (1) Traditional NICs which implement simple offloads, such as checksum and RSS [82], and rely on software implementation for the rest. These can use Ensō Pipes to deliver raw

packets to/from a network stack implemented in software. (2) NICs that implement transport offloads [10, 14, 77, 78] in hardware. These can deliver application-level messages or reassembled bytestreams through the Ensō Pipes. And finally, (3) NICs that implement application logic [41, 49], which can use Ensō Pipes to exchange application data. We elaborate on each of these settings below.

**Traditional NICs:** For traditional NICs that perform simple offloads such as checksum and segmentation, using Ensō is not significantly different than using a packetized interface. In both cases, the network stack is implemented in software and only needs to be changed to use Ensō Pipes. Ensō is designed to support several Ensō Pipes, and for most applications this change does not induce any additional software overheads. Furthermore, high-performance packet processing applications that process packets in order, as is the case for most network functions [68] and applications that use UDP, can consume and transmit raw packets through an Ensō Pipe without copies.

However, applications such as virtual switches [32, 67], that multiplex and demultiplex packets (but do not perform reassembly or other functions that require re-ordering packets, where both interfaces require copies), need to perform an additional copy when forwarding packets to their destination. As we show in §7.2.2, Ensō’s performance advantages can outweigh the cost of copies even for such applications.

**NICs with transport offload:** NICs that implement message-based transports (e.g., SCTP, Homa [60]) or streaming-based transports (e.g., TCP) may also choose to use Ensō Pipes to deliver messages or reassembled bytestreams directly to the application without copies.

**NICs with application logic:** NICs that implement application-layer protocols or include part of the application logic may use Ensō Pipes to exchange application-level messages with applications. For instance, a NIC that is aware of both TCP and HTTP may deliver incoming HTTP requests back to back to a web server, effectively converting the application to a run-to-completion model.

## 7 Evaluation

We now evaluate our design decisions using microbenchmarks, and then use four real-world applications to show how Ensō improves end-to-end performance.

### 7.1 Setup and Methodology

**Device Under Test (DUT):** We synthesize and run the Ensō NIC on an Intel Stratix 10 MX FPGA NIC [42] with 100 Gb Ethernet and a PCIe 3.0 x16 interface. Most of the NIC design runs at 250 MHz. Our baseline uses an Intel E810 NIC [40] with 100 Gb Ethernet and a PCIe 4.0 x16 interface, and uses

**Figure 8:** Raw packet rate. Ensō is bottlenecked by Ethernet while the E810 does not scale beyond two cores. The dashed line represents the 100 Gb Ethernet limit.

DPDK to minimize software overheads. All our experiments are run on a server with an Intel Core i9-9960X CPU [38] with 16 cores running at 3.1 GHz base frequency, 22 MB of LLC, and PCIe 3.0. We disable dynamic frequency scaling, hyper-threading, power management features (C-states and P-states), and isolate CPU cores from the scheduler.

**Packet generator:** The packet generator machine is equipped with an Intel Core i7-7820X CPU [37] with 8 cores running at 3.6 GHz base frequency, 11 MB of LLC, and PCIe 3.0. It includes another Stratix 10 MX FPGA connected back to back to the E810 and the FPGA on the DUT machine.

We found that existing high-performance packet generators such as DPDK Pktgen [85] and Moongen [24] are unable to keep up with Ensō’s packet rate because their performance is limited by the packetized NIC interface. We thus implement EnsōGen, a packet generator based on Ensō. EnsōGen generates packets from a pcap file, and can send and receive arbitrary-sized packets at 100 Gbps line rate using a *single* CPU core. We describe EnsōGen in more detail in Appendix B. We use EnsōGen in all experiments except for MICA, where we send requests from a MICA client (§7.3.3).

**Methodology:** We measure zero-loss throughput as defined in RFC 2544 [11, 61] with a precision of 0.1 Gbps. We report median throughput and error bars for one standard deviation from ten repetitions. We measure latency by implementing hardware timestamping on the FPGA, which achieves 5 ns precision for packet RTTs. EnsōGen keeps a histogram with the RTT of every received packet, which we use to compute median and 99<sup>th</sup> percentile latencies. PCIe bandwidth measurements use PCM [17] and we obtain other CPU counters using perf [65]. To evaluate MICA, we use the same methodology as the original paper [52] for consistency.

### 7.2 Microbenchmarks

We start by using microbenchmarks to evaluate Ensō’s performance and the design decisions we made.

#### 7.2.1 Packet Rate

We start by measuring how fast Ensō can process packets. We compare the performance of an Ensō-based echo server to that of a DPDK-based echo server. On receiving a packet,

**Figure 9:** Throughput when forwarding packets between two queues. Ensō outperforms zero-copy E810 even when it needs to copy packets.

both versions increment a value in each packet’s payload and then send the packet back out through the same interface. We increment the payload value to ensure that all packets are brought into the processing core’s L1d cache. For the Ensō echo server, we use an RX/TX Ensō Pipe, which lets it echo packets without copies.

Figure 8 compares the packet rate for Ensō and DPDK for different numbers of cores. Even with a single core, Ensō is bottlenecked by Ethernet, achieving 148.8 Mpps. In contrast, the E810 with DPDK achieves 59 Mpps with a single core and does not scale beyond two cores, where it peaks at 88 Mpps. Beyond two cores, the experiments with the E810 are bottlenecked by PCIe bandwidth, which is insufficient for transferring packet data and descriptor metadata (§7.2.4). As a result, the number of packets dropped by the E810 NIC increases as we increase the number of cores, and the zero-loss throughput *decreases* beyond two cores.

### 7.2.2 Packet Forwarding with Copies

As we discussed in §3, Ensō’s streaming interface targets applications that process received data in order. With Ensō, applications that multiplex and demultiplex data, such as virtual switches [32, 67], need to copy packets to forward them to their destination. However, as we will see next, Ensō outperforms the E810 even in this scenario.

To quantify the overhead of multiplexing and demultiplexing data, we implement a simple packet forwarding application that swaps MAC addresses and copies incoming packets to a different TX Ensō Pipe. We compare this application against an equivalent zero-copy DPDK implementation. Figure 9 shows the throughput when forwarding packets of different sizes using a single CPU core. Packet copies add overhead to Ensō, which can no longer forward 64-byte packets at 100 Gbps (148.8 Mpps). However, Ensō’s throughput with 64-byte packets (91.7 Gbps) is still more than 2× that achieved by the E810 with DPDK *without* copies (39.6 Gbps). For other packet sizes, Ensō achieves line rate. We also evaluate the throughput for the same application when sending packets from a CAIDA trace [13]. For this trace Ensō’s throughput is 92.6 Gbps, compared to 72.6 Gbps for the E810 with DPDK without copies.

This result came as a surprise to us as our goal with Ensō was never to target multiplexing/demultiplexing in software.

	Ensō	Chaotic Ensō	E810
Throughput	100.0 Gbps	38.0 Gbps	41.1 Gbps
Rate	148.8 Mpps	56.5 Mpps	61.1 Mpps
L1d miss/total	22.8M/11,597M (0.2%)	557M/3,949M (14%)	1,357M/21,339M (6%)
L2 miss/total	2.1M/22.8M (9%)	382M/558M (68%)	747M/1,357M (55%)
LLC miss/total	541/2.1M (0.03%)	348k/382M (0.09%)	9,086/747M (0.001%)

**Table 1:** Effect of chaotic memory accesses on throughput and cache misses. Results are the average of 10 runs, each lasting 10 s.

It also puts into question the usefulness of a packetized interface, as its overheads can be greater than those imposed by packet copies.

Next, we use more detailed microbenchmarks that help explain where Ensō’s performance improvement comes from.

### 7.2.3 Effect of Chaotic Memory Accesses on Cache

We now show that placing messages sequentially in an Ensō Pipe is important for Ensō’s performance. As we discussed previously, not using sequential buffers results in chaotic memory accesses, which reduces the effectiveness of hardware prefetchers (e.g., streaming prefetcher [36]). To evaluate this claim, we built a modified version of Ensō, which we call Chaotic Ensō, that changes the gaps in memory between subsequent messages. We compute the gap deterministically based on the message’s current position in an Ensō Pipe, ensuring that we add no additional software overhead when using Chaotic Ensō.

We benchmarked Ensō, Chaotic Ensō, and the E810 NIC using a program that receives and increments packets (but does not send them back). We measured zero-loss throughput, and cache miss rates at this throughput.

We show the results in Table 1. Observe that Chaotic Ensō achieves a lower throughput of 56.5 Mpps than even the E810. The number of cache misses reveals why: despite processing fewer packets per second (and hence having fewer cache accesses), Chaotic Ensō has an order-of-magnitude (557 million vs. 22.7 million) more L1d cache misses than Ensō. This, in turn, leads to an order of magnitude (558 million vs. 22.8 million) more accesses to L2 cache, thus increasing packet processing overheads. We also observe that the E810 has more cache accesses than either Ensō or chaotic Ensō, this is because it uses a descriptor per packet and thus requires the application to read more data. Finally, we observed that LLC misses were rare in all three configurations.

### 7.2.4 PCIe Bandwidth

Next, we evaluate the importance of reducing packet metadata by eliminating descriptors. We do so by measuring PCIe bandwidth when using the echo server described in §7.2.1 with 64-byte packets. In what follows, PCIe writes refer to DMA transfers from NIC to host memory, while PCIe reads refer to DMA transfers from the host memory to the NIC.

Unlike other microbenchmarks, we do not limit ourselves to zero-loss throughput for this experiment, and instead send

**Figure 10:** PCIe bandwidth utilization for read (RD) and write (WR) transactions. The bars represent the overall PCIe bandwidth utilization, while the lines represent the goodput, i.e., the amount of PCIe bandwidth used to transmit packet data. Ensō uses little PCIe bandwidth for metadata, causing it to achieve a higher goodput while consuming less overall PCIe bandwidth.

packets at line rate. This ensures that software overheads do not limit observed PCIe bandwidth, since drops due to queuing do not reduce throughput. We measure PCIe bandwidth and the rate at which the packet generator receives packets. We use this to calculate the fraction of PCIe bandwidth used for actual packet data (goodput).<sup>5</sup>

We report the results in Figure 10, where we show both PCIe goodput and total PCIe bandwidth for read (RD) and write (WR) directions. We draw four conclusions from it:

1. With one core, the E810 is CPU-bound, and the NIC drops incoming packets because of a lack of buffers in host memory. This reduces goodput and PCIe bandwidth utilization.
2. Beyond two cores, the E810 becomes PCIe bound, and consumes up to 84.1 Gbps of PCIe read bandwidth. This is close to 85 Gbps, the theoretical limit for PCIe Gen3 x16 with 64-byte transfers [62].
3. Even though the E810 has a lower goodput, it consumes more PCIe bandwidth due to metadata. This overhead accounts for up to 39% of the PCIe read bandwidth. In contrast Ensō’s metadata overhead remains below 1.2%.
4. Although barely noticeable in the plot, Ensō’s PCIe write bandwidth utilization increases as we increase the number of cores: going up from 76.4 Gbps (one core) to 77.2 Gbps (eight cores). This is because the NIC sends reactive notifications more frequently when software consumes packets faster.

While newer PCIe generations, including PCIe Gen 4, have higher capacity and will no longer be a bottleneck for 100 Gbps traffic, they will continue to be a problem for NICs that have multiple 100 Gbps interfaces and for future 400 and 500 Gbps NICs. Even with PCIe Gen 5 and a 400 Gbps NIC, the ratio of PCIe to ethernet bandwidth remains the same as in our setting with PCIe Gen 3.

### 7.2.5 Reactive Notifications and Latency

As we discussed in §4.2, Ensō is able to reduce metadata overhead by sending notifications reactively. We measure

<sup>5</sup>The maximum goodput achievable with 64-byte packets and 100 Gb Ethernet is 76.19 Gbps, since Ethernet adds 20 bytes of overhead per packet.

**Figure 11:** RTT for different loads when using a notification per packet or reactive notifications without notification prefetching.

**Figure 12:** RTT for different loads for the E810 as well as Ensō with and without notification prefetching.

the impact reactive notifications have on throughput and latency, by comparing Ensō’s performance (reactive) to that of a variant of Ensō (per-packet) that sends a notification for each packet. We again reuse the echo server from previous microbenchmarks for this.

Figure 11 shows the RTT (50<sup>th</sup> and 99<sup>th</sup> percentiles) as we increase load for both cases. While reactive notifications can sustain up to 100 Gbps of offered load, a design using per-packet notifications can only sustain 50 Gbps. However, reactive notifications also add latency with increased load.

We use notification prefetching to minimize latency under high loads.<sup>6</sup> When using notification prefetching, the software explicitly sends the NIC a request for notifications pertaining to the next Ensō Pipe, while consuming data from the current Ensō Pipe. This effectively doubles the number of notifications that the NIC sends to software at a high rate but ensures that the software does not need to wait for a PCIe RTT before processing the next Ensō Pipe.

Figure 12 shows the RTT with an increasing load for Ensō with and without notification prefetching and for an E810 NIC with DPDK. We observe that notification prefetching significantly reduces Ensō’s latency, and allows us to achieve latency comparable to the E810, while still sustaining 100 Gbps.

### 7.2.6 Sensitivity Analysis

Finally, we use microbenchmarks to evaluate Ensō’s sensitivity to different configuration parameters:

**Impact of the number of Ensō Pipes:** We measure the impact of increasing the number of Ensō Pipes by varying the number of active Ensō Pipes, and using a workload where each incoming packet goes to a different Ensō Pipe. We partition Ensō Pipes evenly across all cores. Our results in Figure 13 show that (a) we need at least two Ensō Pipes to

<sup>6</sup>By default Ensō does not prefetch notifications. Latency-sensitive applications may enable notification prefetching at compile time.

**Figure 13:** Packet rate for different numbers of Ensō Pipes and core counts. The dashed line represents the 100 Gb Ethernet limit.

**Figure 14:** Sensitivity analysis with different numbers of cores and packet sizes. Ensō is bottlenecked by 100 Gb Ethernet in all scenarios.

achieve line rate, since this allows us to mask notification latency; and (b) that throughput drops when a core has more than 32 Ensō Pipes, or eight cores have more than 512. Note that this is a pessimal workload, and realistic workloads are likely to perform better even with many queues [30].

**Impact of packet sizes and cores:** In Figure 14 we measure the impact of varying packet size and number of cores, and find that Ensō can always sustain full line rate, regardless of packet size and core count.

### 7.3 Application Benchmarks

We now evaluate how Ensō impacts the performance of real applications. We ported four different applications to use both DPDK and Ensō. These applications represent three classes of network-intensive applications (raw packets, message-based, and streaming) that we expect to be used with Ensō: Google’s Maglev Load Balancer [23], a network-telemetry application based on NitroSketch [54], MICA Key Value Store [52], and a log monitor inspired by AWS Cloud-Watch Logs [6]. To enable a fair comparison, we use the same processing logic for both DPDK and Ensō-based implementations, changing only the wrapper code used to send and receive packets. Moreover, we only enable simple traditional offloads on the NIC, e.g., RSS, Flow Director, and checksum, for both Ensō and DPDK. We expect Ensō to perform even better with more offloads on the NIC (§6).

#### 7.3.1 Maglev Load Balancer

We implemented Google’s Maglev load balancer [23] as follows. We replicate the consistent-hashing algorithm pro-

**Figure 15:** Packet rate for the Maglev load balancer under two types of workloads. The dashed line is the 100 Gb Ethernet limit.

posed in the Maglev paper, caching recent flows in a flow table, as also suggested in the paper. The load balancer ultimately determines a backend server for every incoming packet, rewriting the packet’s destination IP to that of the chosen backend server. To steer packets among different cores, we use a hash of the 5-tuple (RSS) in both systems. We evaluate our implementation using two extreme types of workloads: one with only 16 flows, which means that packets always hit the flow cache; and another with a SYN flood, which means that packets always miss the flow cache. In both cases, we use small 64-byte packets as Maglev is motivated by the need to load balance small requests [23, §3.2]. For Ensō, we use unified RX/TX Ensō Pipes to avoid copying the packet when forwarding it back.

Figure 15 shows the packet rate with both the E810 NIC using DPDK and Ensō as we scale the number of cores. With a single core and the cached workload, Ensō achieves a packet rate of 138 Mpps, approximately 6× the 23 Mpps achieved by the E810. With the SYN flood workload, Ensō achieves 79 Mpps, approximately 5× the 16 Mpps achieved by the E810.<sup>7</sup> With four cores, Ensō becomes bottlenecked by Ethernet for both workloads; and with eight cores, the DPDK implementation becomes bottlenecked by PCIe (§7.2.4).

#### 7.3.2 Network Telemetry

Sketching algorithms are popular primitives for many network telemetry tasks (e.g., heavy-hitter detection, flow count estimation) because of their small memory footprint and theoretical accuracy guarantees. NitroSketch [54] is a sketching framework that enables *software sketches* to achieve high performance on commodity servers without sacrificing accuracy. To evaluate this class of applications, we implemented a Count-Min Sketch (CMS) using the NitroSketch framework and Ensō. As in Maglev, we use unified RX/TX Ensō Pipes.

We benchmarked our implementation using two workloads: 64B packets (emulating the stress-test performed in [54]), and a busy period sampled from the 2016 CAIDA Equinix 10G dataset [13], with an average packet size of 462B.

<sup>7</sup>We note that DPDK’s packet rate of 16 Mpps with a single core is in fact a good packet rate for DPDK. For instance, NetBricks’ Maglev implementation achieves 9.2 Mpps with a single core [64]. We attribute the improvement in our DPDK numbers to NetBricks’ unoptimized implementation and our use of a newer CPU with better single-thread performance.

**Figure 16:** MICA throughput with 8B keys and values.

**Figure 17:** Mean RTT for MICA as a function of offered load (1 core).

**Figure 18:** Mean RTT for MICA as a function of offered load (4 cores).

**Figure 19:** Log monitor throughput for different target applications.

With a single core, Ensō sustains a zero-loss throughput of 81.5 Gbps (121 Mpps), approximately 3.5× that achieved by the E810 (22.8 Gbps or 33.9 Mpps) on 64B packets. On the CAIDA trace, Ensō achieves 94.9 Gbps, a 21% improvement over the E810 (78.3 Gbps); the application remains compute-bound in this setting, but Ensō shrinks the fraction of time spent performing network I/O, which improves performance.

### 7.3.3 MICA Key-Value Store

MICA [52] is a state-of-the-art key-value (KV) store which is also a popular benchmark in the literature [34,46,47,51,69,79]. Different from Maglev and the Network Telemetry application, that operate on raw packets and forward them back with modifications, MICA represents a typical message-based application whose responses must be constructed separately from the incoming request. Also different from these applications, latency is typically more critical for key-value stores [7]. MICA also entails significantly more work per packet (in terms of both compute and memory accesses) and is, therefore, less likely to become network-bound.

For the following experiments, we set the size for both keys and values to 8B (corresponding to the ‘tiny’ configuration in [52]). We report results for operations skewed 50% towards GET requests and with a uniform distribution of key popularity, but these generalize to other configurations as well. We use the same throughput metric as described in [52] (tolerating <1% loss at the NIC), and the same methodology for measuring end-to-end latency (the client tags each request with an 8B timestamp, then computes latency based on the arrival time of the corresponding response).

Figure 16 shows the steady-state throughput in millions of operations per second (Mops) achieved by MICA for both E810 with DPDK and Ensō for different numbers of cores. With a single core, Ensō achieves 7.65 Mops, a 31% improvement over the E810.<sup>8</sup> While this might seem modest at first (compared to the 6× speedup on Maglev), note that MICA is significantly more compute- and memory-intensive than Maglev. Thus, while DPDK adds considerable CPU overhead, it corresponds to a smaller fraction of the overall compute time.

<sup>8</sup>For consistency, all the MICA experiments use the original, unmodified MICA client implemented with DPDK. We observe even better performance when using a MICA client ported to Ensō (up to 47% improvement in throughput).

With 2 and 4 cores, we see throughput speedups of 33% and 23%, respectively. At 8 cores, the bottleneck moves to a different part of the system (i.e., memory). We report numbers for the ‘tiny’ configuration since it represents a significant fraction of requests found in real workloads [4, 57], while also being the most challenging workload for MICA. We also tested other configurations with larger keys and values, obtaining up to 29% improvement for the ‘small’ workload (16B keys and 64B values) and up to 12% for the ‘large’ workload (128B keys and 1024B values).

We also evaluate latency, plotting the average request latency as a function of the offered load when using a server with a single core (Figure 17) or four cores (Figure 18). For both configurations, we find that Ensō outperforms the E810 in terms of both throughput and latency. With a single core, Ensō reduces latency by up to 8 μs (43% reduction) before the queues start to build up and, with four cores, Ensō reduces latency by up to 6 μs (36% reduction).

### 7.3.4 Log Monitor

To understand Ensō’s effect on streaming applications, we implemented a log monitor. The log monitor is inspired by AWS CloudWatch Logs [6], which lets users centralize logs from different hosts and craft queries to look for specific patterns and raise alarms. Like, AWS CloudWatch Logs Insights [5], the log monitor also supports Hyperscan [84] to search for multiple regular expressions. We use Hyperscan in streaming mode for both Ensō and DPDK implementations. To feed the system, we use MTU-sized packets, carrying system logs extracted from long-running Linux hosts. We also configured the log monitor to look for regular expressions extracted from Fail2ban [45]. We run experiments targeting each of the ten most popular applications supported by Fail2ban according to the Debian package statistics [16].

Figure 19 shows the throughput we achieve when targeting each of the ten applications. Performance is dictated primarily by the number and complexity of the regular expressions that are required by each target. Ensō’s throughput is higher across all targets but the gap is more noticeable for those with simpler or fewer regular expressions, with almost double the throughput when targeting postfix, selinux, or sieve. The reasons for Ensō’s improvement in performance are twofold: First, Hyperscan performs better when

larger chunks of data are handed to it at once. With Ensō, we can invoke Hyperscan with large chunks of contiguous logs delivered from the NIC but with DPDK we need to invoke Hyperscan for every DPDK mbuf. Second, as demonstrated in §7.2.3, Ensō’s memory access patterns are sequential, making better use of the CPU prefetcher.

## 8 Related Work

**Direct application access:** While giving applications direct access to the NIC has been a common theme of research for more than three decades [8, 22, 26, 33, 50, 66, 73, 75, 80, 87, 88], most work accepts the NIC interface as a given and instead look at how to optimize the software interface exposed to applications. A notable exception is Application Device Channels [22], which gives control of the NIC to the kernel while giving applications independent access to different queues. We take inspiration from it in the way that we allow multiple applications to share the same NIC.

**Alternative NIC interfaces:** There are also proposals that try to address some of the performance and abstraction issues that we highlighted for the packetized interface.

In terms of performance, Nvidia MLX 5 NICs [20] provide a feature named Multi-Packet Receive Queue (MPRQ) that can potentially reduce PCIe RD bandwidth utilization with metadata by allowing software to post multiple packet buffers at once. However, this is not enough to completely avoid PCIe bottlenecks as the NIC still needs to notify the arrival of every packet, consuming PCIe WR bandwidth. Another proposed change to the NIC interface is Batched RxList [70]. This design aggregates multiple packets in the same buffer as a way to allow descriptor ring buffers to be shared more efficiently by multiple threads, which in turn could help them avoid the leaky DMA problem [81].

In terms of abstraction, U-Net [83] and, more recently, NICA [27] allow the NIC to exchange application-level messages directly. U-Net proposes a communication abstraction that resembles part of what is now libibverbs (RDMA) [53] and NICA uses a similar mechanism named “custom rings.” However, similar to the packetized interface, both U-Net and NICA use descriptors and scattered buffers and, as such, inherit its performance limitations.

**Application-specific hardware optimizations:** Prior work has optimized the NIC for specific applications. FlexNIC [49] quantifies the benefits that custom NIC interfaces could have to different applications. NIQ [29] implements a mechanism to reduce latency for minimum-sized packets by using MMIO writes to transmit these packets. It also favors MMIO reads over DMA writes for notifying incoming packets. NIQ’s reliance on MMIO means that it is mostly useful for applications that are willing to vastly sacrifice throughput and CPU cycles to improve latency. nm-

NFV [69] stores packet payloads on NIC memory, sending only the packet headers inlined inside descriptors, which is useful for network functions that only need to modify the header. This is orthogonal to Ensō’s interface changes and could also be used in conjunction with it.

**Application-specific software optimizations:** Some proposals avoid part of the overheads of existing NICs with application-specific optimizations in software. TinyNF [68] is a userspace driver optimized for network functions (NFs). It relies on the fact that NFs typically retransmit the same packet after processing. It keeps the set of buffers in the RX and TX descriptor rings fixed, reducing buffer management overheads. eRPC [46] is an RPC framework that employs many RPC-specific optimizations. For instance, it reduces transmission overheads by ignoring completion notifications from the NIC, instead relying on RPC responses as a proxy for completions. FaRM [21] is a distributed memory implementation. It uses one-sided RDMA to implement a message ring buffer data structure that has some similarities to an Ensō Pipe. However, different from an Ensō Pipe, FaRM’s message buffer is not opaque (enforcing a specific message scheme), must be exclusive to every sender, and lacks a separate notification queue (requiring the receiver to fill the buffer with zeros and to probe every buffer for new messages).

## 9 Conclusion

Ensō provides a new streaming abstraction for communication between software and NICs. It is better suited to modern NICs with offloads and improves throughput by up to 6× by being more cache- and prefetch-friendly and by reducing the amount of metadata transferred over the IO bus. While this paper focused on using Ensō for NIC-to-software communication, we believe that a similar approach might also apply to other I/O devices and accelerators, and we hope to explore this in future work.

## Acknowledgments

We thank our shepherd, Jon Crowcroft, and the anonymous OSDI ’23 reviewers for their great comments. We thank Francisco Pereira and Adithya Abraham Philip for their comments on this and earlier drafts of this paper, and Ilias Marinos for the discussions and feedback regarding applications. We also thank the people from Intel and VMware that gave us feedback throughout this work, including Roger Chien, David Ott, Ben Pfaff, Yipeng Wang, and Gerd Zellweger.

This work was supported in part by Intel and VMware through the Intel/VMware Crossroads 3D-FPGA Academic Research Center, by a Google Faculty Research Award, and by ERDF through the COMPETE 2020 program as part of the project AIDA (POCI-01-0247-FEDER-045907). ## Appendix A Rejected Designs for Pointer Updates

Unfortunately, the simplest alternatives for communicating pointer updates from the NIC to software perform poorly. We considered three potential alternative designs to let the NIC inform pointer updates to software. While these designs might seem to suit our needs at first, we ultimately discarded them since they perform poorly due to architectural details of PCIe or the CPU:

**MMIO synchronization:** The simplest design would be for the NIC to update the pointer values to its internal memory and make software periodically issue an MMIO read to fetch the latest value. Unfortunately, software-issued MMIO reads cannot be served from the cache, causing the CPU core to stall until the read request is sent and the response is received (two PCIe transfers). Additionally, PCIe serializes MMIO reads, further reducing performance.

**Shared memory synchronization:** A second simple alternative would be to dedicate an address in host memory to hold the pointer value. The NIC can issue a DMA write whenever it needs to update the pointer value. Software can then periodically poll the same address to figure out if the NIC advanced the pointer. The issue with this design is that it makes the software and the NIC contend for the same cache line, which requires a slow ownership transfer whenever the NIC or the CPU access the cache line. To verify this, we implemented this design and obtained a throughput of less than 5 Gbps when enqueueing 64-byte packets using the same setup as described in §7.

**Inline synchronization:** The last discarded design is motivated by traditional NIC descriptor ring buffers which contain constant-sized descriptors with metadata in a format defined by the NIC. These designs designate a bit of the descriptor as a “flag bit” [25, 39]. Initially, all the descriptor slots in the buffer have their flag bit zeroed. Whenever the NIC DMA writes a new descriptor to host memory, it overwrites the old ‘0’ flag with a ‘1’ flag. To figure out if a new descriptor is ready to be consumed, software simply needs to check if the next slot’s flag is set. After consuming a descriptor, software sets the flag back to ‘0.’ Because many descriptors are likely to be present in the buffer, this reduces the chance that software and the NIC will contend for the same cache line.

Since Ensō Pipes are opaque, implementing the same strategy used in the descriptor ring buffer is impossible. Even if we zeroed the entire buffer after the data is consumed, we do not know what data to expect in the buffer—the next incoming data might also be zero. Therefore we tested an alternative design: we picked a 128-bit random cookie, to make the chance of collision with incoming data negligible and placed it at the beginning of every cache line of the Ensō Pipe. Software now only needs to check if the next 128 bits

match the cookie. Unfortunately, filling the buffer with cookies whenever the data is consumed imposes considerable overhead. For this reason, this design worked well for small data transfers but poorly when using large chunks of data. This design also prevents software from detecting unaligned writes.

## Appendix B EnsōGen Packet Generator

EnsōGen is a software packet generator built on top of the Ensō NIC interface that achieves 100 Gbps with a single core and arbitrary packet sizes. Here we briefly describe how it operates and how we ensure that it is correct.

**Operation:** At startup EnsōGen reads a user-supplied pcap file and allocates enough Ensō Pipes to be able to fit all its packets. At run time, EnsōGen simply needs to round-robin among the pre-allocated Ensō Pipes enqueueing a *single* notification in order to transmit the *entire* 2 MB buffer content. This makes it trivial for EnsōGen to saturate the link with very little CPU overhead. Since transmission is cheap, EnsōGen spends most of its CPU cycles receiving packets. It parses every incoming packet to track the number of bytes and packets received.

**Simple offloads:** We implemented hardware support for timestamping and rate limiting, which helps EnsōGen achieve cycle-accurate precision while saving CPU cycles. These features are also commonly offered in existing NICs [39, 63] and are leveraged by some software packet generators [24]. When hardware timestamping is enabled, EnsōGen keeps a histogram in host memory with the RTT of every received packet with 5 ns granularity (the same precision as the hardware timestamper, which operates at 200 MHz). To spread the load equally among the RX Ensō Pipes regardless of the workload, EnsōGen also configures the hardware to direct packets to pipes in a round-robin fashion [74].

**Correctness:** We verified EnsōGen’s performance and rate-limiting capabilities using another in-house packet generator fully implemented on an FPGA, as well as using software counters, to ensure that the rate limited throughput always matches the specification.

## Artifact Appendix

### Abstract

The paper artifact is composed of Ensō’s hardware and software implementations, the applications used in the evaluation, the EnsōGen packet generator, as well as the code to automatically run most of the experiments. We also include documentation describing how to set up the environment, compile the code, synthesize the hardware, and use Ensō for other purposes—including a detailed description of the software API.

### Scope

The artifact has two main goals: The first is to allow the main claims in the paper to be validated. The second is to allow others to build upon Ensō for their own projects.

We include code to automatically reproduce Figures 8, 11, 12, 13, 14, and 15. We also include the source code for all the applications that we evaluate in §7.3 and for the EnsōGen packet generator.

### Contents

The artifact is split between two git repositories.

#### Ensō Repository

This repository includes Ensō’s source code as well as documentation and example applications. It is structured as follows:

**hardware/:** Source code for the hardware component and scripts to automatically generate all the required IPs.

**software/:** Source code for the software component, which includes both the library and the kernel module. It also includes example applications and EnsōGen under `software/examples`.

**frontend/:** Frontend to programmatically load and configure the hardware from Python as well as a command line interface based on this frontend.

**docs/:** Documentation detailing how to set up the system, compile the software and the hardware, and how to use Ensō’s primitives (RX Pipes, TX Pipes, and RX/TX Pipes) from an application.

#### Ensō Evaluation Repository

This repository includes code to automatically run experiments to verify the main claims in the paper and the applica-

tions that we evaluate in §7.3. Here we briefly describe the main files and directories:

**experiment.py:** Script to automatically run the experiments to verify the main claims in the paper.

**paper\_plots.py:** Script to produce all the plots in the paper.

**setup.sh:** Script to automatically setup the experiment environment.

**maglev/:** Maglev Load Balancer used in §7.3.1.

**nitrosketch/:** Network telemetry application based on NitroSketch used in §7.3.2.

**mica2/:** MICA Key-Value store used in §7.3.3.

**log\_monitor/:** Log monitor application used in §7.3.4.

### Hosting

Both repositories are hosted on GitHub and archived using Zenodo with a permanent DOI. The documentation contained in the Ensō Repository is also automatically deployed using GitHub actions for easy access.

### Requirements

Running Ensō requires a host equipped with an Intel Stratix 10 MX FPGA [42] and an x86-64 CPU. The software component also assumes that the host is running Linux. §7 details the exact environment we used in our experiments.
