With the support of distance filter, VBASE can even support `Join` on high-dimensional vectors, which previous vector systems cannot support efficiently. Semantic-based join has been widely used in document auto-tagging [26, 72], which assigns one or multiple labels for each unseen document by finding the closest label embeddings to a document embedding. Previous systems can only support `Join` by brute-force table scan. VBASE executes a `Join` by nested-loop with index search, which outperforms existing systems by 7000× faster with 0.999 recall accuracy in our experiment.

**More complex queries.** The combination of the above operators can be used to support more complex queries efficiently.

### 4.3 Query Planning

Complex queries often require effective cost estimation on various query plans. In general, it includes vector algebra computation (e.g., distance calculation), selectivity estimation

in case the query contains filters, and index scan cost.

**Vector computation.** Traditional databases estimate the cost of scalar data computation using a constant value  $t$ , e.g.,  $t = 0.0025$ . But vector computation is more expensive, it involves the calculation of the distance between vectors, which is proportional to the number of dimensions. Thus VBASE models the cost of vector computation  $t_v$  as:

$$t_v(dim) = t \cdot c \cdot dim,$$

where  $t$  is a predefined value representing the cost of scalar operation,  $c$  is the coefficient related to SIMD optimizations for vector computation, and  $dim$  denotes vector dimension.

**Selectivity estimation.** If a query contains a filter, the query should estimate selectivity, the ratio of tuples that will pass the filter. VBASE relies on sampling-based methods to measure the distribution of high-dimensional vectors [67, 82]. Specifically, VBASE uniformly samples vector data at a ratio and stores the sampled vectors in the metadata of the database. Given a query  $q$ , it applies the filter on the sampled data to estimate the selectivity  $Sel$  on the full vector data-set.

$$Sel_{sample}(q) \approx Sel_{full\_data}(q).$$

In our experiments, setting the sample rate to 0.001 can produce a good estimation with q-error < 1.1 in most cases while incurring only a tiny extra latency (<1ms). More details will be presented in §5.5.

**Index scan cost estimation.** This includes start-up cost and traversal cost. The start-up cost is the cost to locate the region nearby the target vector before returning vector data; Traversal cost represents the cost to iterate over the matched tuples through the index. For each index traversal step, the cost  $C_{step}$  includes  $t_{IO}$ , the IO cost to fetch the index data from disk, and  $t_v(dim)$ , the cost to calculate the distance:  $C_{step} = t_v(dim) + t_{IO}$ . For partition-based indices like IVFFlat and SPANN, the index scan cost  $C_p$  is:

$$C_p = N_c \times C_{step} + \max(\lceil Sel(q)N/N_p \rceil, m) \times N_p \times C_{step},$$

where  $N$  is the table size,  $N_c$  is the number of centroids,  $N_p$  is the average number of data per partition, and  $m$  is the number of partitions the index traversal algorithm requires to traverse for *relaxed monotonicity* check.

The scan cost,  $C_g$ , of graph-based indices like HNSW is:

$$C_g = N_{start} \times C_{step} + \max(Sel(q)N, N_E) \times R_{iter} \times C_{step},$$

where  $N_{start}$  is the number of steps to traverse upper-layer graphs in `Open` function of HNSW,  $N_E$  is the number of steps to satisfy *relaxed monotonicity* check, and  $R_{iter}$  is the average times of distance function called per step to reach next point.  $N_{start}$ ,  $N_E$  and  $R_{iter}$  are dependent on the hyper-parameters of the index and the distribution of data, which can be automatically estimated by sampling, and this process can be embedded into databases’ `Analyze` routine.

## 4.4 Multi-Column Scan Optimization

To support multi-column vector queries, TopK-based systems can only perform multi-column scan based on the multiple sets of sorted vectors collected by TopK. For example, Milvus performs NRA algorithm [33] for multi-column scan based on TopK. It doubles  $K$  and re-executes the query if the previous results are insufficient. Every attempt to a larger  $K$  is an independent traversal over the underlying vector index. This introduces excessive vector access and computation.

In contrast, VBASE implements NRA algorithm [33] natively based on the index scan operator, thus avoiding the repetitive execution of NRA. The NRA algorithm traverses each vector index in a round-robin manner. We observe that round-robin might not be an efficient choice. In the vector search scenario, different vector indices can return results of different quality, especially when the ranking function is summation with unequal weights from different indices. Figure 4 shows the results of such a case, where the round-robin method will unnecessarily traverse excessive low-quality vectors (i.e., dots in Figure 4).

Figure 4: Index traversal pattern for a 2-index vector query on Recipe1M. The total score is a summation of two vectors’ distance with a weight ratio of 1:2. Lower score means closer to the target vector. Blue dots and red triangles represent the total scores of entities using index1 and index2.

This observation leads us to a new index scan algorithm that scans through high-quality indices more frequently, i.e., triangles in Figure 4, so that the query can terminate earlier with even more accurate results. Such a non-uniform traversal manner may trap in local optima. In Figure 4, a greedy algorithm may prefer to visit index2 only. But the figure shows that index1 does have good quality vectors occasionally.

To balance exploration and exploitation, we use both local and global information to guide the index traversal (See Figure 5). Our approach divides the traversal process into several rounds and adds a traversal decision module. It maintains a local priority queue to store the last round’s results. This local information helps us identify which index is more likely to return better results so we can visit it more in the next round. To avoid being trapped in local optima, the decision module also stores the average score of all traversed entities for each index (i.e.,  $avg_i$  for  $index_i$ ) and updates them each round. Based on this global information, We additionally tra-

Figure 5: Overview of multi-column traversal optimization, assuming there are  $m$  indices.

verse each index  $W_i = \left\lceil n_2 \times \frac{1/avg_i}{\sum_{j=1}^m 1/avg_j} \right\rceil$  times in this round

where  $n_2$  is a hyper-parameter. Therefore, the high-quality index (with low  $avg_i$ ) will be traversed more times while we can still ensure traversing the low-quality index (with high  $avg_i$ ) at least once in each round. Table 7 in §5.3 highlights the benefit of this approach.

## 5 VBASE Evaluation

In this section, we evaluate VBASE in comparison with other state-of-the-art vector search systems and vector-enabled databases based on TopK, and demonstrate VBASE has superior performance and accuracy on vector similarity queries.

### 5.1 Evaluation Benchmark

A lack of a comprehensive relational benchmark for complex vector applications necessitates us to create a vector benchmark to compare VBASE with various vector-similarity-enabled systems. The use of approximate vector processing also needs the benchmark to define new evaluation metrics.

**Vector-scalar relational data-set.** Because current vector search [2,3] and database benchmarks [13,14] have either vector or scalar data-sets *but not both*, we extend Recipe1M [68] to generate vector and scalar hybrid data-sets. Recipe1M data-set is a collection of more than 1 million recipes, each containing ingredients, cooking instructions, and a set of images of the finished dish.

Our evaluation data-set is organized as two tables: *Recipe Table* and *Tag Table*. Their schemas are shown in Table 2 and 3, respectively.

Table 2: Schema of Recipe Table

Column Name	Data Type	Example
recipe_id	identifier	1
images	list of strings	["data/images/1/0.jpg", ...]
description	text	[ingredients] + [instruction]
images_embedding	vector	[0.0421, 0.0296, ..., 0.0273]
description_embedding	vector	[0.0056, 0.0487, ..., 0.0034]
popularity	integer	300

Table 3: Schema of Tag Table

Column Name	Data Type	Example
id	identifier	1
tag_name	text	“salad”
tag_vector	vector	[0.0137,0.0421,...,0.0183]

*Recipe Table* stores 330,922 recipes from Recipe1M<sup>2</sup>. As shown in Table 2, *Recipe Table* inherits *recipe\_id* and *recipe\_images* URIs from Recipe1M as two attributes. We merge Recipe1M’s ingredients and instructions as a single string attribute called *description*.

In addition to the original data from *Recipe1M*, *Recipe Table* has two *vector* attributes, *images\_embedding* and *description\_embedding*. They are two 1,024-dimensional vector embeddings of recipe images and descriptions based on the cross-modal embedding model from [68]. We also extend the recipe item with an additional scalar attribute: *popularity*, a random integer in the range [0,10000].

*Tag Table* samples 10,000 recipes from Recipe1M, and assigns of *tags* for them. As shown in Table 3, *Tag Table* has scalar attributes of *id* and *tag\_name*. Attribute *tag\_name* is a set of strings of manually assigned tags (e.g. dessert, main course, salad, pizza, etc), and *id* is a unique integer assigned to the tag set. Each *Tag Table* row also has a *tag\_vector*, which is a 1,024-dimensional *images\_embedding* of a recipe using the same embedding model of the *Recipe Table*.

**Vector similarity queries in SQL.** We designed 7 SQL queries to emulate various vector online application scenarios (§2.1). In particular, we also designed Q8 which runs an analytic join query based on vector similarity match. These 8 relational queries cover most SQL operators of Projection, Index Scan, Sort with Limit, Filter, Join, which are important for online queries over vector and scalar data-set.

- Q1: Single-Vector TopK.

```
SELECT recipe_id FROM Recipe
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) LIMIT 50;
```

- Q2: Single-Vector TopK + Numeric Filter.

```
SELECT recipe_id FROM Recipe
WHERE popularity <= ${p_popularity}
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) LIMIT 50;
```

- Q3: Single-Vector TopK + String Filter.

```
SELECT recipe_id FROM Recipe
WHERE description NOT LIKE "%${p_ingredient}%"
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) LIMIT 50;
```

- Q4: Multi-Column TopK.

```
SELECT recipe_id FROM Recipe
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) + WEIGHT * INNER_PRODUCT(
    description_embedding, ${p_description_embedding})
LIMIT 50;
```

<sup>2</sup>We remove those in the 1 Million recipes that miss any of the ingredients, cooking instructions, and related images.

- Q5: Multi-Column TopK + Numeric Filter.

```
SELECT recipe_id FROM Recipe
WHERE popularity <= ${p_popularity}
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) + WEIGHT * INNER_PRODUCT(
    description_embedding, ${p_description_embedding})
LIMIT 50;
```

- Q6: Multi-Column TopK + String Filter.

```
SELECT recipe_id FROM Recipe
WHERE description NOT LIKE "%${p_ingredient}%"
ORDER BY INNER_PRODUCT(images_embedding,
    ${p_images_embedding}) + WEIGHT * INNER_PRODUCT(
    description_embedding, ${p_description_embedding})
LIMIT 50;
```

- Q7: Vector Range Filter.

```
SELECT recipe_id FROM Recipe
WHERE INNER_PRODUCT(images_embedding, ${p_images_embedding})
    <= ${D};
```

- Q8: Join.

```
SELECT Recipe.recipe_id, Tag.tag_name
FROM Recipe JOIN Tag
ON INNER_PRODUCT(Recipe.images_embedding, Tag.tag_vector)
    <= ${D};
```

We ran these 8 queries on VBASE and compared them with query processing in other systems. For each query, we generated 10,000 substitution parameters to cover various query conditions. In particular, we set *K* to 50 for TopK queries as in the experiment of Milvus [76]. We also designed the numeric filtering constraints to cover both high and low filtering selectivities. *p\_popularity* is incremented from 1 to 10000. *p\_ingredient* is sampled from ingredients keywords in Recipe1M. *WEIGHT* is 1. *D* is 0.1 in Q7 and 0.01 in Q8.

**Evaluation metrics.** Vector query executions are approximate, hence we evaluate both query accuracy and performance in terms of *recall* and *latency*, respectively. Recall is a new metric to conventional database evaluations. It evaluates query accuracy against the ground truth. Recall has been widely used in approximate vector search systems [2, 3, 76, 86]. They only evaluate recall because for TopK queries, recall and precision are the same as long as a system returns *K* results. For other queries with range filter constraints, precision will always be 1 if the system obeys the constraints. Therefore, we use recall to represent query accuracy. For each query, we calculate the average recall of the query results of all substitution parameters. For each query in Q1-Q7, we measure the *average, median, 99th percentile* latency from the execution results of all substitution parameters. For Q8, we execute it 3 times and measure the *average* execution time.

## 5.2 Experiment Setup

**Evaluation platform.** All evaluations run on an Azure VM, *Standard\_F64s\_v2* [1], with 64 v-CPU and 128 GiB memory running Linux Ubuntu 20.04 LTS. All queries run individually to avoid interference from other queries.

**Baseline systems.** We compare VBASE with the state-of-the-art vector search and database systems that support vector similarity queries.

**Vector search baselines:** We choose *Milvus* [76] and *Elasticsearch* [4] as our vector search baselines. Since they do not support SQL interface, we hand code our benchmark queries. We also implement Iterative Merging algorithm as claimed in Milvus paper [76] to enable multi-column TopK queries, although unavailable in its open-source code [8]. For Elasticsearch we use the version implemented by Open Distro (version 1.13) [9], which supports HNSW index.

**Database baselines:** For databases, we use the open-source PASE [11, 86] that implements the TopK-only solutions using tentative indices, and extended its maximum dimension support from 512 to 1024. We also run queries on *PostgreSQL* (version 13) [12] as a baseline to show the performance of traditional databases in performing vector similarity queries.

**Common index settings.** VBASE and baseline systems all use HNSW [89] with the same vector index settings ( $M = 16, ef\_construction = 200, ef\_search = 64$ ). HNSW is the only vector index supported by PASE, Milvus, and Elasticsearch in common. Since HNSW index is kept in memory when it is used, in order to better compare the performance results of the index-based execution process without being affected by the caching strategy of the main table adopted by different systems, we also save the main table data in memory. All the database baselines and VBASE also created a B-tree index on *popularity* column to expedite numeric filtering.

### 5.3 Evaluation Results

**Overview.** Table 4 summarizes the overall evaluation results. We can see that each baseline system based on approximate vector indices (except PostgreSQL) can only process some of the 8 queries, while VBASE can process all of them.

Although PostgreSQL can process all queries and produce exact results, it uses a brutal force scan with a much higher query latency than the rest of the systems. The  $1000\times$  lower performance of PostgreSQL than other approximate systems makes it irrelevant to address the low-latency “online” scenarios. We run queries on PostgreSQL mostly to get ground truth to calculate the query result accuracy of other systems.

VBASE’s query performance on TopK (Q1) is similar to or better than baseline systems because they essentially run the same algorithm in different implementations. For queries that are more complex than Q1, VBASE outperforms all baseline systems by  $100\times - 1000\times$  because VBASE can determine the optimal  $\tilde{K}$  on-the-fly and others have to try different  $K$ s to get sufficient results. While VBASE produces superior query performance, it can also achieve high recall similar to or even higher than approximate queries on baseline systems.

Next, we discuss each query’s evaluation result in detail.

**Q1 – Single vector TopK.** Q1 is a TopK query without any

filters. All approximate systems including VBASE in our evaluation run the same algorithm and produce identical results, therefore having the exact same recalls.

Nevertheless, we can see variations in Q1 latency from different systems. The reasons for performance variations are two-fold. The first reason is that these systems are implemented in different languages (Milvus/Elasticsearch vs. PASE/VBASE). For example, Milvus are implemented in GoLang and C++, and Elasticsearch is implemented in Java and C++. In comparison, PASE and VBASE are written in C. In general, we can see implementation in C outperforms other high-level language implementations by  $2 - 10\times$ .

The second reason for performance variation (PASE vs. VBASE) is that VBASE needs to fetch slightly more tuples than PASE. Although following the same algorithms and traversing the same amount of vectors in the index, VBASE follows an Iterator Model, which fetches every corresponding tuple from the main table during index traversal. PASE’s implementation visits vectors in the index and only fetches the  $K$  tuples after getting TopK vectors in the index. As a result, VBASE performs slightly worse, 2.8% slower than PASE in terms of average and 99 percentile latency.

**Q2-3 – Single vector TopK with scalar filter.** Q2 and Q3 are vector similarity queries with filtering on scalar attributes. Q2 and Q3 differ in their filter predicates, where Q2 uses numeric filtering on the integer attribute *popularity*, and Q3 runs string filtering based on a regular expression. All baselines support Q2 and Q3, with an exception of Milvus for Q3 because it does not support string data type.

All approximate baselines run a *single shot* of  $K'$ . Based on different guesses of  $K'$ s, baseline systems produce different results. Elasticsearch undershot  $K$  for Q2 and Q3, therefore cannot produce sufficient results and has low query accuracy. Even though Elasticsearch has fewer data traversals than the rest of the approximate systems with higher accuracy, its query latency is still the worst, possibly due to system inefficiency like in Q1. PASE and Milvus overshoot  $K$  and produce high result accuracy like VBASE, but they have longer query latency because they traverse more data than VBASE.

Q3 has a fixed filter selectivity of around 0.9. For Q2 we have 10,000 queries of different parameters with uniform distribution of filter selectivity from 0 to 1. We compared the evaluation results of two best approximate systems VBASE and PASE for Q2, under three representative *filter\_selectivity* values (0.03, 0.3, 0.9) from low to high (Table 5). We found that different filter selectivities result in different optimal  $\tilde{K}$ s: the lower the selectivity, the more data a system needs to examine, therefore larger  $\tilde{K}$ . Because  $\tilde{K}$  is dynamic, PASE’s static guess of  $K'$  cannot produce constantly high recalls under all filter selectivities. A conservatively large guess of  $K' = 10,000$  can produce near-exact results by PASE, however, its query performance deteriorates dramatically. We also present the average  $\tilde{K}$  and standard deviation under different filter selectivities in Table 5.  $\tilde{K}$  varies for different filter se-

<sup>1</sup> We have only run one query parameter for Q8, so average, median and 99th percentile latency are the same.

Figure 6: 99th Percentile Query Latency (ms)

activities. Even under the same selectivity, it also varies for different queries and the standard deviation is very large.

VBASE can always produce the best query performance with high recalls since it can determine  $\tilde{K}$  on the fly.

**Q4-6 – Multi-column TopK.** Only Milvus and VBASE support Q4-6, which are TopK queries over multiple vector indices. Q5,6 adds scalar filtering to Q4 just like in Q2,3, and Milvus cannot support string filter conditions in Q6. Milvus tries different  $K'$  to produce a sufficiently large intersection of multiple TopK results from different indices. Milvus’s performance is worse than PostgreSQL which uses sequential table scan, because it cannot finish after several rounds of TopK guesses and accumulates a large number of random reads. In comparison, VBASE determines the optimal  $\tilde{K}$  per each vector index based on relaxed monotonicity. Consequently, VBASE outperforms Milvus by 200 – 300× in terms of query latencies for Q4-6, and produces higher recalls (96%+).

We also experimented multi-column TopK queries with 4 kinds of weights in the ranking function, with different index-iteration algorithms as introduced in §4.4 (see Table 7). When the difference in weights is large (1:10), the greedy algorithm produces the best performance with high recalls. This is because the greedy approach identifies low-quality indices (i.e. ones with low-ranking weights) quickly, and avoids traversing them as much as possible. However, when weight differentiation decreases, the greedy algorithm can easily get trapped in local optima. This shortcoming of the greedy method is self-evident for a weight ratio of 1:1, where we can see greedy strategy extracts the highest number of entities while producing the lowest recall. In contrast, VBASE shows higher recalls in all situations by dynamically determining a better strategy

to switch among different indices while outperforming by 5% lower latency than the round-robin approach.

**Q7 – Vector range filter.** Table 4 shows that only VBASE supports Q7. PASE does not support Q7 by default. We add a Order By distance clause with a hand-tuned “limit  $K$ ” to force PASE to use its approximate vector index. This way it simulates the results of Q7. Like in Q2, it is difficult to set an appropriate  $K'$  for PASE ahead of time as shown in Table 6. We also present the average  $\tilde{K}$  and standard deviation, which also shows  $\tilde{K}$  changes dramatically for different queries. E.g., sometimes  $K$  is required to be 2300+ for optimality. VBASE can achieve a great trade-off between query latency and recalls because its execution engine can determine  $\tilde{K}$  on-the-fly based on relaxed monotonicity.

On average Q7 only returns a small number of results that fit within the range. However, a small percentage of Q7s produce up to 10,000 results, which incurs high query costs in VBASE. Therefore we can see that, in VBASE, Q7’s 99th percentile latency is much higher than the average (168.9ms vs 10.8ms) while the median is much smaller than the average.

**Q8 – Join.** PostgreSQL performs nested-loop join on table scan to get accurate results. In Q8, VBASE is 7,900x faster with recall=0.9992. Other systems cannot run this query due to the lack of a unified query engine.

## 5.4 VBASE with SPANN

Table 8 shows the evaluation results for VBASE with SPANN [25]. We run VBASE with SPANN on Azure VM Standard\_L16s\_v3 with NVMe disks. SPANN is a partition-based ANNS index that uses external memory, i.e. disks. As

	VBASE	409.31	15.69	<b>0.9961</b>
1 : 10	Round-Robin	363.47	14.81	0.9981
	Greedy <sup>3</sup>	<b>274.86</b>	<b>12.69</b>	0.9985
	VBASE	311.66	13.97	<b>0.9987</b>

<sup>1</sup> The weight ratio of two distances (1 : x) in the ranking function.

<sup>2</sup> The average number of times we scan the two vector indices.

<sup>3</sup> In the greedy method, we first traverse each index 20 times and we find the index with the lowest average distance. Then, we extract candidates from this index only.

a result, query latencies on VBase with SPANN are generally higher than those for HNSW which are in-memory. This shows that VBASE can support both partition-based vector indices as well as graph-based ones. In addition VBASE can integrate indices stored both in memory and on disk seamlessly.

## 5.5 Cost Estimation

**Selectivity estimation accuracy.** We evaluate the accuracy of the selectivity estimation for vector range filter in terms of q-error [61]:

$$Q_{err} = \max\left(\frac{Sel_{esti}}{Sel_{real}}, \frac{Sel_{real}}{Sel_{esti}}\right).$$

As demonstrated in Figure 7, estimation based on sampling can provide a q-error less than 1.1 for most cases. When selectivity is lowest at 0.05, our samples cannot provide a high

Table 8: Queries on VBASE with SPANN (Latency: ms)

Queries	Recall	Latency		
		average	median	99th
Q1	0.9911	9.4	9.2	11.6
Q2	0.9214	10.7	9.3	44.9
Q3	0.9847	9.7	9.4	11.8
Q4	0.9481	32.2	28.7	68.2
Q5	0.9757	87.4	55.9	519.7
Q6	0.9516	40.1	32.1	126.2
Q7	0.9923	17.8	9.3	283.5
Q8	0.9638	87,729.3	- <sup>1</sup>	- <sup>1</sup>

<sup>1</sup> We have only run one query parameter for Q8.

resolution, therefore its q-error increases up to 1.27. Increasing the sampling rate in cost estimation can reduce q-error further, but this increases selectivity estimation time for query planning, which is infeasible for online queries. In our experiments, such estimation accuracy is sufficient to support a good query plan strategy.

In comparison, systems like PASE [11] don't provide an estimation for selectivity and PASE sets the default value of selectivity estimation to 0.5.

Figure 7: Q-error in different selectivity. Default estimated selectivity=0.5

**Query Planning.** We evaluate the efficacy of query planning using the following query.

```
SELECT recipe_id FROM Recipe WHERE
  → INNER_PRODUCT(q, images_embedding) < ${r}
  → AND popularity < ${p};
```

The vector range filter and the scalar filter can be accelerated via vector index or B-tree. Our experiments show that VBASE can correctly choose the best execution plan under different selectivities, because our estimations of selectivity, vector computation, and index scan cost are accurate enough for

VBASE to construct good plans by reusing PostgreSQL’s built-in mechanism.

Figure 8a shows execution times of different planning strategies for varying scalar selectivities and a fixed vector filter selectivity. The default strategy estimates selectivity as 0.5 as PASE does. The result demonstrates that VBASE can produce execution plans that closely match the ground truth of the best choice of index scan strategies. When scalar selectivity is less than 0.18, VBASE predicts accurately that the cost of execution via B-tree index is smaller than vector index traversal, and chooses to run it. Likewise, if scalar selectivity is over 0.18, VBASE correctly chooses vector index traversal.

On the other hand, experiments in Figure 8b vary vector filter selectivities and fix scalar filter selectivity. Like in Figure 8a, the result shows VBASE can create the high efficacy of query planning based on highly accurate cost estimation.

In comparison, systems like PASE do not provide an accurate estimation for selectivity. And they do not tune cost estimation for vector computation and vector index traversal either. The inaccurate estimation causes PASE to always execute queries via B-tree index in this experiment.

Figure 8: Query execution time with different estimation. We fixed range filter selectivity=0.13 in (a), and scalar filter selectivity=0.90 in (b)

## 6 Related Works

**Similarity Query in Databases.** Several works [20, 21, 71, 73, 74] have explored extending database systems to support accurate similarity query of low-dimensional vector data, in which  $K$ -NN( $TopK$ ) and *range filter* query are well described. R-Tree [38], KD-Tree [34], M-Tree [27], Slim-Trees [47] can be used in these works as indices for low-dimensional data. [20] proposes to include similarity queries to SQL and run them on SIREN [21]. [71] presents similarity Join and similarity Group-by operators. The similarity Group-by operator for high-dimensional vector is actually equivalent to the clustering operation, which has been well-studied by [15, 18, 50, 65]. However, all of these works are about clustering data on the main table instead of the vector indices.

**Vector Indices.** Vector indices support approximate nearest neighbor search efficiently on high-dimensional vector by  $TopK$  interface. They can be divided into two categories: graph-based approach and partition-based approach. The

partition-based approach divides the whole vector space into many sub-spaces, and uses some metric (e.g. a centroid, a hash value or a divisional plane) to represent all vectors that belong to a sub-space. During the traverse, it navigates a query to its approximate nearest sub-spaces step by step based on distances between the query and the representative metric of sub-spaces. Representative partition-based approaches include clustering-based solutions [5, 17, 19, 25, 44, 45, 48, 90], hash-based solutions [30, 41, 79, 81, 85], and tree-based solutions [23, 57, 62, 78]. The graph-based approach represents each vector as a vertex, each connected to its nearest vectors (i.e. neighbors) by edges in a graph. There are also some shortcut edges connecting to distant vector vertices, which can speed up the graph traversals. Using this neighborhood graph, index traversal can be guided by a query approximately towards its closest neighbors step by step from a fixed starting point [32, 39, 43, 55, 58, 77].  $TopK$  interface in vector indices has limited query expressiveness.

**Vector Databases based on  $TopK$ .** AnalyticDB-V [80], PASE [86], Milvus [76], and Elasticsearch [4] support complex vector queries based on the original  $TopK$  interface in vector indices. AnalyticDB-V [80] and PASE [86] integrate vector indices into the database engine to support SQL interface for similarity queries. Elasticsearch [4] is a distributed full-text search engine, providing approximate nearest neighbor search based on HNSW [89]. AnalyticDB-V [80], PASE [86], and Elasticsearch [4] begin to support vector search plus scalar attribute filtering. Milvus [76] is a data management system to efficiently manage large-scale vector data, which can additionally support multi-column  $TopK$  queries by iteratively speculating the  $K$  with a growing value. In contrast, VBASE does not rely on a tentative index collected by  $TopK$ .

## 7 Conclusion

This paper presents VBASE, a vector database that integrates high-dimensional vector indices into PostgreSQL, a relational database to facilitate complex approximate similarity queries. Unlike conventional approaches that leverage  $TopK$  to collect the target vector’s  $K$  nearest neighbors where a conventional index is constructed for query execution, VBASE builds on relaxed monotonicity, a common foundation between conventional and high-dimensional indices. This common foundation allows VBASE to build a unified query execution engine that produces query results equivalent to those produced by  $TopK$ -based solutions with the optimal  $\bar{K}$ . As a result, VBASE significantly outperforms state-of-the-art vector systems on complex vector queries.

## Abstract

Transactions are an important feature of database management systems (DBMSs), as they provide the ACID guarantees for a sequence of database operations. Consequently, approaches have been proposed to automatically find transactional bugs in DBMSs. However, they cannot handle complex operations and predicates common in real-world database queries, and thus miss bugs.

This paper introduces a general, effective technique for finding transactional bugs in DBMSs that supports complex SQL queries and predicates. At the conceptual level, we address the test-oracle problem by constructing semantically-equivalent test cases based on fine-grained statement-level dependencies in transactions. At the technical level, we introduce (1) *statement-dependency graphs* to describe dependencies among SQL statements in transactions, (2) *SQL-level instrumentation* to capture possible statement-level dependencies, and (3) *transactional oracle construction* to generate semantically-equivalent test cases using statement-dependency graphs. We also establish the correctness of our approach in generating semantically-equivalent test cases. We have realized our technique as a tool, TxCheck, and evaluated it on three widely-used and well-tested DBMSs, namely TiDB, MySQL, and MariaDB. In total, TxCheck found 56 unique bugs, 52 of which have been confirmed and 18 already fixed. We believe that TxCheck can help solidify DBMSs' support for transactions thanks to its generality and effectiveness.

## 1 Introduction

Database management systems (DBMSs) store and manage data and are crucial for many applications. A key feature of DBMSs is their support for transactions, where a sequence of SQL statements are executed as a single unit, and various properties (*i.e.*, atomicity, consistency, isolation, and durability) are guaranteed. For example, if some transactions are concurrently executed at the *Serializability* isolation level, uncommitted operations by other transactions will be invisible, and the transaction execution results must be equal to

the results when these transactions are executed in a serial order. Benefiting from these properties, transactions have been applied in many critical applications. However, transaction implementations usually involve complex logic (*e.g.*, two-phase locking [7, 45] and multiversion concurrency control [8, 32]), and thus bugs are easily introduced. In this paper, we refer to the bugs in the transaction support of DBMSs as *transactional bugs*. Such bugs are critical because they can paralyze their client applications or, even worse, silently trigger incorrect behaviors in critical operations of client applications.

To improve the reliability and correctness of transaction processing in DBMSs, several approaches [4, 9, 11, 17, 44] have been proposed to test transaction support. These approaches use specific operation patterns to capture the violations of transactional rules. For example, ELLE [4] encodes transaction execution histories<sup>1</sup> by only appending to a conceptual list data structure. It builds transaction-dependency graphs based on the histories, and reports bugs if the graphs violate the desired isolation guarantees. Limited by specific test-case patterns, these approaches use only simple operations (*e.g.*, ELLE appends list with constant values), while many deep bugs may only be triggered by complex operations [21]. Moreover, existing approaches [4, 9, 17, 44] cannot handle predicates (*e.g.*, the condition expressions in **WHERE** clauses) in general. For example, ELLE cannot encode predicate operations in its list data structure. However, predicates are ubiquitous in real-world transactions as they rely on common features such as **WHERE** clauses or **JOINS**. Their lack of predicate support makes existing approaches miss many real bugs. In addition, transactional bugs may be independent of isolation levels (*e.g.*, incorrect results returned by one transaction), while existing approaches focus on testing isolation levels, thus missing bugs.

Figure 1(a) shows a confirmed bug in MySQL at the *Repeatable Read* isolation level. The bug-triggering test case involves two tables and two interleaved transactions. The statement T1.S3 is executed immediately after T1.S2. The

<sup>1</sup>A history records transactional requests to and responses from a database.

Figure 1: A MySQL bug found by TxCheck under the *Repeatable Read* isolation level.

oretically,  $T1.S3$  should fetch exactly those records subsequently updated by  $T1.S2$ , because they use the same predicate (*i.e.*, the same expression in their **WHERE** clause), and no other operations are executed between them. However,  $T1.S2$  fetches only the row (2, 43, 8), while  $T1.S3$  updates rows (2, 43, 8) and (2, 43, 53) due to its incorrect predicate matching. Existing approaches cannot find this bug for two reasons. First, the test case uses an aggregate function (*i.e.*, `min()`) and a subquery (*i.e.*, the **SELECT** in the **UPDATE** statement), which make the test case complex and not follow the test-case patterns of existing approaches (*e.g.*, ELLE can append only constant values instead of `min()` values). Second, the test case uses predicates, for which existing approaches lack support.

Figure 1(b) shows a test case generated by our approach, which is equivalent to the one shown in Figure 1(a). The three **SELECT** statements (*i.e.*,  $S0$ ,  $S1$ , and  $S2$ ) are moved before the two **UPDATE** statements (*i.e.*,  $S3$  and  $S4$ ), because all these **SELECT** statements are oblivious to the effects of the **UPDATE** statements. As  $T1.S3$  is executed immediately after  $T1.S2$ , the database state visible for  $T1.S2$  and  $T1.S3$  should be consistent. Therefore, we keep the statements of  $T1.S2$  and  $T1.S3$  adjacent (*i.e.*,  $S2$  and  $S3$ ). The reordered test case is executed *without using transactions*, and its execution results

should be the same as the original one, because the reordering does not change any expected behavior of each statement. In this case, the bug in MySQL breaks the equivalence.

Our insight is to generate semantically-equivalent test cases that are not wrapped as transactions, but produce the same execution results, by properly reordering the statements. Then, we can validate whether their equivalence indeed holds. Any discrepancy indicates a bug in the target DBMS. While for the aforementioned test case, it is intuitive that reordering the statements will not affect the execution results of follow-up test cases, we must reason, in general, about the dependencies of statements. To this end, we first propose *statement-dependency graphs*, a novel concept to describe the dependencies among executed statements, which provide finer-grained dependency information than transaction-dependency graphs [1, 17, 44]. This facilitates finding more bugs (as will be discussed in Section 5.3). To extract statement dependencies, we propose *SQL-level instrumentation*. Specifically, we insert additional statements to collect the execution results of each target statement in transactions. Based on the collected results, we can track the operation effects—including the effects of predicate operations—of each statement, and thus infer all possible statement dependencies. To generate semantically-equivalent test cases, we propose *transactional oracle construction*. Specifically, we topologically sort the acyclic statement-dependency graphs, whose sorted statement sequences are proved to be semantically equivalent to the original one. To guarantee the acyclicity of graphs, we iteratively delete statements in cycles before sorting. We execute the sorted statement sequences without transactions and compare their results to those from the corresponding transaction executions. Any difference reveals a bug in the tested DBMS.

We realized this approach as a practical tool called TxCheck. We evaluate TxCheck on three popular and extensively tested DBMSs, namely TiDB [46], MySQL [30], and MariaDB [29]. In total, TxCheck found 56 unique bugs, including 23 in TiDB, 18 in MySQL, and 15 in MariaDB. Among them, 52 bugs have been confirmed, 18 fixed, and 8 assigned CVE IDs; 30 are triggered in transaction executions. These results collectively demonstrate that TxCheck can find latent transactional bugs in mature production DBMSs.

Overall, we make the following contributions:

- At the conceptual level, we address the test-oracle problem of DBMS transaction testing by constructing semantically-equivalent test cases.
- At the technical level, we propose (1) statement-dependency graphs, which describe the dependencies among statements in executed transactions, (2) SQL-level instrumentation, which can capture all possible statement dependencies including the predicate-related dependencies, and (3) transactional oracle construction, which refines test cases and generates semantically-equivalent test cases for validation. We formally prove the correctness of our approach.

- At the practical level, we implement our approach into a tool, TxCheck, and evaluate it on three widely-used DBMSs (*i.e.*, TiDB, MySQL, and MariaDB). In total, TxCheck finds 56 unique bugs, most of which cannot be identified by existing approaches. TxCheck is open-sourced at <https://github.com/JZuming/TxCheck>.

## 2 Background

**Transactions in DBMSs.** A database transaction refers to a series of operations, for which DBMSs must guarantee atomicity, consistency, isolation, and durability (*i.e.*, *ACID*) [49]. This paper focuses on relational database management systems (RDBMSs), where a transaction typically consists of a group of SQL (*i.e.*, Structured Query Language) statements. Each statement performs read operations (*e.g.*, **SELECT** statements) or write operations (*e.g.*, **INSERT**, **DELETE**, and **UPDATE** statements). SQL statements commonly involve predicates (*e.g.*, **WHERE** clauses) for choosing desired rows that satisfy the requirements.

**Dependency Graphs.** Adya *et al.* [1, 2] propose transaction dependencies, which can be classified into two categories, namely *item dependencies* and *predicate dependencies*. Item dependencies describe the relationship among transactions on specific items (*i.e.*, rows in tables) they read from or write to. For example, transaction  $T_j$  *item-read-depends* on  $T_i$  if  $T_j$  reads an item version  $x_i$  that is written by  $T_i$ . A predicate dependency describes the relationship between two transactions constructed from the associated predicate operations. For example, transaction  $T_j$  *directly predicate-read-depends* on  $T_i$  if an item version  $x_i$  that is written by  $T_i$  is used for predicate matching of  $T_j$ .

Based on these dependencies, Adya *et al.* propose a transaction-dependency graph, called *Direct Serialization Graph* (DSG). DSGs can be used to formalize the expected behaviors of DBMSs under different isolation levels. For example, *Serializability* (PL-3) proscribes any directed cycle in a DSG, while *Repeatable Read* (PL-2.99) any directed cycles that dismiss certain predicate dependencies. Bailis *et al.* [5, 6] further extend DSGs to define several other isolation levels.

**Existing Approaches.** Both transaction-focused testing and verification approaches [4, 9, 11, 17, 44] have utilized dependency graphs. They typically use specific operation patterns to capture transaction dependencies. For example, to reduce the search space of possible transaction orders, COBRA [44] exploits the read-modify-write (RMW) patterns where a transaction reads from a key before writing to it. By restricting its writes to list-specific operations like “append”, ELLE [4] can naturally infer the transaction order from a list of values read.

While existing approaches [4, 9, 17, 44] such as ELLE have been successful in detecting a wide range of important bugs, they are limited in finding *deep* transactional bugs for two

main reasons. First, these approaches can use only simple operations (*e.g.*, writing key-value pairs) following their restricted operation patterns. However, many deep DBMS bugs can only be triggered by complex operations [21]. Second, existing approaches lack support for predicate operations in general. In contrast to read/write operations whose effects are explicitly reflected in the final execution results, the effects of predicate operations are implicit and difficult to track, because they are typically reflected in the intermediate processes (*e.g.*, choosing *a set of items* that satisfy the predicate conditions for subsequent read/write operations). However, predicates are commonly used in real-world transactions and involved in sophisticated features of DBMSs like predicate optimization [23]. Existing approaches do not consider predicate operations in their test cases, thus missing many bugs with respect to the transaction support of DBMSs. In addition, existing approaches focus on testing isolation guarantees while many transactional bugs are not necessarily related to database isolation.

## 3 Approach

In this section, we present a novel approach for addressing the challenges of testing transaction support in DBMSs, as illustrated in Figure 2. Our core idea is to extract the dependencies among statements in transactions and construct semantically-equivalent test cases according to the extracted dependency information. The constructed test cases are used as oracles to validate the original transaction executions by checking whether all statements in the test cases produce the same results. To realize this idea, we first define statement dependencies and propose a new concept, *statement-dependency graphs*, which describes the dependencies among statements in transactions. To derive statement-dependency graphs, we capture dependency information from specific transaction executions. Then, we generate semantically-equivalent test cases based on the captured information.

**Dependency Capturing.** To capture statement dependencies, we propose *SQL-level instrumentation*, which inserts SQL statements to collect execution information of each original statement in transactions. Using SQL to achieve this makes this approach a *black-box technique* that is applicable even for DBMS where testers lack access to the source code. Specifically, we instrument in two steps, item-tracking instrumentation and version-set-tracking instrumentation, which capture item dependencies and predicate dependencies, respectively. Statement-dependency graphs are built based on the outputs from the inserted and the original statements.

**Oracle Construction.** We propose *transactional oracle construction* to construct semantically-equivalent test cases. We first iteratively remove statements involved in cycles to make the statement-dependency graph acyclic, which is the precondition of the construction. Then, we perform topological sort-

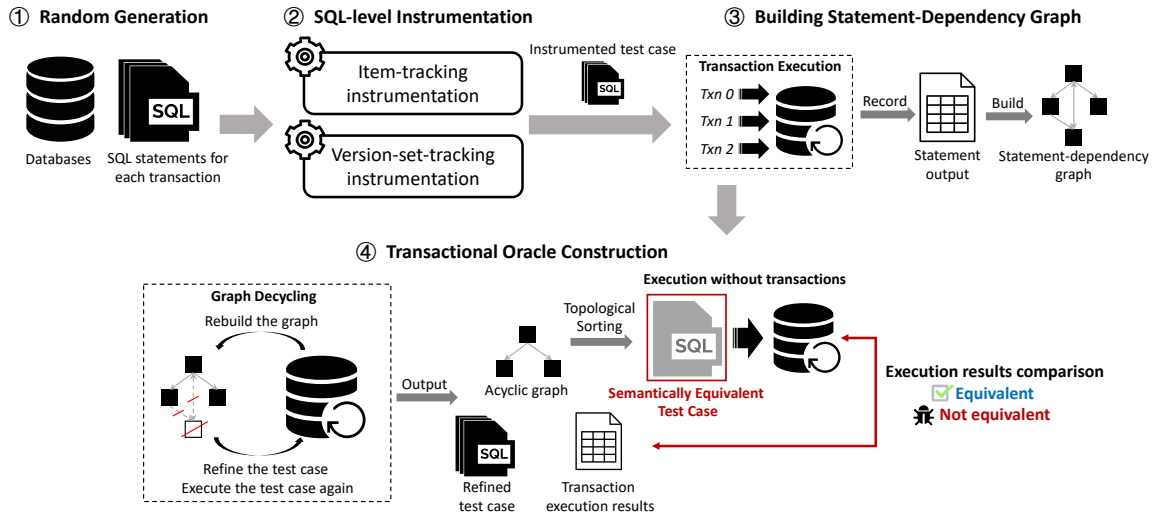

Figure 2: Approach overview.

ing on the acyclic graph to construct semantically-equivalent test cases. We execute these test cases without transactions and compare their execution results to those from the corresponding transaction executions. We prove that, for any correct DBMS, these results should be identical, thus any difference indicates an actual DBMS bug.

### 3.1 Statement-Dependency Graph

To construct semantically-equivalent test cases by reordering statements, we need to identify the dependencies between statements. We define seven kinds of statement dependencies, referring to transaction dependencies defined by Adya *et al.* [1, 2]. Each kind of statement dependency is shown in Figure 3. Specifically, we define three kinds of statement dependencies, shown in Figure 3(a)–(c), to model the relationship of two statements that read or write the same items. Three other kinds of dependencies, shown in Figure 3(d)–(f), are used to represent the dependencies established by predicate operations. The last one, direct stmt-value-write dependency shown in Figure 3(g), is used to model the event that the new value of an item installed by a statement is determined by the value of another item that is installed by another statement. The formal definitions (Definition 2–8) for these statement dependencies are given in Appendix A. Note that we do not count statement orders as dependencies, because when two statements access different data, the statements’ execution order will not affect their results.

In contrast to the dependencies defined by Adya *et al.* [1, 2], which describe the relationship between transactions, our definitions model the relationship between statements to provide finer-grained dependency information. Statement dependencies enable us to analyze the effects of each statement, which is needed for generating semantically-equivalent test cases accordingly, while transaction dependencies lack sufficient

information related to statements. Next, we further propose statement-dependency graphs, *SDG*, to model the executions of test cases at the statement level.

#### Definition 1 (Statement-Dependency Graph)

We define the statement-dependency graph constructed based on a statement execution history  $H$ , denoted as  $SDG(H)$ , as follows.  $SDG(H)$  is a directed graph, whose nodes represent the statements in committed transactions, and whose (directed) edges represent the dependencies between these committed statements. In particular, if statement  $S_j$  depends on statement  $S_i$ , there is a direct edge from  $S_i$  to  $S_j$ .

Note that statement-dependency graphs consider only statements in committed transactions. The statements in aborted transactions are dismissed because these statements conceptually do not affect the manipulated databases and other committed transactions. Figure 4 shows the statement-dependency graph for the test case in Figure 1(a). Statement-dependency graphs contain all dependency information related to statements and reflect the execution results of test cases at the statement level, which is the basis for generating semantically-equivalent test cases.

### 3.2 SQL-Level Instrumentation

To build statement-dependency graphs, we extract statement dependencies from transaction executions. In contrast to existing work, we aim to support test cases whose statements use predicates, without involving too many restrictions on test-case patterns. This section presents *SQL-level instrumentation*, a novel technique for extracting statement dependencies from transaction executions involving predicates.

The basic idea of SQL-level instrumentation is to insert statements to output the handled items before and after the operations performed by target statements. To realize this

Table t (id, value): (0,0)

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> select * from t; --- (0, 1) ← is dependent on
```

(a) Direct stmt-item-read dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> update t set value = 2; --- (0, 1) -> (0,2)
is dependent on ↓
```

(b) Direct stmt-item-write dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> select * from t; --- (0, 0) ← is dependent on ↑
```

(c) Direct stmt-item-anti dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> select * from t where value = 0; --- empty
is dependent on ↓
```

(d) Direct stmt-predicate-read dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> update t set value = 2 where value = 0; --- change nothing
is dependent on ↓
```

(e) Direct stmt-predicate-write dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> select * from t where value = 1; --- empty
is dependent on ↑
```

(f) Direct stmt-predicate-anti dependency

```
Sj> update t set value = 1; --- (0,0) -> (0,1)
...
Sj> insert into t values (1, (select min(value) from t)); --- insert (1, 1)
is dependent on ↓
```

(g) Direct stmt-value-write dependency

Figure 3: Examples for each kind of statement dependency.

Figure 4: Statement-dependency graph for Figure 1(a).

idea, SQL-level instrumentation requires tables in manipulated databases to contain at least two columns. We name these two columns as *PrimaryKey* column and *VersionKey* column, respectively. The column *PrimaryKey* is used to identify different items, and should not change after the items are inserted. The column *VersionKey* is used to identify different versions of each item, and should be assigned a new value different from any earlier values when the item is updated by statements. Besides these two, tables may have additional columns whose properties are unrestricted.

The statements in test cases should also follow these restrictions. Specifically, the statement performing write operations (e.g., **UPDATE** and **INSERT**) should change the *VersionKey* of the handled items to a new value, and each item updated by the same statement has the same *VersionKey*. The statement performing read operations (e.g., **SELECT**) should at least output the *PrimaryKey* and *VersionKey* of the items. Except for the *PrimaryKey* and *VersionKey* of items, we eschew imposing any additional restrictions for the generated statements.

SQL-level instrumentation operates in two phases: (1) item-tracking instrumentation, and (2) version-set-tracking instrumentation. Figure 5 shows how each phase instruments the test case in Figure 1. In item-tracking instrumentation, we insert a *Before-Write Read (BWR)* statement before each statement performing write operations (e.g., see T0.S1.BWR and T1.S3.BWR in Figure 5). *BWR* statements are designed to output the items that will be written and thus use the same predicates as the target statements. *BWR* statements can work only under isolation levels that satisfy Assumption 3, which

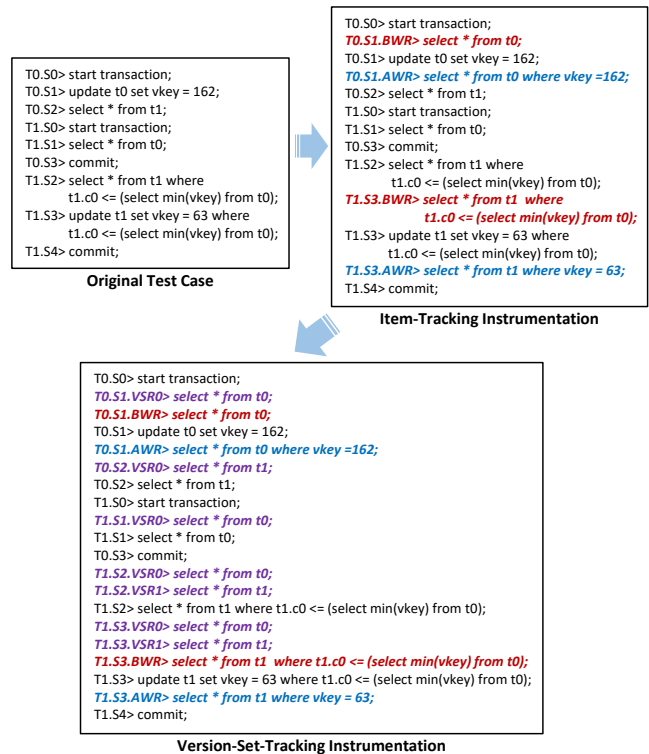

Figure 5: SQL-level instrumentation for Figure 1(a).

is discussed subsequently. We insert an *After-Write Read (AWR)* statement after each statement performing write operations (e.g., see T0.S1.AWR and T1.S3.AWR in Figure 5). *AWR* statements are used to output the new values of the items processed by target statements. To do so, *AWR* statements select items whose *VersionKeys* are equal to the assigned values in the target statements. In version-set-tracking instrumentation, we insert some *Version-Set Read (VSR)* statements before each statement (e.g., see T0.S1.VSR0 and T0.S2.VSR0 in Figure 5). To output the item versions referenced by target statements, *VSR* statements output all items in the tables ref-

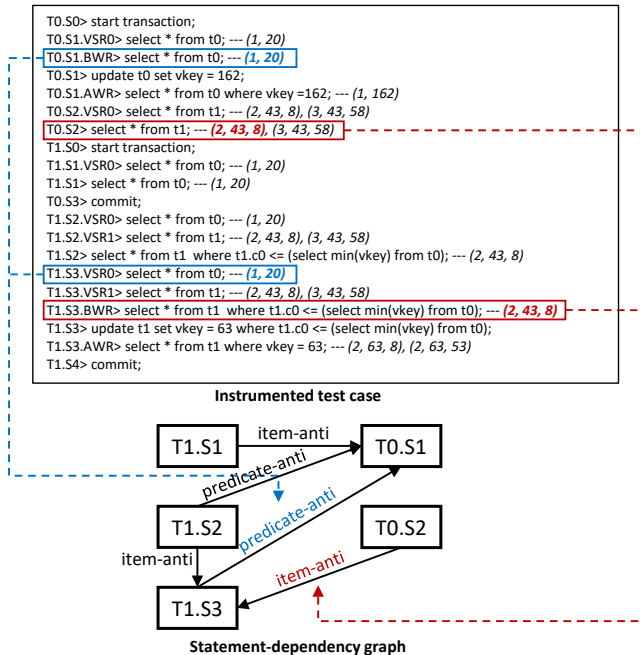

Figure 6: Inferring statement-dependency graphs for Figure 1.

erenced by the target statements.

Using the inserted *BWR*, *AWR*, and *VSR* statements, we can collect the execution information of each statement in transactions, and thus can infer possible statement dependencies. Figure 6 shows how the inserted statements are used to infer statement dependencies for the test case in Figure 1. To check whether statements  $T1.S3$  and  $T0.S2$  have dependencies between each other, we analyze the outputs of the corresponding statements and their inserted statements. The output of  $T0.S2$  and the output of *BWR* of  $T1.S3$  have an overlapping part (*i.e.*, item (2, 43, 8)), which means  $T0.S2$  reads an item that has not been updated by  $T1.S3$ . Therefore,  $T0.S2$  is (stmt-item-anti) depended on  $T1.S3$ . The outputs of *BWR* of  $T0.S1$  and *VSRs* of  $T1.S3$  also have an overlapping part (*i.e.*, item (1, 20)), which means that  $T0.S1$  will update an item that has been referenced by the predicates of  $T1.S3$ . Therefore,  $T1.S3$  is (stmt-predicate-anti) depended on  $T0.S1$ . Other dependencies can be inferred similarly.

We prove that each statement dependency proposed in Section 3.1 can be inferred based on the outputs of statements under certain assumptions. The detailed proof (Lemma 1–7) is presented in Appendix B. The assumptions are shown below:

**Assumption 1** No synchronization issues happen during the execution of transactions.

**Assumption 2** Statements can use item versions only in the tables that they have referenced.

**Assumption 3** For any two transactions,  $T_i$  and  $T_j$ , it is prohibited that  $T_i$  item-anti-depends on  $T_j$  for the item  $x$  while  $T_j$  item-write-depends on  $T_i$  for the same item  $x$ .

Figure 7: Isolation-level hierarchy defined by Adya *et al.* [1,2] and isolation levels supported by our approach.

These assumptions generally hold when we test DBMSs deployed locally (*i.e.*, without synchronization issues) with a proper isolation guarantee, which can be satisfied by the isolation levels equal to or stronger than Cursor Stability (PL-CS) or Monotonic View (PL-2L), according to Adya *et al.*'s definitions [1, 2]. Figure 7 shows the supported isolation levels. Specifically, Assumptions 1 and 2 are independent of isolation levels. In a transaction dependency graph, Cursor Stability prohibits cycles with an anti-dependency and one or more write-dependency edges such that all edges are related to one specific object. Assumption 3 prohibits cycles with exactly one anti-dependency edge and one write-dependency edge such that both edges are related to one specific object. Therefore, Cursor Stability satisfies Assumption 3. Monotonic View disallows cycles containing exactly one anti-dependency edge from one transaction to another transaction. It satisfies Assumption 3, because the phenomenon prohibited by Assumption 3 contains cycles with exactly one anti-dependency edge between transactions.

SQL-level instrumentation can accurately capture item dependencies without any false positives or negatives, but it may capture spurious predicate or value dependencies, according to Lemma 1–7. Such inaccuracies may be introduced by *VSR* statements; *VSR* statements output all items in the tables referenced by target statements. However, target statements may use only a part of the items in the tables to perform their predicate matching and value capturing, depending on the specific implementations of the DBMS. Therefore, *VSR* statements may output items that are not referenced by target statements. If these incorrectly outputted items match the outputs of other statements, spurious dependencies are captured. Therefore, the statement-dependency graph built by SQL-level instrumentation is a super graph of the actual statement-dependency graph. This issue does not affect the correctness of our testing approach (see Section 3.3 for the detailed discussion).

We further discuss the time complexity of using SQL-level instrumentation to infer dependencies. Suppose the database contains  $n$  items, and the test case contains  $m$  statements. In

the worst case, each *BWR* or *AWR* statement can output  $n$  items, and the *VSR* statements of each target statement can output, in total,  $n$  items. If the target statement is a read statement, it can output at most  $n$  items. When both two target statements are write statements, we need to check  $6n$  items (*i.e.*, outputs of *BWR*, *AWR*, and *VSR* statements of each target statement), while we need only check  $5n$  items when one of the target statements is a read statement (*i.e.*, outputs of *BWR*, *AWR*, and *VSR* statements of the write statement and outputs of the read statement and its *VSR* statements). Therefore, in the worst case, we may check whether two target statements have dependencies in  $O(6n)$  time using hash tables. To confirm the dependencies among  $m$  statements, we should check  $m(m - 1)$  dependencies, and thus the worst-case time complexity of the entire process is  $O(6n \cdot m(m - 1))$ , *i.e.*,  $O(m^2n)$ .

Existing work proves that checking histories in isolation levels is a polynomial-time (*e.g.*, *Read Committed*) or even NP-complete problem (*e.g.*, *Serializability* and *Snapshot Isolation*) [9, 33]. ELLE [4] can recover histories in  $O(m \cdot p)$ , where  $m$  is the number of operations, and  $p$  is the number of concurrent processes. However, ELLE restricts their test cases whose write operations can only append and cannot handle histories involving predicates. In contrast, SQL-level instrumentation can recover histories involving predicates and only requires test cases to maintain *PrimaryKey* and *VersionKey* for each item, within  $O(m^2n)$  time.

### 3.3 Transactional Oracle Construction

The statement-dependency graphs enable us to construct semantically-equivalent test cases. Our intuition is that if there is a reordered statement sequence whose statements follow the same dependency order in the statement dependency graph, the reordered statement sequence should produce the same results as the original one. To effectively test DBMSs' transaction support, we execute the reordered statements without transactions, which provides an oracle for validating the original test cases by checking whether each statement in the test cases produces the same results. To formalize our intuition, we first introduce a theorem based on statement-dependency graphs. The theorem is given below, and the details of its proof can be found in Appendix C.

**Theorem 1**  $SDG(H)$  is the statement-dependency graph built according to execution history  $H$ ,  $S(SDG(H))$  is the statement sequence generated by performing topological sorting on  $SDG(H)$ , and  $History(S(SDG(H)))$  is the history of the sorted statement sequence executed without transactions. If  $SDG(H)$  is acyclic,  $History(S(SDG(H)))$  and  $H$  give the same results for each statement in  $S(SDG(H))$ .

Theorem 1 suggests a high-level method for constructing semantically-equivalent test cases. Theorem 1 is not constrained to any specific isolation level and thus can apply at various isolation levels. Moreover, Theorem 1 can tolerate the

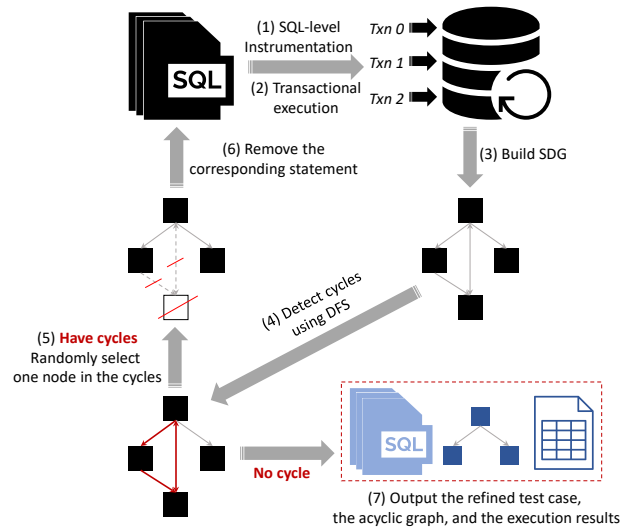

Figure 8: The process of refining test cases, whose SDG eventually becomes acyclic.

spurious predicate dependencies that stem from SQL-level instrumentation. Suppose  $G$  is the actual statement dependency graph and  $G'$  is  $G$  with additional spurious predicate dependencies, *i.e.*,  $G$  is a subgraph of  $G'$ . The semantically-equivalent test case constructed from  $G'$  will follow all the dependencies in  $G'$ , thus following all the dependencies in  $G$ . Hence, the constructed test case is also one of the topological sorting results of  $G$ . That is, the test case constructed from  $G'$  can also serve as an oracle.

Note that Theorem 1 has a precondition, *i.e.*, the  $SDG(H)$  should be acyclic. To satisfy this precondition, we perform *graph decycling* to eliminate all cycles in the graph. Then, we perform *oracle checking* to generate semantically-equivalent test cases by topologically sorting acyclic graphs. We execute these equivalent test cases without transactions and use their results to validate transaction executions.

**Graph Decycling.** The overview of graph decycling is shown in Figure 8. The idea is to break cycles in the graph by removing those statements involved in the cycles. Given a test case, we first instrument it (Step (1) in Figure 8) and then execute the instrumented test case using transactions (Step (2)). We can infer the SDG using the collected information from instrumented statements (Step (3)). Then, we check whether there is a cycle in the constructed SDG using depth-first search [39] (Step (4)). If there is at least one cycle in the graph, we randomly select one node in the cycles (Step (5)) and remove the corresponding statement in the test case (Step (6)). We re-execute the refined test case on the DBMS and start a new round of test-case refinement. Note that the re-execution is necessary, because a refined test case may result in the construction of a significantly different SDG, which might also contain new cycles. At the beginning of each round, the tested DBMS is reset to its initial state. When no cycle is detected in the SDG built from the refined test case, we output the refined

23    stmt ← GetStmtFromNode(node, test_case, graph);
24    PushToList(oracle_test_case, stmt);
25    RemoveNode(tmp_graph, node);
26  return oracle_test_case;

```

test case, its corresponding acyclic SDG, and its transaction execution results (Step (7)). The graph decycling always converges, because it cannot indefinitely remove statements from the test case where the number of statements is finite.

**Oracle Checking.** Algorithm 1 shows the workflow of oracle checking. The inputs to this workflow are the refined *test case*, the acyclic *graph*, and the transaction execution results *t\_results* from graph decycling. We first generate a semantically-equivalent test case, that is, *oracle\_test\_case*, using topological sorting (Line 2). Specifically, we initialize *oracle\_test\_case* as an empty sequence and *tmp\_graph* as *graph* (Line 18–19). In each round, we randomly select one node whose in-degree—the number of edges directed into the node—is zero and append the statement corresponding to this node to the end of *oracle\_test\_case* (Line 21–24). Then, we remove the node from *tmp\_graph* and delete the edges incident to this node (Line 25). The loop terminates if all nodes in *tmp\_graph* are removed (Line 20), and the process returns the constructed *oracle\_test\_case* (Line 26). After *oracle\_test\_case* is available, we initialize the target DBMS and execute the statements in *oracle\_test\_case* in order without transactions (Line 3–4). According to Theorem 1, for any correct DBMS implementation, *test\_case* and *oracle\_test\_case* should produce the same result. We first compare each statement output (Line 5–10). If their outputs differ, we have found a bug. If these comparisons succeed, we further check whether the final database contents are the same (Line 11–15). If they are different, a bug is also found.

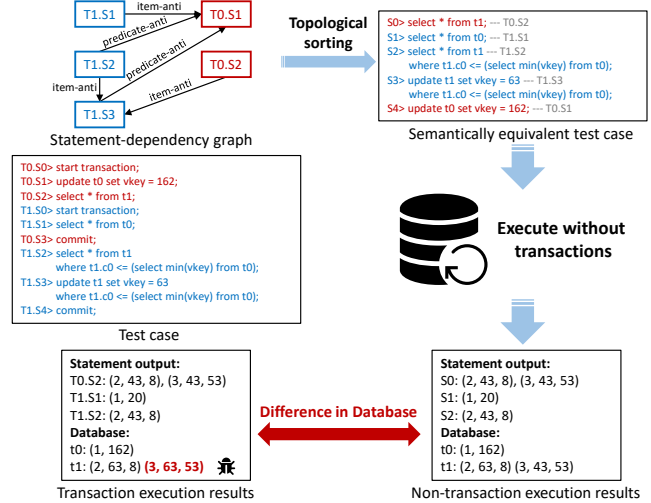

Figure 9: Oracle checking for the bug in Figure 1.

Figure 9 shows how we perform oracle checking on the test case in Figure 1(a). We first perform topological sorting on the acyclic statement-dependency graph. In the first round, T1.S1, T1.S2, and T0.S2 have zero in-degree, so we randomly pick one of them, for example, T0.S2. Then, T1.S1 and T1.S2 are picked. After T0.S2 and T1.S2 are removed from the graph, the in-degree of T1.S3 becomes zero, and T1.S3 is picked. Finally, T0.S1 is chosen as it is the only node in the graph. Therefore, the sorted statement sequence is [T0.S2, T1.S1, T1.S2, T1.S3, T0.S1]. Then, we execute the statement sequence without transactions and record the statement outputs and final database contents. These results are compared to the results produced by the original test case. We first check their statement outputs, which turn out to be the same. Then, we check their final database contents. Because their database contents are different on the value of one of the rows in table t1, we have found a bug.

## 4 Implementation

Based on our approach, we realized a tool, TxCheck, on top of SQLsmith [43]. The overall codebase consists of 14k lines of C++ code, where we implemented our approach with 3.5k lines (not including the code for supporting DBMSs).

Figure 10 shows the architecture of TxCheck. To test a DBMS, TxCheck first randomly generates a test case, which will be instrumented by SQL-level instrumentation. The instrumented test case is then refined by graph decycling to eliminate cycles in its statement-dependency graph, and by blocking scheduling to make sure that the instrumented statements will not be reordered by the blocking mechanism of the tested DBMS. TxCheck uses the refined test case and its transaction execution results to construct an oracle, which is a test case that is not wrapped as transactions (e.g., the test case shown in Figure 1(b)), but should produce the same results

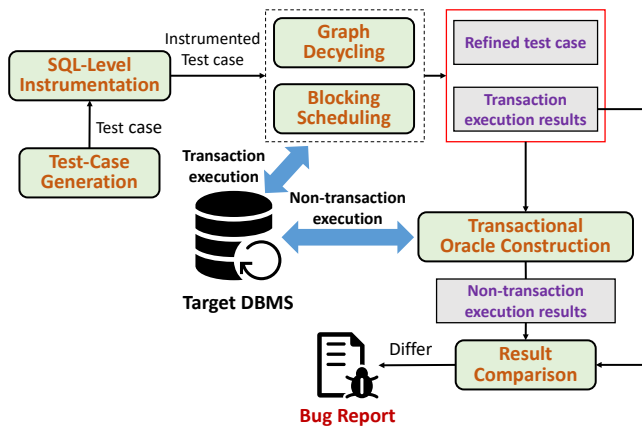

Figure 10: Architecture of TxCheck.

as the refined test case, according to Theorem 1. TxCheck then checks whether their results are indeed the same. If their results differ, TxCheck reports a bug. The following describes the implementation of TxCheck in detail.

**Test-case Generation.** TxCheck randomly generates a test case consisting of multiple transactions, and randomly determines the order in which the statements in these transactions are executed. For example, in Figure 1(a), T0 and T1 are the generated transactions, and [T0.S0, T0.S1, T0.S2, T1.S0, T1.S1, T0.S3, T1.S2, T1.S3, T1.S4] is the execution order for the statements in these transactions. The generated statements follow the constraints described in Section 3.2. As we do not restrict the statement format, TxCheck can apply other approaches to implementing statement generation. In this paper, we use SQLsmith [43] as the statement generator.

**Transaction Execution.** For each transaction in a test case, TxCheck sets up a client session that is responsible for issuing the statements of a transaction to which it is assigned. To avoid introducing non-determinism from concurrent executions, TxCheck sends statements to the DBMS following the order determined in the test-case generation. The order might be updated by block scheduling. After sending a statement, TxCheck sends the next statement only after the DBMS indicates that its execution is completed or blocked. While some concurrency bugs may be missed, sequential execution makes it significantly easier to reproduce bugs, which is generally appreciated by developers.

**Non-transaction Execution.** For each test case that is not wrapped as transactions (e.g., the test case in Figure 1(b)), TxCheck sets up only one client session for sequentially issuing the statements in the test case.

**Blocking Scheduling.** When statements in different transactions try to access the same data, a DBMS may block some of these statements to schedule transaction execution, which can disrupt the inserted statements of SQL-level instrumentation. Figure 11(a) shows an example in MySQL using *Repeatable Read* isolation level. T1.S1.BWR is the *BWR* statement of

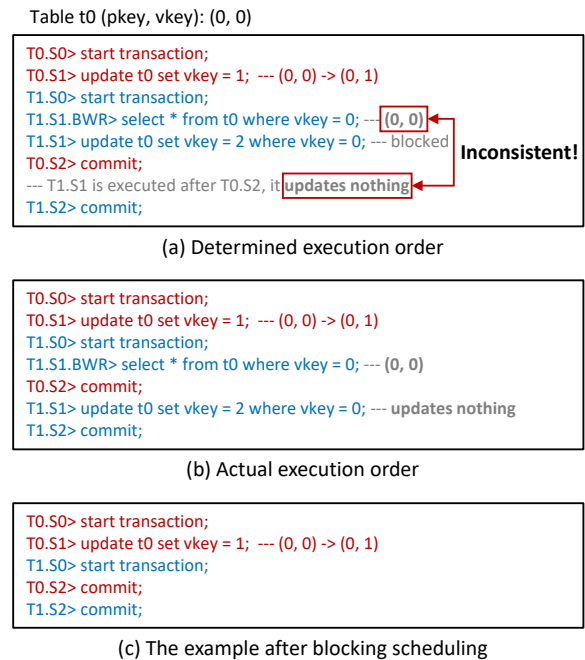

Figure 11: Example of MySQL blocking mechanism (in *Repeatable Read*) and blocking scheduling.

T1.S1. The DBMS executes T1.S1.BWR and outputs 1 row, and then tries to execute T1.S1. T1.S1 is blocked, because it tries to update the items that are being updated by T0.S1. The DBMS continues to execute T0.S2. After T0.S2 is executed, transaction T0 is finished, and then T1.S1 is executed automatically by the DBMS. T1.S1 updates nothing because there is no row whose vkey is 0. By design, T1.S1.BWR should output the items that will be updated by T1.S1. However, their results are inconsistent because T1.S1.BWR is executed before T0 commits but T1.S1 is executed after T0 commits. Figure 11(b) shows the actual execution order of the example. T1.S1.BWR and T1.S1 are separated by the COMMIT of T0.

To address the issues caused by the blocking mechanism of DBMSs, TxCheck adapts blocking scheduling, which makes sure that the inserted statements and the target statements will not be separated. TxCheck first executes statements according to the determined execution order. It records the actual statement execution order, which may be different from the determined order because some statements may be blocked. It checks whether there are situations where the inserted statements and their corresponding target statements are executed apart. It deletes the inserted statements and target statements in such situations. For example in Figure 11, T1.S1.BWR and T1.S1 are deleted. The refined test case is executed again following the recorded execution order in the last round. In the new execution, if all the target statements and corresponding inserted statements are executed adjacently, the blocking scheduling ends. Otherwise, it deletes statements according to the newly recorded real execution order and executes the re-

finer test case again. This process always converges, because it cannot delete statements indefinitely. Figure 11(c) shows the example refined by blocking scheduling.

**DBMS Support.** TxCheck can be easily adapted to test specific DBMSs. On average, we use 650 lines of code to support one DBMS. Each tested DBMS should provide interfaces to set up the DBMS, connect to the DBMS, shut down the DBMS, send statements in transaction sessions, and obtain execution results. In addition, if a DBMS can block statements in transaction execution, TxCheck needs to be provided with an interface for determining whether a statement is blocked. Setting a timeout for statements is an alternative way to check for blocking situations. However, it is inaccurate, because the DBMS may just be executing a long-running statement.

**Isolation Bug Detection.** TxCheck can also find isolation bugs, because statement dependencies can be easily converted to transaction dependencies according to their definitions. For example, if a statement  $S_i$  in transaction  $T_i$  depends on statement  $S_j$  in transaction  $T_j$ ,  $T_i$  depends on  $T_j$ . Therefore, TxCheck can convert statement-dependency graphs to transaction-dependency graphs. Then, TxCheck detects bugs that violate their isolation levels according to graph restrictions [1, 2, 5, 6]. However, because TxCheck may infer spurious predicate dependencies (Section 3.2), which introduce false alarms of isolation bugs, we only consider item dependency, which is accurate, in isolation bug detection.

**Memory Bug Detection.** As TxCheck involves both transaction and non-transaction executions, memory bugs triggered with or without transactions can be detected by TxCheck. We use ASan [40] as its memory bug checker.

## 5 Evaluation

We have evaluated TxCheck on three DBMSs, namely TiDB [46], MySQL [30], and MariaDB [29]. These DBMSs are widely used by industry and extensively tested by DBMS fuzzers [21, 22, 25, 35–37, 43, 53]. According to DB-Engines Ranking [13], MySQL is the second most popular relational DBMS, MariaDB the 8th, and TiDB the 49th. The GitHub repositories of TiDB, MySQL, and MariaDB have been starred more than 32K, 8K, and 4K times, respectively, demonstrating their popularity and maturity. We perform our evaluation on Ubuntu 20.04 with a 64-core AMD Epyc 7742 CPU at 2.25G Hz and 256GB RAM.

We evaluated TxCheck on the latest available releases of the targeted DBMSs. Specifically, for TiDB, we tested versions 5.4.0, 6.1.0, and 6.3.0, for MySQL, versions 8.0.28 and 8.0.30, and for MariaDB, versions 10.8.3 and 10.10.1. We tested MySQL and MariaDB under *Read Committed*, *Repeatable Read*, and *Serializability*, respectively. We did not test *Read Uncommitted* because it does not satisfy Assumption 3 (see Figure 7). TxCheck can be used to test *Read Committed*

Table 1: Numbers of bugs found by TxCheck and their status

DBMS	Found	Confirmed	Known	Fixed
TiDB	23	19	1	9
MySQL	18	18	1	3
MariaDB	15	15	4	1
<b>Total</b>	56	52	6	13

in MySQL (as also in MariaDB) because it supports consistent nonlocking reads [31] (e.g., read operations of SELECT), thus satisfying Assumption 3. We tested TiDB with its optimistic transaction mode and *Snapshot Isolation*, which is the only isolation level compatible with this mode [48]. We did not test the pessimistic transaction mode of TiDB [47], which does not satisfy Assumption 3.

We used TxCheck to continuously test the targeted DBMSs for three months; we stopped and restarted TxCheck only when we improved TxCheck with new SQL features. In general, TxCheck was able to find new bugs within several days after we implemented new features; however, certain bugs took more time to trigger (e.g., one or two weeks).

### 5.1 Bug Detection

As shown in Table 1, TxCheck found 56 unique bugs, including 23 in TiDB, 18 in MySQL, and 15 in MariaDB. Among them, 52 bugs were confirmed, 18 fixed, and 6 known.

**Bug Severity.** Regarding the 23 bugs found in TiDB, two were classified as *Critical* bugs, while 7 as *Major* bugs. The other bugs found in TiDB were assigned low severity (e.g., *Minor*). In MariaDB, all the found bugs were classified as *Critical* (9) or *Major* (6). Most of the bugs reported to the MySQL developers are confidential due to security concerns, so their severity is unavailable. 8 CVEs have been assigned to these security-related bugs. Additionally, 4 bugs posted publicly were classified as *Severe*. These results demonstrate that TxCheck is practical and effective in detecting critical bugs in production DBMSs.

**Bug Classification.** We classify the 56 bugs according to their root causes. Table 2 shows the results. The class "Transaction" includes the bugs found in transaction executions, and "Non-transaction" the bugs triggered in non-transaction executions, i.e., when the semantically-equivalent test cases are executed (see Section 3.3). The column "Crash" shows the number of bugs that crash DBMS servers, and "Oracle" refers to the bugs that are identified by oracle checking.

In total, TxCheck found 30 bugs triggered in transaction executions, which demonstrates TxCheck's capability for finding real transactional bugs in DBMSs. Among these bugs, 19 were identified by our oracle, and 11 crashed DBMS servers. In addition, 26 bugs were identified in the non-transaction executions, among which 23 crashed DBMS servers and 3

Table 2: Classifying the detected bugs

DBMS	Transaction		Non-transaction	
	Oracle	Crash	Oracle	Crash
TiDB	11	4	1	7
MySQL	4	2	0	12
MariaDB	4	5	2	4
<b>Total</b>	19	11	3	23

Figure 12: Venn diagrams showing the number of bugs found at different isolation levels. Bugs associated with a smaller circle of isolation level can also be found at larger circles of isolation levels.

were identified by oracle checking. Note that several bugs triggered in non-transaction executions make the execution results incorrect and different from the ones in transaction executions. This demonstrates that TxCheck can also detect incorrect behaviors triggered in non-transaction executions.

**Bugs at Different Isolation Levels.** For the 30 transactional bugs, Figure 12 shows the isolation levels where they are triggered. All 15 TiDB bugs are identified at *Snapshot Isolation*, which is the only tested isolation level in TiDB. In MySQL, 5 bugs can be found at all three tested isolation levels, while 1 only at *Repeatably Read*. In MariaDB, 6 bugs can be detected at all three tested isolation levels, while 1 at both *Read Committed* and *Repeatably Read*, and 2 only at *Read Committed*. Note that several transactional bugs are independent of isolation guarantees, which can be effectively detected by TxCheck at various levels.

## 5.2 Comparison with State of the Art

We demonstrate the advantages of our approach by (1) checking whether TxCheck can find new transactional bugs that cannot be found by the state of the art, and (2) discussing selected interesting bugs to show the effectiveness of TxCheck.

For comparison, we analyze the bug-triggering test cases of the 19 transactional bugs found by our oracle checking. We reduce each test case to a minimal bug-inducing version before analysis. Given that there exists no approach for finding general transactional bugs, we select ELLE [4] as competing tool (part of the prevalent testing framework Jepsen [18]). Elle is the state-of-the-art black-box checker for finding isolation

Table 3: Feature analysis of the 19 bug-triggering test cases

ID	DBMS	Features		ELLE
		Complex	Predicate	
1	TiDB	✓	✓	-
2	TiDB	✓	✓	-
3	TiDB	✓	✓	-
4	TiDB	-	-	✓
5	TiDB	-	-	-
6	TiDB	✓	✓	-

17	MariaDB	✓	✓	-
18	MariaDB	✓	✓	-
19	MariaDB	✓	✓	-

bugs, which are a specific kind of transactional bugs.

As shown in Table 3, among the 19 test cases, 17 use both complex statements and predicates. ELLE cannot generate such test cases, because (1) the complex statements do not follow the test-case patterns of ELLE whose write operations can only append; and (2) ELLE does not support predicates. Figure 1 depicts one of such bugs triggered by complex statements and predicates. Regarding the two bugs that do not involve complex operations and predicates, ELLE can find only one of them. We also analyze 11 transactional bugs that crash DBMS servers and find that all of them involve complex statements and predicates, for which ELLE lacks support. In the following, we first illustrate the only bug that can be found by both TxCheck and ELLE. Then, we discuss three representative bugs that are missed by ELLE.

**TiDB Bug: Isolation Violation.** Figure 13 shows a bug-triggering test case. ELLE can only detect this bug from the 56 bugs found by TxCheck as the corresponding test case does not contain predicates or complex operations. This bug triggers a prohibited phenomenon, *G-Slb*, in Snapshot Isolation [1, 2] used by TiDB. *G-Slb* is an anomaly where the transaction-dependency graph contains a cycle with exactly one anti-dependency edge. To find this bug, TxCheck converts the constructed statement-dependency graph to a transaction-dependency graph (see Section 4) and checks whether there is any prohibited phenomenon. This bug-finding process illustrates that TxCheck can also find isolation bugs.

**MySQL Bug: Aborted Transactions Have Effects.** Figure 14 shows a test case with two interleaving transactions. Transaction  $T_1$  inserts four items into table  $t_0$  and then rollbacks. Transaction  $T_0$  updates the items that satisfy a complex

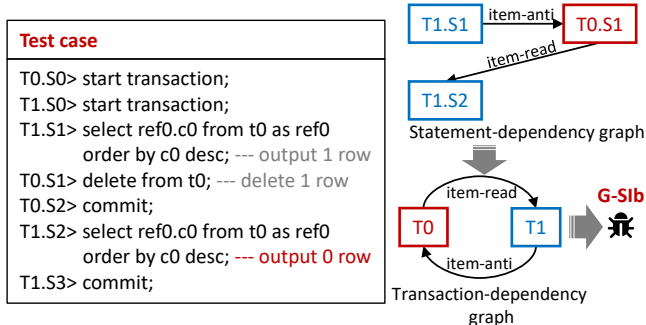

Figure 13: A test case violates *Snapshot* Isolation in TiDB.

Test case	Oracle
T0> start transaction; T1> start transaction; T1> insert into t0 values (141, 210000, ..., 74), ..., (141, 213000, ..., null); T1> rollback; T0> update t0 set vkey = 116 where t0.c5 not in ( select subq0.c0 as c0 from (select ...) as subq0 where subq0.c0 < (select ...) order by c0 asc); --- update 39 rows ✘ T0> commit;	update t0 set vkey = 116 where t0.c5 not in ( select subq0.c0 as c0 from (select ...) as subq0 where subq0.c0 < (select ...) order by c0 asc); --- update 0 row

Figure 14: An aborted transaction affects the results of a committed transaction in MySQL.

predicate (*i.e.*, the **WHERE** clause of the **UPDATE** statement) from table  $t_0$  and then commits. This test case is semantically-equivalent to executing the **UPDATE** statement on the same databases as the aborted transaction must not cause any visible side effects [1, 41]. However, MySQL produces different results: one test case updates 39 rows while the other zero rows. ELLE cannot find this bug as it involves predicates and complex operations, for which ELLE lacks support.

**TiDB Bug: Incorrect Transactional Calculation.** As shown in Figure 15, the test case contains only one transaction and uses only simple operations without predicates. ELLE can generate such a test case, at least conceptually. However, ELLE cannot find this bug, because it does not violate any isolation specification rather than makes the DBMS return incorrect results. TxCheck finds this bug by constructing semantically-equivalent test cases.

**MariaDB Bug: Crash Caused by Transactions.** As shown in Figure 16, the test case contains two interleaved transactions. Transaction T1 first inserts a couple of items into table  $t_0$ . Then, transaction T0 executes a **DELETE** statement with a complex **WHERE** clause as its predicate. The deletion is blocked because its predicate matching references certain items of table  $t_0$ , which have just been updated by the **INSERT** statement of T1. Only after T1 commits or aborts, can the **DELETE** statement be unblocked. While the deletion of T0 is blocked, transaction T1 executes a simple **UPDATE** statement, which eventually crashes the MariaDB server. This bug is

Test case	Oracle
T0> start transaction; T0> update t_0 set c_0 = t_2.c_1; T0> select count(c_2) from t_0; --- output 39 ✘ T0> commit;	update t_0 set c_0 = t_2.c_1; select count(c_2) from t_0; --- output 36

Figure 15: A test case makes TiDB return incorrect results.

Test case
T0> start transaction; T1> start transaction; T1> insert into t0 (vkey, pkey, c0) values (89,188000,40), ..., (97, 230000, 9); T0> delete from t1 where exists ( select ref0.c0 from t2 as ref0 where t1.c0 not in ( select ref3.vkey as c0 from (t0 as ref2 left outer join t2 as ref3 on (ref2.vkey = ref3.vkey)) where ref3.pkey >= ref2.vkey)); --- blocked T1> update t2 set vkey = 99; --- crash ✘

Figure 16: Two transactions crash the MariaDB server.

due to a concurrency issue where one of the threads performs complex operations that make the DBMS enter erroneous states. ELLE cannot find this bug as it does not support such complex operations involving predicates.

### 5.3 Design Choice Analysis

We had two considerations while designing our approach. First, can we use existing transaction-dependency graphs, *e.g.*, Directed Serialization Graph (DSG) [1, 2], instead of the proposed statement-dependency graphs? Second, when performing topological sorting, TxCheck randomly selects one node if there are multiple nodes with zero in-degree. Does the random strategy affect the results?

**Using Transaction-dependency Graphs.** We argue that using transaction-dependency graphs may miss bugs. A transaction-dependency graph in some isolation levels may have cycles as some transactions reference the items that other transactions have referenced. To construct transactional oracles, we must refine a test case to ensure the acyclicity of the associated graph. However, a test case may have an acyclic statement-dependency graph, but a cyclic transaction-dependency graph. Such test cases are unable to be topologically sorted at the transaction level, and thus interesting test cases may be discarded.

To demonstrate that using transaction-dependency graphs may miss bugs, we check the transaction-dependency graphs of the 19 transactional bugs found by our oracle checking. We first check the graphs built on minimized test cases and find that all the constructed transaction-dependency graphs miss cycles. It is unsurprising as, when minimizing the test cases, we delete all the unnecessary clauses and statements,

Table 4: Analysis of transaction-dependency graphs

DBMS	Test cases	Txn-cycle
TiDB	11	3
MySQL	4	1
MariaDB	4	2
<b>Total</b>	<b>19</b>	<b>6</b>

Figure 17: The statement-dependency and transaction-dependency graphs of the test case in Figure 1.

which makes the test cases reference much fewer items than the non-minimized ones. However, randomly generated test cases inevitably contain many redundant parts [28, 34]. To understand whether the test cases generated by TxCheck contain cycles in transaction-dependency graphs, we check the non-minimized test cases accordingly. Table 4 shows the results. The column *Txn-cycle* refers to the number of test cases that have cycles in transaction-dependency graphs.

The results show that 6 bug-triggering test cases have cycles in transaction-dependency graphs. If we use transaction-dependency graphs instead of statement-dependency graphs, these test cases are not suitable for constructing oracles as topological sorting cannot be performed for cyclic graphs. Hence, around one-third (6 out of 19) of the bugs would be missed. The test case in Figure 1 exemplifies such a bug. Figure 17 presents its corresponding statement-dependency and transaction-dependency graphs, respectively. The statement-dependency graph does not have cycles, so topological sorting can be performed at the statement level, which reveals the bug. Topological sorting is infeasible at the transaction level as the transaction-dependency graph is cyclic.

**Random Topological Sorting.** TxCheck topologically sorts statement-dependency graphs to construct oracles. If TxCheck encounters multiple nodes whose in-degrees are zero during sorting, it randomly selects one of them. In this way, TxCheck chooses only one of the topological sorting results to construct the oracle. For any correct DBMS, all the topological sorting results must be the same as the transaction execution results according to Theorem 1. However, when bugs are triggered, the test cases executed with transactions and some of the sorted test cases may produce the same, yet incorrect results. If TxCheck, unfortunately, chooses such sorted test cases, bugs may be overlooked.

Table 5: Analysis of topological sorting: \* labels the test cases that generate millions of topological sorting results, where we randomly select 10k to check whether they can trigger bugs

ID	DBMS	Sort	Trigger	ID	DBMS	Sort	Trigger
1	TiDB	1	1 (100%)	11	TiDB	1260	1224 (97%)
2	TiDB	32	32 (100%)	12	MySQL	6	6 (100%)
3	TiDB	12	12 (100%)	13	MySQL	1	1 (100%)
4	TiDB	-	-	14	MySQL	1	1 (100%)
5	TiDB	1	1 (100%)	15	MySQL	10k*	10k (100%)
6	TiDB	6	6 (100%)	16	MariaDB	2	2 (100%)
7	TiDB	6	6 (100%)	17	MariaDB	1	1 (100%)
8	TiDB	30	30 (100%)	18	MariaDB	1	1 (100%)
9	TiDB	96	96 (100%)	19	MariaDB	10k*	10k (100%)
10	TiDB	36	36 (100%)				

We show that such missed bugs are rare in practice. Typically, transactional bugs affect the results of transaction executions, while non-transaction executions of the topologically sorted test cases would not be affected. Therefore, most sorted test cases should execute correctly and can be used as oracles to reveal bugs. To demonstrate this, we analyze the 19 transactional bugs found by our oracle checking. The analyzed test cases are not minimized as we intend to obtain results that are close to those from the generated test cases in practice. Table 5 shows the results. The column *Sort* shows the number of all possible topological sorting results for the statement-dependency graphs. The column *Trigger* refers to the number of sorting results that successfully trigger the bugs.

Among the 19 test cases, the sorting results of 17 can stably trigger the bugs with 100% success rates. Bug 4 is found by checking transaction-dependency graphs, which do not involve topological sorting, as discussed in Section 5.2. The test case for bug 11 produces 1260 possible sorting results, among which 1224 can trigger the bug. It indicates that missed bugs can indeed happen with, however, a low probability (less than 3%). Two bug-triggering test cases (bugs 15 and 19) generate millions of sorting results. Both of them contain dozens of statements and involve few dependencies. When the dependency constraint is weak, the number of possible topological sorting will explode (*e.g.*, without any dependency, 12 statements can already amount to 12!, *i.e.*, over 480 million, sorting results). We randomly select 10K sorting results for each test case and find that all of them can trigger the bugs. These results show that randomly selecting one topological sorting result for oracle checking is practical and effective.

## 6 Discussion

**Test-case Generation.** TxCheck generates databases and transactions randomly for testing. Such random generation may be inefficient to explore corner test cases and thus may miss bugs. Fuzzing is a promising technique for generating infrequently executed test cases [3, 10, 16, 19, 27], and has been adopted in DBMS testing [21, 50, 53]. However, traditional fuzzing techniques cannot be directly utilized in DBMS

transaction testing. First, code coverage, which is commonly used as the fuzzing feedback, is not well suited because it cannot measure transaction interleavings. Second, random mutations used by most fuzzers are ineffective for generating transactions with complex data dependencies. One promising approach to addressing these challenges is to design new coverage feedback and mutation strategies following work on concurrency fuzzing [12, 20, 51].

**Predicate Handling.** It is challenging to recover transaction histories involving predicates [4, 44], for which we provide a possible solution. We instrument *Version-Set Read (VSR)* statements to capture items referenced by predicates by counting all items in the referenced tables. However, as discussed in Section 3.2, this method may overcount the referenced items because it is unnecessary that all items in the referenced tables would be referenced. Therefore, TxCheck may build spurious dependencies between statements. To mitigate this issue, one may utilize domain-specific knowledge. For example, we can customize *VSR* statements for each specific kind of statement used in transactions by referring to the corresponding SQL grammars and features.

**Data-intensive Transaction.** Existing work [21, 22, 35–37, 53] demonstrates that many DBMS bugs can be triggered without using much data. We follow this insight; each database generated by TxCheck generally contains 50-80 rows of data. However, some transactional bugs may hide in code only reached when intensive data is processed. To find such bugs, we plan to enable TxCheck to generate databases with large amounts of data. However, as TxCheck needs to reset database states after each test, its performance will be significantly degraded when TxCheck resets complicated databases. We plan to experiment with snapshot techniques to help improve testing performance by following and adapting existing work [24, 38].

## 7 Related Work

**Transaction Testing.** Transaction-testing approaches validate the correct uses of transactions in applications [14, 15] or the correct implementations of transaction support of DBMSs [4, 9, 11, 17, 44]. AGENDA [14, 15] tests DB-based applications that utilize transactions to perform certain tasks. It generates test cases according to user-provided specifications. A bug is reported if the application incorrectly constructs transactions that violate the provided specifications. The black-box isolation checkers ELLE [4], COBRA [44], and POLYSI [17] examine whether the transaction support of DBMSs functions correctly. ELLE generates transactions that use “append” operations as writes and can naturally recover their version order according to the list of values. COBRA and POLYSI focus respectively on validating the *Serializability* and *Snapshot Isolation* guarantees of transactions in DBMSs and develop several techniques (e.g., read-modify-

write transaction-based version order inferring, compact constraint encoding for SMT solving, and parallel hardware) to enable fast dependency inference. Unlike existing checkers, TxCheck focuses on testing the transaction support of DBMSs while relaxing the constraints on test-case patterns and enabling complex transaction generation. Moreover, TxCheck provides a practical solution to inferring predicate dependencies, a challenging problem in DBMS transaction testing.

**DBMS Testing.** Automated testing approaches have been proposed to find other types of bugs in DBMSs, such as logic bugs [35–37, 52], security bugs [21, 43, 50, 53], and performance bugs [22, 26]. SQLancer [42] is a well-known DBMS testing tool for detecting logic bugs, which integrates several approaches [35–37]. PQS [37] constructs queries that require DBMSs to return target items from manipulated databases: a logic bug is reported if the tested DBMS fails to return such items. TLP [36] designs some patterns to partition an original query into three separate queries, so that the union of the separated queries’ results must be the same as the original query’s result; otherwise, TLP reports a bug. Focusing on memory bugs, both SQUIRREL [53] and DynSQL [21] can generate more diverse test cases. SQUIRREL utilizes intermediate representations to model the structures of queries and the dependencies between statements. This enables SQUIRREL to generate queries containing multiple statements. By merging the query generation and query processing, DynSQL incrementally generates complex and valid queries using the state information of DBMSs. We also design TxCheck for tackling the oracle problem. However, TxCheck focuses on bugs triggered in transactional scenarios. In addition, with moderate test-case pattern constraints, TxCheck can handle complex test cases and expose deep transactional bugs.

## 8 Conclusion

We have presented a novel DBMS transaction testing approach, along with the practical tool TxCheck. Our approach is based on statement-level dependency graphs and can generate semantically-equivalent test cases to validate the transaction executions. TxCheck has found 56 unique bugs in three widely-used DBMSs, among which 52 have been confirmed and 18 fixed. Thanks to its generality and effectiveness, we expect TxCheck to help developers design and implement correct and reliable DBMS transaction support. Moreover, our approach could be utilized to infer predicate-related dependencies in recovering transaction histories.

## Acknowledgments

We thank the anonymous OSDI reviewers and our shepherd, Tianyin Xu, for their valuable feedback on earlier versions of this paper. We also thank the DBMS developers for triaging and fixing our reported bugs.

## A Definition for statement dependencies

We define statement dependencies in the same fashion as for the transaction dependencies defined by Adya *et al.* [1, 2].

### Definition 2 (Directly stmt-item-read-depends)

Statement  $S_j$  directly stmt-item-read-depends on statement  $S_i$  if  $S_i$  installs an item version  $x_i$  while  $S_j$  reads  $x_i$ .

### Definition 3 (Directly stmt-item-write-depends)

Statement  $S_j$  directly stmt-item-write-depends on statement  $S_i$  if  $S_i$  installs an item version  $x_i$  while  $S_j$  installs  $x$ 's next version (after  $x_i$ ) in the version order.

### Definition 4 (Directly stmt-item-anti-depends)

Statement  $S_j$  directly stmt-item-anti-depends on statement  $S_i$  if  $S_i$  reads an item version  $x_k$  while  $S_j$  installs  $x$ 's next version (after  $x_k$ ) in the version order.

### Definition 5 (Directly stmt-predicate-read-depends)

Statement  $S_j$  directly stmt-predicate-read-depends on statement  $S_i$  if  $S_j$  performs an operation  $r_j(P: \text{Vset}(P))$  while  $S_i$  installs an item version  $x_i$  that is included in  $\text{Vset}(P)$ .

### Definition 6 (Directly stmt-predicate-write-depends)

Statement  $S_j$  directly stmt-predicate-write-depends on statement  $S_i$  if either (1)  $S_j$  overwrites an operation  $w_i(P: \text{Vset}(P))$  performed by  $S_i$ , or (2)  $S_j$  executes an operation  $w_j(Q: \text{Vset}(Q))$  while  $S_i$  installs an item version  $x_i$  that is included in  $\text{Vset}(Q)$ .

### Definition 7 (Directly stmt-predicate-anti-depends)

Statement  $S_j$  directly stmt-predicate-anti-depends on statement  $S_i$  if  $S_j$  overwrites an operation  $r_i(P: \text{Vset}(P))$  performed by  $S_i$ .

### Definition 8 (Directly stmt-value-write-depends)

Statement  $S_j$  directly stmt-value-write-depends on statement  $S_i$  if either (1)  $S_i$  executes an operation  $w_i^{\text{value}}(E: \text{Vset}(E))$  where  $x_k$  is included while  $S_j$  install  $x$ 's next version (after  $x_k$ ) in version order, or (2)  $S_j$  executes an operation  $w_j^{\text{value}}(F: \text{Vset}(F))$  while  $S_i$  installs  $x_i$  that is included in  $\text{Vset}(F)$ . Here, statement  $S_i$  performs  $w_i^{\text{value}}(E: \text{Vset}(E))$  if  $S_i$  installs an item version whose values are based on expression  $E$  and the system (conceptually) reads all needed versions in  $\text{Vset}(E)$ .

## B Proof related to SQL-level instrumentation

Assumption 1 prohibits statements use old item versions while the newer ones are conceptually available. This can happen in distributed DBMSs when a new item version is produced but not well-synchronized, and thus the old version is still used in some machines. However, this work focuses on bugs in database engines deployed in local machines. Therefore, it is reasonable to assume that every item version is well-synchronized. Assumption 2 ensures that the inserted VSR

statements can correctly work. Assumption 3 ensures that the inserted BWR statements read the same item version used in the target statements.

**Lemma 1** Statement  $S_j$  directly stmt-item-read-depends on statement  $S_i \Leftrightarrow$  outputs of the AWR statement of  $S_i$  and outputs of  $S_j$  have intersections.

**Proof:** (1) Statement  $S_j$  directly stmt-item-read-depends on statement  $S_i \Rightarrow$  outputs of the AWR statement of  $S_i$  and outputs of  $S_j$  have intersections. Because  $S_j$  directly write-read depends on  $S_i$ , there is an item  $x$  such that  $S_i$  installs version  $x_i$  and  $S_j$  reads  $x_i$ .  $S_i$  installs version  $x_i$ , so  $x_i$  must be included in the output of AWR of  $S_i$ .  $S_j$  reads  $x_i$ , so  $x_i$  must be in the output of  $S_j$ . So the output of AWR of  $S_i$  and the output of  $S_j$  have intersections.

(2) Statement  $S_j$  directly stmt-item-read-depends on statement  $S_i \Leftarrow$  outputs of the AWR statement of  $S_i$  and outputs of  $S_j$  have intersections. Suppose  $x_k$  is one of the intersected item versions.  $x_k$  is in the output of AWR of  $S_i$ , so  $x_k$  must be installed by  $S_i$  because  $S_i$  is the only one statement that can assign the corresponding *VersionKey* value to  $x_k$  that matches the predicates of AWR of  $S_i$ .  $x_k$  is also in the output of  $S_j$ , so  $x_k$  is read by  $S_j$ . So  $S_i$  installs an item version  $x_k$  and  $S_j$  reads  $x_k$ . Therefore,  $S_i$  write-read depends on  $S_j$ .

Combining (1) and (2), we prove Lemma 1.

**Lemma 2** Statement  $S_j$  directly stmt-item-write-depends on statement  $S_i \Leftrightarrow$  outputs of the AWR statement of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections.

**Proof:** (1) Statement  $S_j$  directly stmt-item-write-depends on statement  $S_i \Rightarrow$  outputs of the AWR statement of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections. Because  $S_j$  directly write-write depends on  $S_i$ ,  $S_i$  installs a version  $x_i$  and  $S_j$  installs  $x$ 's next version (after  $x_i$ ) in the version order.  $S_i$  installs a version  $x_i$ , so  $x_i$  must be in the output of AWR of  $S_i$ . Suppose  $x_k$  is the version of item  $x$  that is used in the predicate matching of  $S_j$ .  $x_k$  must satisfy the predicate of  $S_j$  because  $S_j$  is going to install a new version for item  $x$ . As BWR of  $S_j$  uses the same predicate as  $S_j$ ,  $x_k$  must be in the output set of BWR of  $S_j$ . Suppose  $S_j$  is going to install  $x_j$ , there must be  $x_k \ll x_j$ . And  $x_j$  is  $x_i$ 's next version, so  $x_k$  is  $x_i$ , or  $x_k \ll x_i$ .

We assume that  $x_k \ll x_i$ . (a) If  $S_i$  and  $S_j$  are in the same transaction.  $x_i$  must be installed before  $x_j$ , which is installed by  $S_j$ , and  $x_k \ll x_i$ . Therefore, the BWR of  $S_j$  must read version  $x_i$  instead of  $x_k$ . Conflict. (b) If  $S_i$  and  $S_j$  are in different transactions,  $T_i$  and  $T_j$ . Because  $T_j$  reads  $x_k$ , and  $T_i$  installs  $x_i$ , which is after  $x_k$ ,  $T_i$  item-anti-depends on  $T_j$ . Because  $T_i$  installs  $x_i$ , and  $T_j$  installs  $x_j$  that are after  $x_i$ ,  $T_j$  item-write-depends on  $T_i$ . Conflict with Assumption 3.

Combining (a) (b), we get  $x_k \ll x_i$  in conflict. So  $x_k$  is  $x_i$ . So  $x_i$  is in the output of BWR of  $S_j$ . And  $x_i$  is in the output of

AWR of  $S_j$ . The output of AWR of  $S_i$  and the output of BWR of  $S_j$  have intersections.

(2) Statement  $S_j$  directly stmt-item-write-depends on statement  $S_i \Leftarrow$  outputs of the AWR statement of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections. Suppose  $x_k$  is one of the intersected item versions.  $x_k$  is in the output of AWR of  $S_i$ , so  $x_k$  must be installed by  $S_i$  because  $S_i$  is the only one statement that can assign the corresponding *VersionKey* value to  $x_k$  that matches the predicates of AWR of  $S_i$ .  $x_k$  is in the output of BWR of  $S_j$ , so  $x_k$  satisfies the predicate of BWR of  $S_j$ , and it satisfies the predicate of  $S_j$ . Therefore,  $S_j$  will install a new version of  $x$ . So  $S_i$  installs a version  $x_k$  and  $S_j$  installs  $x$ 's next version (after  $x_k$ ) in the version order, which means that  $S_j$  directly write-write depends on  $S_i$ .

Combining (1) and (2), we prove Lemma 2.

**Lemma 3** Statement  $S_j$  directly stmt-item-anti-depends on statement  $S_i \Leftrightarrow$  outputs of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections.

**Proof:** (1) Statement  $S_j$  directly stmt-item-anti-depends on statement  $S_i \Rightarrow$  outputs of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections. Because  $S_i$  directly stmt-item-anti depends on  $S_j$ ,  $S_i$  reads an item version  $x_k$  and  $S_j$  installs  $x$ 's next version (after  $x_k$ ) in the version order. Suppose  $x_h$  is the version of item  $x$  that is used in the predicate matching of  $S_j$ .  $x_h$  must satisfy the predicate of  $S_j$  because  $S_j$  is going to install a new version for item  $x$ . As BWR of  $S_j$  uses the same predicate as  $S_j$ ,  $x_h$  must be in the output of BWR of  $S_j$ . Suppose  $S_j$  is going to install  $x_j$ , there must be  $x_h \ll x_j$ . While  $x_j$  is  $x_k$ 's next version, so  $x_k$  is  $x_h$ , or  $x_h \ll x_k$ .

We assume that  $x_h \ll x_k$ : (a)  $S_i$  and  $S_j$  are in the same transaction.  $S_i$  must be before  $S_j$ .  $S_i$  reads version  $x_k$ , and thus  $S_j$  must use a version of  $x$  that is after  $x_k$  or equal to  $x_k$  (Assumption 1). However,  $S_j$  uses version  $x_h$ , and  $x_h \ll x_k$ . Conflict. (b)  $S_i$  and  $S_j$  are in different transactions,  $T_i$  and  $T_j$ . Suppose statement  $S_k$  of transaction  $T_k$  installs version  $x_k$ . If  $T_k$  is  $T_j$ ,  $S_k$  must be before  $S_j$  because  $S_j$  installs  $x_k$ 's next version. So  $x_k$  is visible to  $S_j$ , and  $S_j$  must use  $x_k$  instead of  $x_h$  ( $x_h \ll x_k$ ). Conflict. So  $T_k$  is not  $T_j$ . Because  $T_j$  reads  $x_h$ , and  $T_k$  installs  $x_k$  that are after  $x_h$ , so  $T_k$  item-anti-depends on  $T_j$ . And  $T_j$  installs  $x_j$  that are after  $x_k$ , so  $T_j$  item-write-depends on  $T_k$ . Conflict with Assumption 3.

Combining (a) (b), we get  $x_h \ll x_k$  in conflict. So  $x_k$  is  $x_h$ . So  $x_k$  is in the output of BWR of  $S_j$ . And  $x_k$  is in the output of  $S_i$ , The output of  $S_i$  and the output of BWR of  $S_j$  have intersections.

(2) Statement  $S_j$  directly stmt-item-anti-depends on statement  $S_i \Leftarrow$  outputs of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections. Suppose  $x_k$  is one of the intersected items.  $x_k$  is in the output of BWR of  $S_j$ , so  $x_k$  satisfies the predicate of BWR of  $S_j$ , and thus it satisfies the predicate of  $S_j$  ( $S_j$  and BWR of  $S_j$  use same version of  $x$ ). Therefore,  $S_j$  will install a version after  $x_k$ .  $x_k$  is in the output of  $S_i$ , so  $x_k$  is read by  $S_i$ . So  $S_i$  reads a item version  $x_k$  and  $S_j$  installs  $x$  with

a version after  $x_k$  in the version order. Therefore,  $S_i$  directly stmt-item-anti-depends on  $S_j$ .

Combining (1) and (2), we prove Lemma 3.

**Lemma 4** Statement  $S_j$  directly stmt-predicate-read-depends on statement  $S_i \Rightarrow$  outputs of the AWR statement of  $S_i$  and outputs of one of the VSR statements of  $S_j$  have intersections.

**Proof:** Statement  $S_j$  directly stmt-predicate-read-depends on statement  $S_i$ , which means that  $S_j$  performs an operation  $r_j(P: Vset(P))$ , and there is an item version  $x_i$  that is installed by  $S_i$  and  $x_i \in Vset(P)$ . Because  $x_i$  is installed by  $S_i$ , the  $x_i$  must be included in the output of AWR of  $S_i$ . Because VSRs of  $S_j$  outputs all item versions in the referenced tables, according to Assumption 2, all referenced item versions should be outputted by VSRs of  $S_j$ . Because  $x_i \in Vset(P)$ , at least one of the VSRs of  $S_j$  outputs  $x_i$ . So outputs of the AWR statement of  $S_i$  and outputs of one of the VSR statements of  $S_j$  have intersections. Proved.

**Lemma 5** Statement  $S_j$  directly stmt-predicate-write-depends on statement  $S_i \Rightarrow$  (1) outputs of one of the VSR statements of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections, or (2) outputs of the AWR statement of  $S_i$  and outputs of one of the VSR statements of  $S_j$  have intersections.

**Proof:** If statement  $S_j$  directly stmt-predicate-write-depends on statement  $S_i$ , according to Definition 6, it can be (1)  $S_j$  overwrites an operation  $w_i(P: Vset(P))$  performed by  $S_i$ , or (2)  $S_j$  executes an operation  $w_j(Q: Vset(Q))$  while  $S_i$  installs an item version  $x_i$  that is included in  $Vset(Q)$ .

For case (1),  $S_j$  overwrites operation  $w_i(P: Vset(P))$ , which means that  $S_i$  performs an operation  $w_i(P: Vset(P))$ , and there exists  $x_k \in Vset(P)$  that  $S_j$  installs  $x$ 's next version (after  $x_k$ ). Because  $x_k \in Vset(P)$ ,  $x_k$  must be in the output of one of the VSRs of  $S_i$ . Suppose  $x_h$  is the version of  $x$  that is used in  $S_j$  for predicate matching. Because  $S_j$  installs  $x$ 's next version (after  $x_k$ ),  $x_h$  must satisfy the predicate of  $S_j$  because  $S_j$  is going to install a new version for item  $x$ . As BWR of  $S_j$  uses the same predicate as  $S_j$ ,  $x_h$  must be in the output of BWR of  $S_j$  too. Suppose  $S_j$  is going to install  $x_j$ , there must be  $x_h \ll x_j$ . And  $x_j$  is  $x_k$ 's next version, so  $x_k$  is  $x_h$ , or  $x_h \ll x_k$ .

We assume that  $x_h \ll x_k$ : (a)  $S_i$  and  $S_j$  are in the same transaction.  $S_i$  must be before  $S_j$ .  $S_i$  uses version  $x_k$ , and thus  $S_j$  must use a version of  $x$  that is later than or equal to  $x_k$ . However,  $S_j$  uses  $x_h$  and  $x_h \ll x_k$ . Conflict. (b)  $S_i$  and  $S_j$  are in different transactions,  $T_i$  and  $T_j$ . Suppose statement  $S_k$  of transaction  $T_k$  installs version  $x_k$ . If  $T_k$  is  $T_j$ ,  $S_k$  must be before  $S_j$  because  $S_j$  install  $x_k$ 's next version. So  $x_k$  is visible to  $S_j$ , so  $S_j$  must use  $x_k$  instead of  $x_h$  as  $x_h \ll x_k$ . Conflict. So  $T_k$  is not  $T_j$ . Because  $T_j$  reads  $x_h$  (BWR of  $S_j$ ) while  $T_k$  installs  $x_k$  that are after  $x_h$ ,  $T_k$  item-anti-depends on  $T_j$ . Because  $T_j$  installs  $x_j$  that are after  $x_k$ ,  $T_j$  item-write-depends on  $T_k$ . Conflict with Assumption 3.

Combining (a) (b), we get  $x_h \ll x_k$  in conflict. So  $x_k$  is  $x_h$ . So  $x_k$  is in the output of BWR of  $S_j$ . And  $x_k$  is in the output of one of the VSRs of  $S_i$ , the outputs of one of the VSR statements of  $S_j$  and the output of BWR of  $S_j$  have intersections.

For case (2),  $S_j$  executes an operation  $w_j(Q: Vset(Q))$  while  $S_i$  installs an item version  $x_i$  that is included in  $Vset(Q)$ . Because  $x_i$  is installed by  $S_i$ , the  $x_i$  must be included in the output of AWR of  $S_i$ . Because  $x_i \in Vset(Q)$ ,  $x_i$  must be in the output of one of the VSRs of  $S_j$ . So the output of AWR of  $S_i$  and the output of one of the VSRs of  $S_j$  have intersections.

Combining (1) and (2), we prove Lemma 5.

**Lemma 6** Statement  $S_j$  directly stmt-predicate-anti-depends on statement  $S_i \Rightarrow$  outputs of one of the VSR statements of  $S_i$  and outputs of the BWR statement of  $S_j$  have intersections.

**Proof:** Statement  $S_j$  directly stmt-predicate-anti-depends on statement  $S_i$ , which means that  $S_j$  performs an operation  $r_i(P: Vset(P))$ , and there exists  $x_k \in Vset(P)$  that  $S_j$  installs  $x$ 's next version (after  $x_k$ ). Because  $x_k \in Vset(P)$ ,  $x_k$  must be in the output of one of the VSRs of  $S_i$ . Suppose  $x_h$  is the version of  $x$  that is used in  $S_j$  for predicate matching. Because  $S_j$  installs  $x$ 's next version (after  $x_k$ ),  $x_h$  must satisfy the predicate of  $S_j$  because  $S_j$  is going to install a new version for item  $x$ . As BWR of  $S_j$  uses the same predicate as  $S_j$ ,  $x_h$  must be in the output of BWR of  $S_j$  too. Suppose  $S_j$  is going to install  $x_j$ , there must be  $x_h \ll x_j$ . And  $x_j$  is  $x_k$ 's next version, so  $x_k$  is  $x_h$ , or  $x_h \ll x_k$ .

We assume that  $x_h \ll x_k$ : (a)  $S_i$  and  $S_j$  are in the same transaction.  $S_i$  must be before  $S_j$ .  $S_i$  uses version  $x_k$ , and thus  $S_j$  must use a version of  $x$  that is later than or equal to  $x_k$ . However,  $S_j$  uses  $x_h$  and  $x_h \ll x_k$ . Conflict. (b)  $S_i$  and  $S_j$  are in different transactions,  $T_i$  and  $T_j$ . Suppose statement  $S_k$  of transaction  $T_k$  installs version  $x_k$ . If  $T_k$  is  $T_j$ ,  $S_k$  must be before  $S_j$  because  $S_j$  install  $x_k$ 's next version. So  $x_k$  is visible to  $S_j$ , so  $S_j$  must use  $x_k$  instead of  $x_h$  as  $x_h \ll x_k$ . Conflict. So  $T_k$  is not  $T_j$ . Because  $T_j$  reads  $x_h$  (BWR of  $S_j$ ) while  $T_k$  installs  $x_k$  that are after  $x_h$ ,  $T_k$  item-anti-depends on  $T_j$ . Because  $T_j$  installs  $x_j$  that are after  $x_k$ ,  $T_j$  item-write-depends on Conflict with Assumption 3.

Combining (a) (b), we get  $x_h \ll x_k$  in conflict. So  $x_k$  is  $x_h$ . So  $x_k$  is in the output of BWR of  $S_j$ . And  $x_k$  is in the output of one of the VSRs of  $S_i$ , the outputs of one of the VSR statements of  $S_i$  and the output of BWR of  $S_j$  have intersections. Lemma 6 is proved.

**Lemma 7** Statement  $S_j$  directly stmt-value-write-depends on statement  $S_i \Rightarrow$  (1) outputs of one of the VSR statements of  $S_i$  and outputs of the BWR statement of  $S_j$  have overlapping parts, or (2) outputs of the AWR statement of  $S_i$  and outputs of one of the VSR statements of  $S_j$  have intersections.

**Proof:** If statement  $S_j$  directly stmt-value-write-depends on statement  $S_i$ , according to Definition 8, it can be (1)  $S_i$  executes an operation  $w_i^{value}(E: Vset(E))$  where  $x_k$  is included

while  $S_j$  installs  $x$ 's next version (after  $x_k$ ) in version order, or (2)  $S_j$  executes an operation  $w_j^{value}(F: Vset(F))$  while  $S_i$  installs  $x_i$  that is included in  $Vset(F)$ .

For case (1), because  $x_k \in Vset(E)$ ,  $x_k$  must be in the output of one of the VSRs of  $S_i$ . Suppose  $x_h$  is the version of  $x$  that is used in  $S_j$  for predicate matching. Because  $S_j$  installs  $x$ 's next version (after  $x_k$ ),  $x_h$  must satisfy the predicate of  $S_j$  because  $S_j$  is going to install a new version for item  $x$ . As BWR of  $S_j$  uses the same predicate as  $S_j$ ,  $x_h$  must be in the output of BWR of  $S_j$  too. Suppose  $S_j$  is going to install  $x_j$ , there must be  $x_h \ll x_j$ . And  $x_j$  is  $x_k$ 's next version, so  $x_k$  is  $x_h$ , or  $x_h \ll x_k$ .

We assume that  $x_h \ll x_k$ : (a)  $S_i$  and  $S_j$  are in the same transaction.  $S_i$  must be before  $S_j$ .  $S_i$  uses version  $x_k$ , and thus  $S_j$  must use a version of  $x$  that is later than or equal to  $x_k$ . However,  $S_j$  uses  $x_h$  and  $x_h \ll x_k$ . Conflict. (b)  $S_i$  and  $S_j$  are in different transactions,  $T_i$  and  $T_j$ . Suppose statement  $S_k$  of transaction  $T_k$  installs version  $x_k$ . If  $T_k$  is  $T_j$ ,  $S_k$  must be before  $S_j$  because  $S_j$  install  $x_k$ 's next version. So  $x_k$  is visible to  $S_j$ , so  $S_j$  must use  $x_k$  instead of  $x_h$  as  $x_h \ll x_k$ . Conflict. So  $T_k$  is not  $T_j$ . Because  $T_j$  reads  $x_h$  (BWR of  $S_j$ ) while  $T_k$  installs  $x_k$  that are after  $x_h$ ,  $T_k$  item-anti-depends on  $T_j$ . Because  $T_j$  installs  $x_j$  that are after  $x_k$ ,  $T_j$  item-write-depends on Conflict with Assumption 3.

Combining (a) (b), we get  $x_h \ll x_k$  in conflict. So  $x_k$  is  $x_h$ . So  $x_k$  is in the output of BWR of  $S_j$ . And  $x_k$  is in the output of one of the VSRs of  $S_i$ , the outputs of one of the VSR statements of  $S_i$  and the output of BWR of  $S_j$  have intersections.

For case (2), because  $x_i$  is installed by  $S_i$ , the  $x_i$  must be included in the output of AWR of  $S_i$ . Because  $x_i \in Vset(F)$ ,  $x_i$  must be in the output of one of the VSRs of  $S_j$ . So the output of AWR of  $S_i$  and the output of one of the VSRs of  $S_j$  have intersections.

Combining (1) and (2), we prove Lemma 7.

## C Proof for Theorem 1

**Inductive proof:**  $n$  is the number of statements in the statement-dependency graph (SDG).  $[T_{x1}S_{y1}, T_{x2}S_{y2}, \dots, T_{xn}S_{yn}]$  is the statement sequence executed within transactions.  $[S_{z1}, S_{z2}, \dots, S_{zn}]$  is the statement sequence generated by performing topological sorting on SDG.

when  $n = 1$ , obviously  $T_1S_1$  and  $S_1$  give the same results.

Suppose  $n = k$ , its SDG  $G_k$  is acyclic, and  $[T_{x1}S_{y1}, T_{x2}S_{y2}, \dots, T_{xk}S_{yk}]$  and  $[S_{z1}, S_{z2}, \dots, S_{zk}]$  produce the same results. When  $n = k + 1$ , we add a new statement at the end of the transactional statement sequence. Therefore, the sequence becomes  $[T_{x1}S_{y1}, T_{x2}S_{y2}, \dots, T_{xk}S_{yk}, T_{x(k+1)}S_{y(k+1)}]$ . We need to prove that Theorem 1 holds for  $k+1$  if the SDG is acyclic.

Because  $T_{x1}S_{y1}, T_{x2}S_{y2}, \dots$ , and  $T_{xk}S_{yk}$  are executed before  $T_{x(k+1)}S_{y(k+1)}$ , they are not affected by  $T_{x(k+1)}S_{y(k+1)}$ , and thus their execution results are the same as  $[T_{x1}S_{y1}, T_{x2}S_{y2}, \dots, T_{xk}S_{yk}]$  in the  $k$ -length case. So  $T_{x1}S_{y1}, T_{x2}S_{y2}, \dots$ , and  $T_{xk}S_{yk}$  still generate graph  $G_k$ . And then  $T_{x(k+1)}S_{y(k+1)}$

is executed and produces some dependencies to some of the executed statements. Therefore,  $G_{k+1}$  is a super graph of  $G_k$ . By performing topological sort, it generates several normal execution sequences. Suppose  $[S_{w1}, S_{w2}, \dots, S_{wk}, S_{w(k+1)}]$  is one of the sequences. Taking out the new statement  $S_{y(k+1)}$  from this sequence, we can get  $[S_{z1}, S_{z2}, \dots, S_{zk}]$ . Because we use topological sort, and  $G_{k+1}$  is a super graph of  $G_k$ ,  $[S_{z1}, S_{z2}, \dots, S_{zk}]$  follows the edges in  $G_{k+1}$  and thus follows the edges in  $G_k$ . Therefore,  $[S_{z1}, S_{z2}, \dots, S_{zk}]$  must be one of the topologically sorting results of  $k$ -length cases.

Now we consider the new statement  $S_{y(k+1)}$ . Suppose  $[S_{z1}, S_{z2}, \dots, S_{zp}, S_{y(k+1)}, S_{z(p+1)}, \dots, S_{zk}]$  is one of the topologically sorting results of  $k+1$ -length cases.  $[S_{z1}, S_{z2}, \dots, S_{zk}]$  is the topologically sorting results of  $k$ -length cases.

$S_{y(k+1)}$  will not affect the statements that are executed before it. Therefore, the  $S_{z1}, S_{z2}, \dots, S_{zp}$  produce the same results as they are in transaction execution (according to the  $k$ -length case). — **(Conclusion 1)**

Now, we need to prove: (1)  $S_{y(k+1)}$  produce the same results as  $T_{x(k+1)}S_{y(k+1)}$ ; and (2)  $S_{z(p+1)}, \dots, S_{zk}$  are not affected by  $S_{y(k+1)}$ , that is, they will produce the same results as they produce in transaction execution.

**(1)  $S_{y(k+1)}$  produce the same results as  $T_{x(k+1)}S_{y(k+1)}$ .**

**Proof:** If  $S_{y(k+1)}$  and  $T_{x(k+1)}S_{y(k+1)}$  produce different results, there must be at least one item  $x$  whose version  $x_i$  is referenced by  $S_{y(k+1)}$  and  $x_j$  is referenced by  $T_{x(k+1)}S_{y(k+1)}$ , and  $x_i$  is different from  $x_j$ . There are only two possible cases:

(a)  $x_i \ll x_j$ . Suppose  $T_{xj}S_{yj}$  installs item version  $x_j$ , so  $T_{x(k+1)}S_{y(k+1)}$  depends on  $T_{xj}S_{yj}$  because  $T_{x(k+1)}S_{y(k+1)}$  references the item version installed by  $T_{xj}S_{yj}$ . Therefore, topological sorting will put  $T_{xj}S_{yj}$  before  $T_{x(k+1)}S_{y(k+1)}$ . Suppose  $S_{zj}$  is the statement in sorted sequence corresponding to  $T_{xj}S_{yj}$ .  $S_{zj}$  is before  $S_{y(k+1)}$ , so  $S_{zj}$  should produce the same results as  $T_{xj}S_{yj}$  according to Conclusion 1. So  $S_{zj}$  also installs version  $x_j$ . So  $S_{y(k+1)}$  must reference the version of item  $x$  later than or equal to  $x_j$ . However,  $S_{y(k+1)}$  reference  $x_i$ , and  $x_i \ll x_j$ . Conflict.

(b)  $x_i \gg x_j$ . Suppose  $x_i$  is installed by  $S_{zi}$ . Because  $S_{y(k+1)}$  reference  $x_i$ ,  $S_{zi}$  must be before  $S_{y(k+1)}$ . According to Conclusion 1,  $S_{zi}$  produces the same results as it is in transaction execution. Suppose  $T_{xi}S_{yi}$  is the corresponding statement in the transaction execution.  $T_{xi}S_{yi}$  installs item version  $x_i$  while  $T_{x(k+1)}S_{y(k+1)}$  reference  $x_j$  that is older than  $x_i$ , so  $T_{xi}S_{yi}$  depends on  $T_{x(k+1)}S_{y(k+1)}$ . Therefore, topological sorting will put  $T_{xi}S_{yi}$  after  $T_{x(k+1)}S_{y(k+1)}$ , *i.e.*,  $S_{zi}$  is after  $S_{y(k+1)}$ , which is in conflict with that  $S_{zi}$  must be before  $S_{y(k+1)}$ .

Combining (a) and (b), we can get that there is no item that  $S_{y(k+1)}$  and  $T_{x(k+1)}S_{y(k+1)}$  reference its different version. Therefore,  $S_{y(k+1)}$  can produce only the same results as  $T_{x(k+1)}S_{y(k+1)}$ .

**(2)  $S_{z(p+1)}, \dots, S_{zk}$  are not affected by  $S_{y(k+1)}$ .**

**Proof:** We assume at least one of the statements in  $S_{z(p+1)}, \dots, S_{zk}$  is affected by  $S_{y(k+1)}$ . Suppose  $S_{zh}$  is the closest statement to  $S_{y(k+1)}$  among the statements that is affected by  $S_{y(k+1)}$ .

That is, there is not any statement between  $S_{zh}$  and  $S_{y(k+1)}$ , or statements between  $S_{zh}$  and  $S_{y(k+1)}$  should not be affected by  $S_{y(k+1)}$ . Because  $S_{zh}$  is affected, it must reference at least one item version that is installed by  $S_{y(k+1)}$ .

Suppose  $x_i$  is one of the item versions that are installed by  $S_{y(k+1)}$  and referenced by  $S_{zh}$ .  $S_{y(k+1)}$  and  $T_{x(k+1)}S_{y(k+1)}$  produce the same results, so  $T_{x(k+1)}S_{y(k+1)}$  also installs  $x_i$ . Suppose  $T_{xh}S_{yh}$  is the corresponding statement of  $S_{zh}$  in the transaction execution sequence. Because  $T_{xh}S_{yh}$  and  $S_{zh}$  are the same statement and thus use the same predicate,  $T_{xh}S_{yh}$  must reference one of the versions of item  $x$ . Suppose the item version is  $x_j$ .  $x_j$  must be different from  $x_i$  as  $T_{xh}S_{yh}$  is executed before  $T_{x(k+1)}S_{y(k+1)}$ , which is the last statement in transaction execution, and  $T_{xh}S_{yh}$  cannot reference an item version that has not been installed yet. There are only two possible cases:

(a)  $x_i \gg x_j$ .  $T_{xh}S_{yh}$  reference  $x_j$  while  $T_{x(k+1)}S_{y(k+1)}$  installs  $x_i$ , and  $x_i \gg x_j$ , so  $T_{x(k+1)}S_{y(k+1)}$  depends on  $T_{xh}S_{yh}$ . According to the topological sort,  $S_{zh}$  must be before  $S_{y(k+1)}$ . However,  $S_{zh}$  is after  $S_{y(k+1)}$ . Conflicts.

(b)  $x_i \ll x_j$ . Suppose  $x_j$  is installed by  $T_{xj}S_{yj}$ . Because  $T_{xj}S_{yj}$  installs  $x_j$  and  $T_{xh}S_{yh}$  reference  $x_j$ ,  $T_{xh}S_{yh}$  depends on  $T_{xj}S_{yj}$ .  $T_{xj}S_{yj}$  installs  $x_j$  while  $T_{x(k+1)}S_{y(k+1)}$  installs  $x_i$ , and  $x_i \ll x_j$ , so  $T_{xj}S_{yj}$  depends on  $T_{x(k+1)}S_{y(k+1)}$ . So  $T_{x(k+1)}S_{y(k+1)} \ll T_{xj}S_{yj} \ll T_{xh}S_{yh}$ . According to topological sorting,  $S_{y(k+1)}$  must be before  $S_{zj}$ , and  $S_{zj}$  must be before  $S_{zh}$ . Because  $S_{zh}$  is the closest statement that is affected by  $S_{y(k+1)}$ , and  $S_{zj}$  is before  $S_{zh}$ ,  $S_{zj}$  is not affected by  $S_{y(k+1)}$ . So  $S_{zj}$  will also install  $x_j$ . Therefore,  $S_{zh}$  should use a version later than or equal to  $x_j$ . However,  $S_{zh}$  references version  $x_i$  that is older than  $x_j$ . Conflicts.

Combining (a) and (b), we can get that there is no statement in  $[S_{z(p+1)}, \dots, S_{zk}]$  that is affected by  $S_{y(k+1)}$ . Therefore,  $S_{z(p+1)}, \dots, S_{zk}$  should produce the same results as they produce in transaction execution.

Combining (1) and (2), we can get that  $[T_{x1}S_{y1}, T_{x2}S_{y2}, \dots, T_{xk}S_{yk}, T_{x(k+1)}S_{y(k+1)}]$  and its topological sorting produce the same results. So for  $n = k + 1$ , the theorem still holds. Therefore, Theorem 1 is proved.

# Take Out the TraChe: Maximizing (Tra)nsactional Ca(che) Hit Rate

## Abstract

Most caching policies focus on increasing object hit rate to improve overall system performance. However, these algorithms are insufficient for transactional workloads. In this work, we define a new metric, transactional hit rate, to capture when caching reduces latency for transactions. We present DeToX, a caching system that leverages transactional dependencies to make eviction and prefetching decisions. DeToX is able to significantly outperform single-object alternatives on real-world workloads and popular OLTP benchmarks, providing up to a 1.3x increase in transaction hit rate and 3.4x improvement in cache efficiency.

## 1 Introduction

To improve latency at scale, application developers often layer caching systems, such as Memcached [69] and Redis [2], over standard data stores. These systems traditionally optimize for *object hit rate*, or how often requested objects can be served from cache. Consequently, current caching policies fail to capture the transactional nature of many application workloads. On a production workload from Meta [26], we find that up to 90% of objects cached by least recently used (LRU) and least frequently used (LFU), two popular caching algorithms, do not have any impact on latency despite high object hit rates. Existing policies fail to capture the *all-or-nothing* property of transactions: all objects requested in parallel must be present in cache, or there will be little performance improvement because latency is dictated by the slowest access.

Accordingly, object hit rate is the wrong objective for transactional workloads. Instead, we propose a new metric, *transactional hit rate*, or how often objects requested in parallel can all be served from cache. This metric precisely captures when the cache reduces latency for transactions.

In this paper, we present DeToX, the first high-performance caching system that optimizes for transactional hit rate. In accordance with standard caching algorithms, DeToX assigns scores to objects and evicts those with the lowest values.

As such, its policy is easily adaptable to existing caching systems. To rank objects in the transactional context, DeToX leverages the following insight: objects accessed in parallel within the same transaction should be scored together since they must all be cached to reduce transactional latency.

While scoring keys together might seem simple, the structure of transactional workloads complicates matters. Unlike previous work on caching for parallel jobs [11] and web applications [7, 10, 18, 90, 91], transactions need to be modeled as non-trivial directed acyclic graphs (DAGs) of read and write operations [22, 94]. Crucially, some keys within a transaction are accessed in parallel, but others are not. Consequently, a transaction's latency is determined by its *critical length*, or the number of sequential accesses on its longest, non-cached path (transactional hit rate captures the reduction of critical length). Rather than considering all keys in a transaction together, we must focus on caching the *groups* of keys that reduce critical length.

Implementing a caching policy based on grouping presents several significant challenges. (1) For an arbitrary transaction, there can be an exponential number of groups, making scoring prohibitively expensive. (2) Identifying groups requires inferring transactional DAGs through static analysis, which may not always be possible. (3) Objects that are accessed by different transactions can belong to different groups, which have varying latency benefits if cached, and we need to capture these disparities.

We address each of these issues in DeToX. (1) To reduce the overhead of an exponential number of groups, we introduce the notion of *interchangeable* keys: if two keys can replace each other in any group and still reduce critical length, then they can be represented by the same group. Interchangeable keys drastically curb the number of groups that need to be scored. (2) When transactional DAGs are not accessible, we propose a simplified policy that dynamically infers groups based on which requests are executed in parallel (termed *levels*). (3) Finally, we account for group membership when scoring keys to ensure these values precisely reflect each object's contribution to transactional hits.

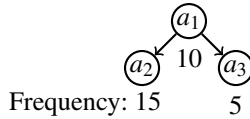

Figure 1: GetLinkedAccounts transaction.

Moreover, while our approach is primarily targeted at eviction, it also enables prefetching (Section 6). Our prefetching policy tracks dependencies within transactions to preemptively bring groups of items into the cache.

Our eviction and prefetching algorithms are implemented in DeToX, which presents a key-value API that supports drivers for Redis [2], Postgres [3], and TiKV [4]. We evaluate our system on real-world workloads from TAOBench [26], a social network benchmark that models Meta’s production workloads, as well as standard OLTP benchmarks (Epinions [37], SmallBank [87], and TPC-C [33]). Compared to single-object caching algorithms and systems, including ChronoCache [45], GDSF [27], LIFE [11], LFU, and LRU, our algorithm can achieve up to a 1.3x increase in *transactional hit rate*, leading to a 3.4x improvement in cache efficiency (defined as the least amount of cache space required to achieve a particular transactional hit rate). For a Redis-Postgres setup, this translates into 31% higher throughput and 30% lower latency.

Our transactional hit rate metric prioritizes *latency* and exposes a new trade-off in caching enabled by the cloud’s elastic resources: optimizing for latency versus reducing system load. In contrast, single-object policies focus on maximizing *object* hit rate to decrease load to the data store but do not always improve transaction request times.

In summary, we make the following contributions:

- We define a new metric, transactional hit rate, to evaluate the latency reduction of caching for transactions (Section 3).
- We provide the first formalization of transactional caching, and we prove that the problem is NP-Hard (Section 3.4).
- We present a new caching system, DeToX, that leverages transactional dependency information to optimize for transactional hit rate and significantly improve performance on popular workloads (Sections 4 – 8).

## 2 Motivation

In this section, we illustrate why single-object eviction algorithms perform poorly for transactional workloads. Specifically, we show that a well-known optimality result in caching does not hold for transactions and that popular caching algorithms achieve low transactional hit rates.

### 2.1 Object Hit Rate is Insufficient

Most existing cache eviction algorithms focus on maximizing object hit rate, or the fraction of single object requests served from cache. However, this approach fails to capture the

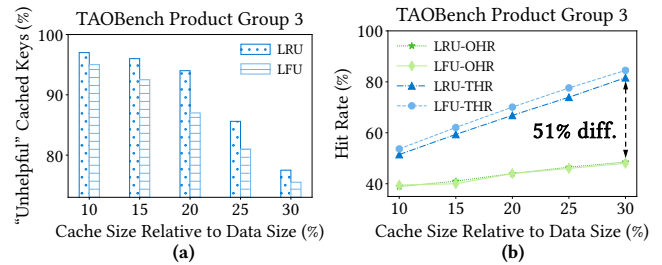

Figure 2: Single-object policy performance.

inter-object dependencies within transactions. Consider for example a simple transaction `GetLinkedAccounts` that returns secondary bank accounts  $a_2$  and  $a_3$  linked with a primary account  $a_1$  (Figure 1). This transaction must first read  $a_1$  before accessing both secondary accounts  $a_2$  and  $a_3$  in parallel. Thus,  $a_1$ ,  $a_2$  and  $a_3$  are all on the longest path of the transaction. If we cache  $a_1$ , we can reduce the end-to-end latency of the transaction. However, if we additionally cache  $a_2$ , the overall latency does not improve because we still need to access  $a_3$  from disk. In fact, caching either  $a_2$  or  $a_3$  individually does not improve performance; transaction latency remains equal to the case in which *neither* key was cached. On the other hand, caching *both*  $a_2$  and  $a_3$  does improve latency.

Transactions have an implicit *all-or-nothing* property on groups of objects that traditional caching algorithms fail to capture. This can lead popular eviction algorithms, such as LRU and LFU, to make poor caching decisions. Consider a situation in which, over all transactions,  $a_2$  is more frequently accessed than  $a_1$  and  $a_3$ . LFU and LRU would choose to evict  $a_1$  and  $a_3$  over  $a_2$ , resulting in no latency improvement for this transaction. In this case, a “hot” (frequently accessed) key  $a_2$  is requested in parallel alongside a “cold” (rarely accessed) key  $a_3$ . If all accesses of  $a_2$  are sent in parallel with requests to different cold keys, there is no benefit to caching  $a_2$  unless all these cold keys are cached. In effect, cold keys can “contaminate” (degrade the cacheability of) hot keys like  $a_2$ .

**Real-world workloads.** This observation is not limited to our simple example: we find that single-object eviction algorithms also perform poorly for complex, real-world workloads. Figure 2a illustrates that over 90% of cached keys do not have any impact on latency (“unhelpful” keys) for the Product Group 3 workload of TAOBench [26]. The root cause is simple: these algorithms optimize for *object* hit rate (OHR) rather than transactional hit rate (THR). As we see in Figure 2b, LRU and LFU achieve high object hit rates but up to 51% lower transactional hit rates. Transactions in this workload access either a combination of hot keys and warm keys, or hot keys and cold keys. Single-object algorithms, which use only individual object features to score keys, retain only hot keys but evict most warm keys and all cold keys. As a result, they achieve few transactional hits. A transactionally-aware policy would instead recognize that cold keys contaminate their associated hot keys and prioritize retaining only the hot and warm keys that are accessed together.

T	Keys accessed	Cache state	Optimal cache state
1	$a_1, a_2, a_3$	-	-
2	$a_4, a_5, a_6$	$a_1, a_2, a_3$	$a_1, a_2, a_3$
3	$a_4, a_5, a_7$	$a_1, a_4, a_5$	$a_1, a_2, a_3$
4	$a_1, a_2, a_3$	$a_1, a_4, a_5$	$a_1, a_2, a_3$

Figure 3: Non-optimality of Belady.

## 2.2 Optimality

Our observations also have theoretical implications. We find that Belady [16], the offline, optimal eviction algorithm for uniformly-sized objects does not make the best decisions for maximizing transactional hit rate. This policy evicts keys that are accessed furthest in the future but fails to take into account whether these keys generate transactional hits.

We prove that Belady is *not* optimal even for the simplest case of uniformly-sized transactions with uniformly-sized objects (Figure 3). In this example, we have four transactions with a cache size of 3.  $T_1$  and  $T_4$  access keys  $a_1, a_2, a_3$ , while  $T_2$  accesses  $a_4, a_5, a_6$  and  $T_3$  accesses  $a_4, a_5, a_7$ . Belady chooses to first cache  $a_1, a_2, a_3$  and then replaces the last two keys with  $a_4, a_5$  since these keys give object hits (but no latency reduction) for  $T_3$ . However, keeping  $a_2, a_3$  in the cache would lead to a transactional hit (and latency improvement) for  $T_4$ .

## 2.3 Towards a new approach

Our results highlight how single-object caching strategies yield low transactional hit rates by storing many unhelpful objects. Web caching algorithms suggest a way forward: they acknowledge the need to cache multiple objects together (e.g., page-level hit ratio) but only consider flat dependencies [11, 91]. In contrast, transactions can have complicated topologies with multiple levels of dependencies.

To develop a transactionally-aware caching system, we must address three challenges: (1) formalizing caching in the transactional context, including optimality analysis (Section 3), (2) identifying which groups of objects lead to transaction hits, given the potentially complex structure of transactions (Section 4.1), and (3) scoring the individual objects in these groups to determine which objects to store in the cache (Section 4.2). In our design, we are careful to emphasize compatibility with existing caching systems, such as Memcached and Redis, so that our approach can be easily implemented for greater applicability.

## 3 Transactional Caching

In this section, we formalize the transactional caching problem. We define a new metric, *transactional hit rate*, to capture the latency reduction of caching transactions.

```

1 id = SELECT cId FROM ACCOUNTS WHERE name = cName
2 s = SELECT savings FROM SAVINGS WHERE cId = id
3 c = SELECT checking FROM CHECKING WHERE cId = id
4 return s + c

```

Listing 1: Code for Figure 4. The dependencies for Lines 2 and 3 on the output of Line 1 are highlighted in red.

## 3.1 Transactions

Transactions consist of read and write requests that must be applied atomically [22]. Some of these operations are independent and can execute in parallel, while others are *dependent* on the result of preceding operations. For instance, a read operation may query a key determined by the return value of a previous operation. As a result, these operations must be run sequentially. In effect, transaction execution can be captured by a DAG of operations. More formally, we apply the notion of a logical dependency, generalizing the model from Wu et al. [94]:

**Definition 1** (*Logical dependency*). Given two operations  $tp$  and  $t$  of a transaction, an operation  $t$  is logically dependent on operation  $p$  if  $p$  determines the key or value accessed by  $t$ .

Traditionally, these dependencies are not captured by the system, which observes only sequences of reads and writes. In practice, these relationships can be captured statically through program analysis or specified at run time by the developer. Together, operations and logical dependencies define a transaction execution graph:

**Definition 2** (*Transaction execution graph*). For transaction  $T$ , a transaction execution graph  $G = (V, E)$  is a DAG, where each vertex in  $V$  represents a pair  $(x, X)$  of a read or write operation to key  $x$  in table  $X$ , and each edge in  $E$  represents a logical dependency between operations.

Each transaction execution graph corresponds to a transaction type:

**Definition 3** (*Transaction type*). Transactions of the same type have identical execution graphs when only considering tables.

We infer transaction execution graphs and their resulting types through static analysis, as done in prior work [36, 94]. Note that we only extract table accesses and graph structure; the individual keys accessed by transactions are known only at run time. As such, we make no assumptions about the DAG structure and support general-purpose, interactive transactions. For example, the SmallBank workload [87] contains the transaction types: Amalgamate, Balance, DepositChecking, SendPayment, TransactSavings, and WriteCheck. For the Balance transaction (Listing 1), requests to both the Savings ( $S$ ) and Checkings ( $C$ ) tables are dependent on the result of the read to the Accounts table ( $A$ ). The corresponding execution graph consists of three nodes, one for each operation, and logical dependencies  $r[A] \rightarrow r[S]$  and  $r[A] \rightarrow r[C]$ . While the reads to  $S$  and  $C$  are independent

(a) Cache state:  $\{\}$  (b) Cache state:  $\{a\}$  (c) Cache state:  $\{c\}$

Figure 4: SmallBank Balance transactions.

and can be executed in parallel, they cannot proceed until after the read to  $A$  finishes. At run time, a Balance transaction that reads the keys  $a, s, c$  from the tables  $A, S, C$  respectively can be mapped onto the same execution graph (Figure 4a).

## 3.2 Cache

The previous section presents the notion of a transaction, including the logical dependencies that constrain its execution. We now formalize how *caching* affects transactions, drawing from Abrams et al. [48] for notation.

**Definition 4 (Cache state).** A cache state is a set of keys  $C$  for which  $|C| \leq n$ , where  $n$  is the capacity of the cache.

In line with prior work [29], we assume that the cache state does not change for the duration of each transaction.

By assumption, objects are served with lower latency from the cache than from the underlying data store. We make the simplifying assumption that requests served from the cache have *zero* latency for notational simplicity (we explore the effects of varying cache latency in Section 8.6). Under this model, transaction latency is defined by the number of sequential, *non-cached* accesses. This corresponds to the longest path in the transaction’s execution graph  $G$ , excluding vertices with cached keys.

We formalize this notion as the critical length:

**Definition 5 (Critical length).** Given a transaction  $T$  with transaction execution graph  $G$ ,  $K$  number of keys, and cache state  $C$ , the critical length is the length of the longest path from any source vertex (no incoming edges) to any sink vertex (no outgoing edges), excluding vertices corresponding to keys in  $C$ . We define the function  $L: G \times 2^K \rightarrow \mathbb{N}$  for which  $2^K$  is the powerset of all keys, such that  $L(G, C)$  is the critical length.

Given a transaction  $T$  with execution graph  $G$ ,  $L(G, \{\})$  represents the length of the longest path in  $G$  when the cache is empty. For example, Figure 4a has longest paths  $\{r[a], r[c]\}$  and  $\{r[a], r[s]\}$  with critical length  $L(G, \{\}) = 2$ . Caching key  $a$  (Figure 4b) would shorten the critical length to  $L(G, \{a\}) = 1$ , as the longest paths are reduced to  $\{r[c]\}$  and  $\{r[s]\}$ . However, caching key  $c$  (Figure 4c) does not change the critical length, since  $\{r[a], r[s]\}$  remains the longest path with  $L(G, \{c\}) = 2$ . Informally, we refer to each length reduction as a *transactional hit*.

## 3.3 Transactional Hit Rate (THR)

Having defined the necessary formalisms for transaction latency and caching, we can now introduce transactional hit rate. Informally, this metric captures how much latency improves

when caching for transactions, much like how its single-object counterpart, object hit rate, does so for individual requests.

We first present THR in the context of a single transaction:

**Definition 6 (Individual transactional hit rate).** Given transaction  $T$  with execution graph  $G$  and cache state  $C$ , the individual transactional hit rate is  $\frac{L(G, \{\}) - L(G, C)}{L(G, \{\})}$ .

The difference in critical length represents the reduction in sequential, non-cached accesses after caching. We normalize this difference by dividing by the total critical length. This metric captures the impact of caching for the execution of a single transaction (note that if the transaction execution graph is a sequential list of dependent reads, then transactional hit rate is equivalent to object hit rate). We easily extend this definition to a sequence of transactions:

**Definition 7 (Transactional hit rate).** Given a sequence of transactions  $T_1, T_2, \dots, T_m$  with execution graphs  $G_1, G_2, \dots, G_m$  and the respective cache states at the time of execution  $C_1, C_2, \dots, C_m$ , the transactional hit rate is  $\frac{\sum_{i=1}^m (L(G_i, \{\}) - L(G_i, C_i))}{\sum_{i=1}^m L(G_i, \{\})}$ .

## 3.4 Optimality Analysis

Single-object caching is a well-studied problem and is known to be NP-Hard in the general case [29]. We show that the optimal transactional caching is NP-Hard through a reduction from variable-sized caching of single objects (proof in Appendix A). In summary, we reduce each variable-sized object of size  $X$  to a transaction with  $X$  unit-sized operations.

## 4 Group Identification and Scoring

Designing an optimal caching policy is impractical for transactional caching, since it would run in exponential time. Unfortunately, traditional heuristics perform poorly for transaction hit rate (Section 2) because they fail to identify the keys that must be cached as a *group* in order to yield a transactional hit. This notion of grouping is central to developing a transactionally-aware caching policy. We proceed in two steps: first, we identify which groups of keys lead to transactional hits when cached together (*group identification*). Next, we determine what scores should be assigned to each key within a group (*group scoring*).

Figure 5 gives an overview of DeToX. Our system first extracts transaction execution graphs (Section 3) from application code and identifies groups of table accesses (Section 4.1) at compile time. The number of groups that DeToX needs to consider can be reduced at compile time through the notion of *interchangeability* (Section 5.1). DeToX then scores groups based on key accesses at run time (Section 4.2). If application code is not available, DeToX constructs approximate groups at run time by using *levels* (Section 5.2).

Figure 5: Overview of DeToX (gray boxes). Blue edges on the right represent the path taken if application code is not available.

## 4.1 Group Identification

Intuitively, a group is a set of keys that reduces critical length if cached together. Specifically, we define a *complete group* as one from which we cannot remove any key without increasing critical length. Completeness optimizes cache efficiency by storing the minimal subset of keys necessary to reduce latency. Formally:

**Definition 8 (Complete group).** Given a transaction  $T$  and its execution graph  $G$ , a complete group is a subset of keys  $g$  accessed in  $T$  such that  $\forall g' \subset g, L(G,g) < L(G,g')$ .

We identify complete groups of table accesses at compile time, using the transaction execution graphs  $G$  extracted via static analysis, as seen in Figure 5. A simple algorithm to identify groups is to iterate through the powerset of possible table accesses and compute their resulting reductions in critical length. These table accesses are replaced at run time with key accesses. The application passes along metadata with requests to indicate the corresponding vertex in the transaction execution graph of each key access.

Consider Figure 6a, which has a critical length of three (serial accesses of  $a, c, d$ ) and seven complete groups ( $\{a\}$ ,  $\{c\}$ ,  $\{d\}$ ,  $\{a, c\}$ ,  $\{a, d\}$ ,  $\{b, c, d\}$ ,  $\{a, b, c, d\}$ ). Note that  $\{c, d\}$  is not a complete group. If  $c$  and  $d$  are both cached, then the critical length is two (serial accesses of  $a, b$ ). However, only caching  $c$  already yields the same critical length (accesses to  $a, b, d$ ). Similarly,  $\{a, b\}$  is not a complete group, because it yields a critical length of two (serial accesses  $c, d$ ), which could also be achieved by just caching  $a$ .

In the worst case, the number of complete groups can be exponential in the size of the transaction, even for simple transaction topologies. Fortunately, many of these groups are, in fact, *equivalent*. We describe this notion more precisely in Section 5.1 and present an optimization that drastically reduces the number of groups that need to be considered.

## 4.2 Scoring

Caching policies typically assign scores to keys and evict keys with lower values. We adopt the same strategy by mapping complete groups to individual key scores at run time, as seen in Figure 5. This approach has two benefits: (1) we can draw from prior work on single-object caching

Parameter	Description
$\text{SCORE\_G}(\text{group})$	Score of a group
$F_{\text{group}}$	Set of all key frequencies in a group
$L_{\text{group}}$	Transactional hits of a group
$S_{\text{group}}$	Sum of key sizes in a group
$\text{SCORE\_K}(\text{key})$	Score of a key
$TS_{\text{key}}$	Sum of instance scores for a key
$F_{\text{key}}$	Frequency of a key
$A_{\text{global}}$	Global aging factor

Table 1: Scoring parameters.

algorithms, and (2) we minimize implementation changes needed for real-world caching systems.

### 4.2.1 Scoring a Group in a Single Transaction

We begin by assigning numerical scores to each group (*group scores*) with higher values representing groups that are more beneficial to cache. We draw inspiration from GDSF, a high-performing web caching algorithm [27]. GDSF considers three metrics to score keys: frequency (access count), recency, and size. Specifically, GDSF uses the following formula:  $\text{SCORE}_{\text{GDSF}}(\text{key}) = F_{\text{key}}/S_{\text{key}} + A_{\text{global}}$ , where  $F_{\text{key}}$  is frequency of the key,  $S_{\text{key}}$  is size of the key, and  $A$  is a global recency factor (described in Section 4.2.3). GDSF gives equal weight to each of these factors, and we follow this approach. We leverage frequency and size to score each group as follows (and incorporate recency into key scores in Section 4.2.3):

$$\text{SCORE\_G}(\text{group}) = \frac{\min(F_{\text{group}}) \times L_{\text{group}}}{S_{\text{group}}}$$

$F_{\text{group}}$  is a list of all key frequencies in the group.  $L_{\text{group}}$  is the number of transactional hits generated if this group is cached.  $S_{\text{group}}$  is the sum of all key sizes in the group. All scoring parameters can be found in Table 1. For the transactions in Figure 6 (which will be used as running examples), the group scores of each complete group for these transactions are shown in Figures 6b and 6d. The transaction in Figure 6a has keys  $a, b, c, d$  with frequencies of 1, 29, 99, and 50, respectively and sizes of 1. The score of group  $\{a, b, c, d\}$  is thus  $\frac{\min(1, 29, 99, 50) \times 3}{4} = 0.75$ .

**Frequency ( $F_{\text{group}}$ ).** Keys within a complete group may vary in frequency but must all be cached to yield a transactional

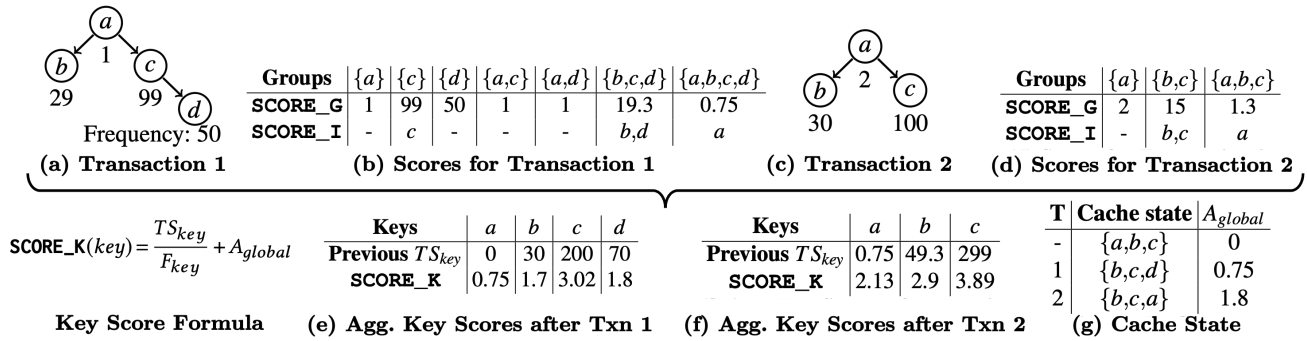

Figure 6: Example transactions and scores. Key sizes are 1, cache size is 3, and  $A_{global}$  starts at 0. The cache initially stores  $\{a,b,c\}$ .  $a$  is evicted after T1, and  $d$  is evicted after T2, with  $A_{global}$  updated on each eviction.

hit. For example, if a high-frequency key  $x$  is only associated with a group of keys  $\{y_1, \dots, y_k\}$  (each with much lower frequency than  $x$ ), then it is not beneficial to cache  $x$ . Essentially, the key with the minimum frequency determines the cacheability of the entire group. Thus, we take the minimum of all key frequencies in calculating the group score. Consider for instance the transaction in Figure 6c: key  $b$  is less frequently accessed than key  $c$  and drives down the frequency of the group  $\{b,c\}$  to  $\min(F_{group}) = \min(30, 100) = 30$ . In this example,  $b$  contaminates  $c$ .

**Critical length reduction ( $L_{group}$ ).** This parameter captures the reduction in critical length when caching a group ( $L_{group} = L(G, \{\}) - L(G, group)$ ). Other factors being equal, groups with greater reductions are better choices to cache and should thus be assigned a higher score.

**Size ( $S_{group}$ ).**  $S_{group}$  represents the cache space needed to store the group. Since all keys in a group must be present in cache to generate a transactional hit, THR is maximized by retaining groups of smaller sizes (more groups can be cached).

Next, we describe how to go from group scores to key scores.

#### 4.2.2 Scoring Across Groups in a Single Transaction

Mapping group scores to keys is challenging: for a given transaction, a key can belong to multiple complete groups, each with a separate group score (SCORE\_G). In this section, we focus on assigning scores to keys within a single transaction; we assign each key an instance score (SCORE\_I) based on one of its group scores. We combine instance scores across transactions in Section 4.2.3.

Our algorithm leverages the insight that out of all the keys in a transaction, the highest-scoring complete group is the most beneficial set of keys to cache. Thus, our protocol first finds the complete group with the highest group score SCORE\_G and sets the instance score of all keys in that group to SCORE\_G. In Figure 6b,  $\{c\}$  has the highest group score (SCORE\_G=99), so  $c$  is assigned the instance score of 99. We then score the remaining keys of the transaction assuming that keys in the highest-scoring group will be cached.

In subsequent iterations, our algorithm finds the highest-scoring complete group that is a *superset* of all keys that

have been assigned instance scores. In Figure 6b, having scored  $c$ , the highest-scoring complete group that subsumes  $c$  is  $\{b,c,d\}$ , with a group score of 19.3. The unscored keys ( $b,d$ ) are then assigned the score of this complete group (19.3). Intuitively, this is the next set of keys that should be retained assuming that the highest-scoring complete group is already in cache. Our algorithm captures the fact that, once  $c$  is cached,  $d$  should only be cached when  $b$  is cached. The low score of  $b$  contaminates  $d$  but should not contaminate  $c$  (since  $c$  by itself can lead to a transactional hit).

The iterative process described above is repeated until all keys are scored. For our example, the next highest-scoring complete group that is a superset of  $\{b,c,d\}$  is  $\{a,b,c,d\}$ , with a group score of 0.75, which is assigned to key  $a$ , completing the scoring protocol for Figure 6b. Note that all keys will eventually be scored by this algorithm, since they are all part of the trivial complete group containing every key in the transaction.

#### 4.2.3 Scoring Across Transactions

Finally, we describe how to integrate instance key scores across multiple transactions into an *aggregate* value. This final score will be used by the system to decide which keys to evict from the cache. We adopt the following formula:

$$\text{SCORE\_K}(key) = \frac{TS_{key}}{F_{key}} + A_{global}$$

$TS_{key}$  is the sum of all instance scores from Section 4.2.2 across all transactions accessing this key.  $F_{key}$  is the frequency of this key.  $A_{global}$  is the global aging factor.

**Averaging instance scores.** To combine instance key scores into a single value for a given key, we take the running average of these scores. Each time a key is accessed, we add its instance score to the total score  $TS_{key}$  and increment  $F_{key}$  before calculating a new aggregate score. Figure 6e gives the key scores of  $a,b,c,d$  after the execution of the transaction in Figure 6a, assuming that the aging factor is initialized to 0, key size is 1, and the previous  $TS_{key}$  values are 0, 30, 200, and 70 respectively. For example,  $c$  has an instance score of 99 (Figure 6b) for the transaction in Figure 6a, a previous  $TS_{key}$  of 200, and frequency of 99, giving  $\text{SCORE\_K}(c) =$

$\frac{200+99}{99} + 0 = 3.02$  in Figure 6e. Taking the average allows us to account for contamination between different groups.

**Recency.** To account for shifts in object access distributions over time, GDSF, along with other algorithms [8], uses an aging factor to capture object recency. Since previously popular objects can remain in the cache for extended periods of time (due to their high frequencies) and prevent newly popular objects from being stored, the scores of more recent objects should be higher than those of older objects. Towards this end, GDSF applies  $A_{global}$ , a global value that is added to the score of a key upon each access to increase the scores of more recently accessed objects and age older objects out of cache. The value of  $A_{global}$  is updated each time an object is evicted and set as that object’s score. Thus, the factor increases monotonically and ensures that all accesses after this eviction will have scores higher than the last evicted key. In essence, this factor acts as a “reset” on key scores. In Figure 6,  $a$  is evicted after the transaction in Figure 6a executes, and  $A_{global}$  is set to  $a$ ’s score (0.75). This value is then added to  $SCORE\_K$  for each key accessed in the subsequent transaction (Figure 6c). For example,  $c$  has an instance score of 15 (Figure 6d), a previous  $TS_{key}$  of 299, frequency of 100, and  $A_{global}$  of 0.75, giving  $c$  an aggregate key score of  $SCORE\_K(c) = \frac{299+15}{100} + 0.75 = 3.89$  in Figure 6f.

## 5 Optimizations

While our current approach precisely captures the cacheability of each group, it can be prohibitively expensive when the number of complete groups is exponential for some transaction topologies. We address this problem in two ways. First, we observe that many complete groups capture redundant information and introduce *interchangeable groups* to avoid scoring all complete groups, reducing run time overhead. Second, we present a restricted form of grouping, *levels*, that dynamically approximates groups at run time. This technique also enables us to score keys when we do not have access to transaction code (i.e., we do not know the transaction execution graphs).

### 5.1 Interchangeability

We find that the number of complete groups can be exponential with respect to transaction size, even for simple topologies. For example, the TPC-C *Order-Status* transaction in Figure 7a has a depth of three, and the number of complete groups for this transaction is exponential with respect to its depth:  $\{c\}$ ,  $\{o\}$ ,  $\{ol_1, ol_2\}$ ,  $\{c, o\}$ ,  $\{o, ol_1, ol_2\}$ ,  $\{c, ol_1, ol_2\}$ ,  $\{c, o, ol_1, ol_2\}$  make up  $2^3 - 1 = 7$  complete groups.

We observe that transactions often contain complete groups that differ by only a single key. For instance, for every group in which  $c$  is present in Figure 7a, there exists an identical group in which  $o$  replaces  $c$  (and vice-versa). In effect, these keys can be “swapped” with each other and still produce a

Figure 7: Transactions to demonstrate interchangeability. Figure 7a is a TPC-C *Order-Status* transaction.

complete group. This interchangeability property is powerful: if two keys can be exchanged in any complete group, then deciding to cache one key over the other is entirely dependent on the *individual* scores of these keys, as all other parameters are shared. Consequently, we do not need to calculate the scores of each their complete groups in order to score each key. Consider the groups  $\{c, ol_1, ol_2\}$  and  $\{o, ol_1, ol_2\}$  for the TPC-C *Order-Status* transaction in Figure 7a, assuming  $c$  has a higher individual score than  $o$ . Since  $c$  and  $o$  are interchangeable, we know that  $\{c, ol_1, ol_2\}$  must have a higher group score than  $\{o, ol_1, ol_2\}$ , as all other parameters (the scores of  $ol_1$  and  $ol_2$ ) are shared. Our scoring algorithm favors caching groups with higher scores, so we can avoid calculating the score of  $\{o, ol_1, ol_2\}$  at run time while determining the score for  $o$ .

We can further generalize the idea of interchangeability to *sets* of keys that can also be “swapped” with each other. Continuing the example above, the set of keys  $\{ol_1, ol_2\}$  is interchangeable with  $\{c\}$ , because any complete group that contains  $\{ol_1, ol_2\}$  will remain a complete group if  $\{ol_1, ol_2\}$  is swapped with  $\{c\}$ . We call such sets interchangeable groups:

**Definition 9 (Interchangeable groups).** Let  $s_1$  and  $s_2$  be distinct sets of keys in a transaction with execution graph  $G$ . We define  $s_1$  and  $s_2$  to be interchangeable if

- (1)  $\forall$  complete groups  $g_1$  such that  $s_1 \subseteq g_1$  and  $s_2 \cap g_1 = \emptyset$ ,  $g'_1 = g_1 \setminus s_1 \cup s_2$  is also a complete group and  $L(G, g_1) = L(G, g'_1)$ , and
- (2)  $\forall$  complete groups  $g_2$  such that  $s_2 \subseteq g_2$  and  $s_1 \cap g_2 = \emptyset$ ,  $g'_2 = g_2 \setminus s_2 \cup s_1$  is also a complete group and  $L(G, g_2) = L(G, g'_2)$ .

Like complete groups, interchangeable groups of table accesses can be identified at compile time, as seen in Figure 5. Key accesses are mapped to the vertices at run time. Computationally, interchangeability allows us to reduce the number of complete groups that need to be scored. We compress the representation of complete groups and reduce run time complexity of the scoring algorithm as follows, using Figure 7b as a running example:

• (Compile time) **Find** all interchangeable groups of vertices from the set of complete groups. The complete groups are:  $\{a, e\}$ ,  $\{b, f\}$ ,  $\{c, g\}$ ,  $\{d, h\}$ ,  $\{a, e, b, f\}$ ,  $\{c, g, b, f\}$ ,  $\{d, h, b, f\}$ ,  $\{a, e, c, g\}$ ,  $\{a, e, d, h\}$ ,  $\{c, g, d, h\}$ ,  $\{a, e, b, f, c, g\}$ ,  $\{a, e, b, f, d, h\}$ ,  $\{a, e, c, g, d, h\}$ ,  $\{c, g, b, f, d, h\}$ ,  $\{a, e, b, f, c, g, d, h\}$ . Consider replacing  $\{a, e\}$  with  $\{d, h\}$  in any complete group; the resulting group is still complete. Thus,  $\{a, e\}$  and  $\{d, h\}$  are interchangeable. Using the same

logic, we find that  $\{a,e\},\{b,f\},\{c,g\},\{d,h\}$  are all mutually interchangeable.

- (Compile time) **Compress** complete groups. Denote an access to any one of the mutually interchangeable groups— $\{a,e\},\{b,f\},\{c,g\},\{d,h\}$ —as  $[C]$ . For example,  $\{a,e,b,f,d,h\}$  becomes  $[C,C,C]$ . In this particular example, all groups of size four can be written as  $[C,C]$ , groups of size six as  $[C,C,C]$ , and groups of size eight as  $[C,C,C,C]$ . We call these representations compressed groups.

- (Run time) **Score** compressed groups by replacing vertices with individual keys in each group. Recall from Section 4.2.2 that our instance scoring algorithm scores all complete groups before greedily selecting the highest-scoring ones. With interchangeability, we no longer need to score all complete groups. Assume the minimum scores of the following interchangeable groups are:  $\{a,e\} : 1, \{b,f\} : 10, \{c,g\} : 30, \{d,h\} : 50$ . Since we know that  $\{a,e\}$  and  $\{d,h\}$  are interchangeable and that  $\{d,h\}$  has a higher score, for any complete group containing  $\{a,e\}$ , there must be another complete group containing  $\{d,h\}$  that has the same (or higher) score. Applying this intuition, the highest-scoring complete group corresponding to the compressed group  $[C,C]$  must be composed of the highest and second-highest-scoring interchangeable groups,  $\{d,h\}$  and  $\{c,g\}$  respectively.

In this example, interchangeability decreases the number of groups that need to be considered at run time from fifteen to four. Overall, interchangeability drastically reduces the number of complete groups that must be scored, lowering run time overhead.

## 5.2 Levels

For cases when we do not have access to transaction code, we design a simplified protocol to dynamically infer groups. We first define a *level* to be a set of keys in a transaction that are sent to the data store in parallel; a similar definition is used to group tasks to optimize caching for parallel job execution [11]. In practice, many applications batch parallel reads to the caching system, which often provides an explicit API to support these requests [2]. We assume that applications send requests as soon as their logical dependencies are fulfilled. For instance, the transaction in Figure 6a has levels  $\{a\}, \{b,c\}$ , and  $\{d\}$ . We have  $d$  as a standalone level since it can only be requested once the level containing both  $b$  and  $c$  has finished executing.

Levels produce identical results to our previous grouping strategies for transactions in which all keys and groups are interchangeable (e.g., Figures 7a and 7b). Many real-world workloads are comprised of such transactions (including all the ones we evaluate in Section 8). When transactions do *not* have these properties, levels can miss out on performance opportunities since they only capture a subset of all possible complete groups. For example, in Figure 6a,  $b$  and  $c$  are always scored together under levels, lowering  $c$ 's score. To

maximize transactional hits,  $b$  should instead be scored with  $d$  since both are colder keys, and  $c$  should be given a high score because caching just this key is likely to lead to a transactional hit. We measure the tradeoff between different grouping strategies in Section 8.

## 6 Prefetching

Prefetching is a popular technique to reduce the client-perceived latency of requests by caching items before they are requested [10, 24, 44, 45, 90]. We revisit this strategy in the context of transactions and design a new prefetching algorithm that uses logical dependencies to minimize latency.

Our policy leverages conditional probabilities: once key  $a$  is accessed, it may be very likely that key  $b$  will also be requested in the same transaction. Consider for example `GetLinkedAccounts` in Figure 1: the access to a primary account is almost always followed by requests to the same subsidiary accounts. Our prefetching algorithm tracks these correlated accesses and preemptively brings dependent objects into the cache ( $a_2$  and  $a_3$  are requested alongside the read to  $a_1$ ). Specifically, DeToX stores, for every request  $r$ , sets of keys in subsequent accesses that are logically dependent on  $r$ . DeToX also tracks the frequency of each set and preemptively fetches in the most popular set into cache alongside  $r$ . To bound memory overheads, we restrict the number of dependency sets that can be stored per key and set a frequency threshold below which we do not retain prefetching metadata.

## 7 Implementation

In this section, we describe our implementation of DeToX, which consists of 7K lines of Java. We adopt a standard two-tier architecture in which we layer a Redis (7.0) cache on top of a data store (Postgres (12.10) and TiKV (5.4.3) are supported). A shim layer routes requests, manages concurrency control, and enables prefetching.

### 7.1 Shim Layer

All client requests are directed to our shim layer, which mediates accesses to the cache and data store to support serializable transactions. Read requests go first to Redis. In the absence of a cache hit, the shim forwards the request to the data store and updates the cache with the result. All writes are sent directly to the data store. While our shim layer currently supports a key-value API, we can convert SQL queries to this format, as previous systems have done [34, 35, 47, 58–61, 65–67, 78, 81–84, 92, 98]. We choose to implement a stand-alone shim layer since there is limited open-source support for concurrency control between caching systems and data stores [9, 43, 45, 46, 75, 76, 85, 88]. Furthermore, our shim layer allows us to

easily plug in different systems. We will explore integrating transactional caching directly into systems in future work.

**Concurrency control.** We implement two-phase locking [22] with timeout-based deadlock detection in the shim layer to ensure serializability. The system maintains the following invariant: values in the cache will either 1) reflect the value committed in the (serializable) data store or 2) be protected by an exclusive write lock.

To achieve this, the shim acquires locks on individual objects before sending requests to either storage system. Writes are buffered at the shim layer until commit. Once values are committed in the data store, they are updated in the cache before write locks are released. To handle crashes, we rely on the data store as the source of truth, similar to previous work [46, 75, 76], and we clear the cache after failures to prevent stale reads. We view applying transaction caching to multiversioned systems as a promising avenue for future work.

**Extracting transaction types and execution graphs.** We leverage prior work [36, 94] to obtain transaction execution graphs with table accesses from application code. The widespread adoption of JDBC-style drivers presents a common interface for extracting transactions across applications.

## 7.2 Eviction

Our eviction policy scores keys as a function of their groups as well as their frequency, size, and recency. The latter three are all features that are already available in Redis, which natively supports LRU and LFU. We reuse these metrics to minimize code changes when implementing our algorithm. We make two primary modifications to Redis: we add (1) a global aging factor that is updated during eviction (as detailed in Section 4.2.3) and (2) support for scoring groups of keys. Specifically, we modify the existing method Redis provides for fetching multiple objects to delineate which keys are accessed together. We update key scores only after a transaction has completed so that we have sufficient information to calculate all group scores. Our changes involve less than 100 lines of code and suggest that DeToX can be easily integrated into any caching system. We also implement a trace-driven simulator in Python to evaluate the offline Belady and Transactional Belady algorithms.

## 8 Evaluation

In this section, we evaluate DeToX against existing caching policies on a range of different workloads. Specifically, we aim to answer the following questions:

- How does DeToX compare to single-object algorithms in terms of transactional hit rate and cache efficiency?
- What is the impact of our grouping techniques?
- What is the tradeoff between optimizing for object hit rate and transactional hit rate?

## 8.1 Experimental Setup

We run our shim layer and Postgres on separate c5a.4xlarge Amazon EC2 instances (16 CPUs, 32GB RAM) and use a memory-optimized r5.4xlarge machine (16 CPUs, 128GB RAM) for Redis. Clients run on c5a.16xlarge instances (64 CPUs, 128GB RAM). We host all machines in the same region with low network latency (0.2ms). For our experiments, we report the average of three 5-minute runs with 60 seconds of warm-up time. When an eviction is needed, we score 10 random samples and choose one to evict among these candidates. This strategy removes the overhead of maintaining a sorted list of keys without degrading performance and is popular in many caching systems [2, 79], including Redis.

**Benchmarks.** We evaluate DeToX against single-object baselines as well as the policies developed in PACMan [11] (their LFU-F is equivalent to our LFU; we evaluate their LIFE algorithm) and ChronoCache [45], a state-of-the-art prefetching system that leverages transactional dependencies. We measure performance on a range of workloads. **TAOBench** [26] is an open-source social network benchmark based on Meta’s production traces. We run the Product Group 1, 2, and 3 workloads, which represent distinct sets of (anonymized) applications at Meta that share data and use the same product infrastructure. All workloads are read-heavy and skewed, typical of most social networks. They contain point reads and writes (inserts, updates, and deletes) as well as read-only and write-only transactions. All transactions are “flat” (they contain no logical dependencies). Since transaction code is not available for this benchmark, we use levels to score groups for eviction.<sup>1</sup> We run experiments with 100M objects for a total data size of around 1 TB. **Epinions** [37] consists of nine transaction types that represent behavior observed on a consumer reviews website. We run the benchmark with 2M user and 1M items for a total data size of roughly 1 TB. **SmallBank** [87] contains six types of transactions that model a simple banking application. We configure it to run with 500M (uniformly accessed) accounts (total size of 1 TB). **TPC-C** [33], a standard OLTP benchmark, simulates the business logic of e-commerce suppliers with five types of transactions. We configure TPC-C to run with 100 warehouses (total size of 8GB). In line with prior transactional key-value stores [34, 81], we use a separate table as a secondary index on the Order table to locate a customer’s latest order in the Order-Status transaction, and on the Customer table to look up customers by their last names (for the Order-Status and Payment transactions).

## 8.2 Application Benchmark Results

We show THR over different cache sizes for all benchmark workloads in Figures 8 and 10. We omit some throughput and

<sup>1</sup>TAOBench [26] chooses to model workloads using probability distributions rather than fixed query types for adaptability.

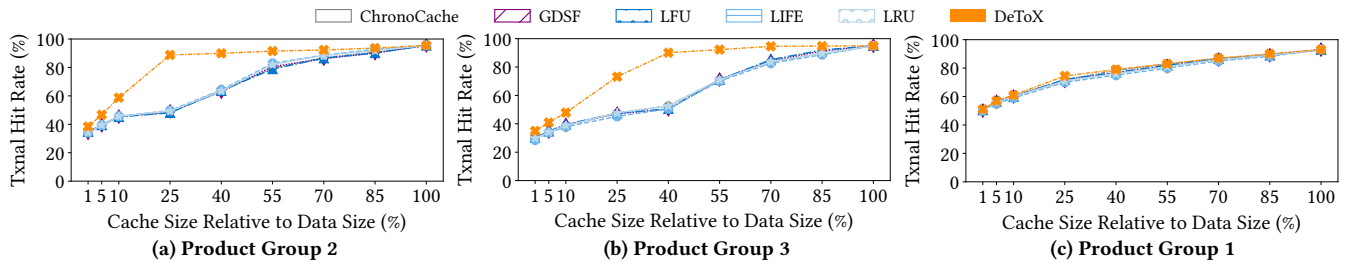

Figure 8: TAOBench THR results.

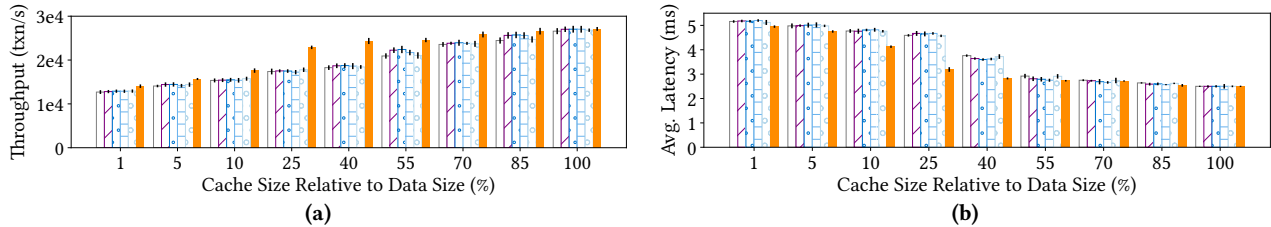

Figure 9: TAOBench PG2 results.

latency graphs for space but describe results in text. Since all transactions in these workloads have symmetric structures, there is no difference in performance between our various grouping techniques. We detail the tradeoffs between these optimizations in the next section.

**TAOBench.** DeToX obtains up to 76% higher transactional hit rates on the TAOBench PG2 and PG3 workloads compared to single-object caching algorithms (Figures 8a and 8b). DeToX achieves this with better cache efficiency: at the 25% cache size relative to data size (a common setup following the “80-20 rule”), the protocol achieves an 88% transactional hit rate while the best single-object algorithm requires 3.4x more cache space to attain the same result on PG2. Results are similar for PG3 for which the system requires a 2.2x smaller cache. Throughput increases by 31% (from 18K txns/s to 24 txns/s) for PG2 and 30% for PG3 (from 31K txns/s to 40 txns/s), while latency decreases by 30% (4.6ms to 3.2ms) for PG2 (Figure 9b) and 29% for PG3 (2.3ms to 1.6ms).

PG2 is read-dominant (>96%) with a mix of point reads, short transactions (<10 operations), and larger read transactions that span up to 40 keys. The point reads and shorter transactions make up 60% of the workload and largely access a small group of hot keys. Consequently, all algorithms achieve a THR of over 45% for small cache sizes (10% relative size). The longer read transactions follow one of two patterns: transactions access either a combination of hot and warm keys (25%), or hot and cold keys (11%). Transactions from the first category are more beneficial to cache since their keys are more frequently accessed and more likely to lead to transactional hits. There is little benefit in caching any of the keys in the second category since the cold keys contaminate all the other ones.

Under DeToX, the cache initially chooses to cache keys that belong to transactions in the first category. Thus, transactional hit rate improves as the cache size increases from 10% to

40% (Figure 8a). Past this point, the cache begins to retain more keys from transactions in the second category, but the performance benefit is limited since these requests rarely lead to transactional hits. In contrast, single-object algorithms use only individual object features to score keys, so they retain hot keys from transactions in both categories. Transactional hit rate increases slowly up to the 55% cache size at which point the cache becomes large enough to begin storing the warm keys from the first transaction category. Since the TAOBench workloads have no temporal patterns, GDSF and LFU provide slightly higher hit rates compared to LRU for all cache sizes. While LIFE uses levels, it performs poorly because it only uses the size of levels to make eviction decisions.

Similarly, in PG3, DeToX achieves better cache efficiency by not retaining contaminated keys. This workload has a smaller portion of point reads and shorter transactions (50%), so hit rates at smaller cache sizes are lower for all policies. Longer read transactions span up to 60 items and also fall into two categories. There are more transactions in the first category (33% compared to 25% in Product Group 2), so transactional hit rates grow more slowly with respect to cache size since more warm keys need to be cached.

In contrast to the other workloads, PG1 (Figure 8c) consists mainly of point reads and some short read transactions (of size four or smaller), which together make up over 97% of all requests. Our algorithm does not improve transactional hit rate over single-object policies because most hits result from standalone requests and short read transactions to a set of highly popular keys, which single-object algorithms already cache effectively. Throughput increases by 2% (from 82K txn/s to 84K txn/s), and latency decreases by 2% (from 0.61ms to 0.60ms).

ChronoCache has similar hit rates to single-object algorithms since there are no dependencies within transactions for this benchmark; the results simply reflect its eviction policy, LRU. The middleware layer, which does dependency

Figure 10: OLTP benchmark THR results.

Figure 11: SmallBank results.

analysis at run time, quickly becomes the bottleneck.

**Epinions.** Epinions centers around user interactions and item reviews. It contains five read-only transactions and four update transactions. Users have both an n-to-m relationship with items (i.e., representing user reviews and ratings of items) and an n-to-m relationship with other users. There are no logical dependencies in the transactions of this workload (all operations can be parallelized).

DeToX provides up to 41% increase in transactional hit rate (Figure 10a), translating into 29% improvement in throughput (from 12K txn/s to 17K txn/s) and 25% decrease in latency (from 6.9ms to 5.5ms). At the 25% cache size, DeToX is 1.6x more efficient than the other algorithms. The transactions in Epinions request some group of objects related to a particular user or item (e.g., get all the reviews from one user), so our policy is able to successfully capture the n-to-m relationships in the data with its scoring mechanism. In contrast, the single object policies focus on caching individually popular keys without taking into account correlation between accesses. Since there are no dependencies between or within transactions for this workload, ChronoCache is unable to successfully prefetch objects.

**SmallBank.** SmallBank consists of requests to the Accounts, Checking, and Savings tables with six transaction types. Its transactions are relatively small, involving four distinct keys at most. Roughly two-thirds of operations are reads. Each customer account is materialized as three separate entries in each table and is accessed with a uniform distribution. There is high correlation between accesses to a customer’s row in the Accounts table and the customer’s rows in the other two tables.

Our algorithm provides up to a 1.3x increase in transactional hit rate (Figure 10b). The absolute hit rates remain relatively low for smaller cache sizes because of the uniform access distribution to customer accounts. Transactional hit rate increases linearly for all algorithms since more cache space directly

results in more hits. DeToX is 1.6x more efficient than the next best-performing algorithm at the 25% cache size.

We observe up to a 28% increase in throughput (from 12K txn/s to 16K txn/s) and 26% decrease in latency (from 6.8ms to 5.4ms) on this workload (Figures 11a and 11b). The long tail in access patterns and short transactions of this workload limit the benefits of our eviction algorithm over single-object alternatives, which all have similar performance.

For this workload, around two-thirds of performance improvement can be attributed to prefetching. We compare our eviction algorithm without prefetching (DeToX-E), LRU with prefetching (LRU-P), and our full policy (DeToX). DeToX-E increases throughput by 9%, LRU-P by 19%, and DeToX by 28% (graph omitted for space).

**TPC-C.** TPC-C is notably write-heavy and has transactions that can span over 50 items. Its requests tend to fall into two categories: either they access a small set of popular keys (i.e., those in the Warehouse and District tables) or a larger range of keys from a distribution with a long tail (Customer, Item, Stock). Single-object caching algorithms are designed to cache the former while the latter almost always results in transactional misses. For instance, *New-Order* accesses a key in each of the Warehouse, District, and Customer tables before requesting 10 to 15 items from the Item and Stock tables, which are chosen from a skewed distribution.

Consequently, TPC-C cannot benefit from transactional caching: most transactions access a small set of hot keys that are already in the cache (the object hit rate is >50% with a 10% cache size in Figure 10c) along with a larger set of cold keys that are unlikely to be cached and contaminate the other keys (hit rate grows slowly as cache size increases). Moreover, transactions tend to access keys in quick succession (e.g., once an order is placed, it is then processed, paid for, and delivered), so recency is especially important in this workload. All algorithms incorporate recency in some form,

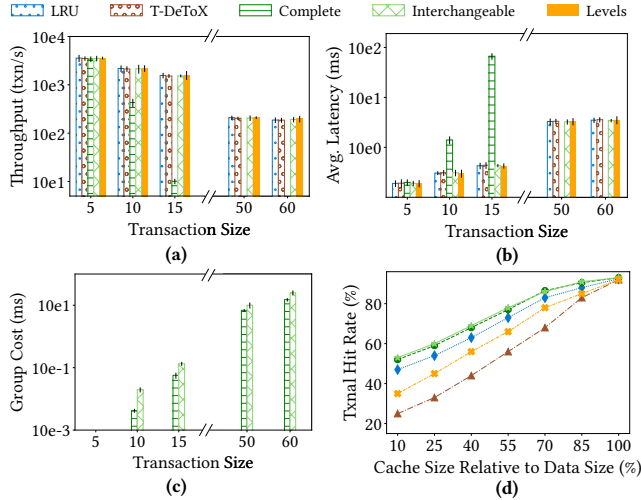

Figure 12: (a),(b),(c). Microbench. 1 (d) Microbench. 2.

so performance is similar across these policies, with up to 9K txns/s and 27ms avg. latency. DeToX performs on par with single-object policies.

### 8.3 The Need for Dependency Analysis

In this section, we investigate the relative merits of our grouping optimizations. The dependency analysis required for complete groups can impose overheads in two ways: (1) the cost of updating the scores of each key in each group and (2) metadata overhead associated with scoring. Interchangeability can reduce the number of groups that need to be scored, leading to better performance. On the other hand, levels discount unbalanced topologies while T-DeToX, a baseline that scores all keys of a transaction together, ignores dependencies. These simpler policies reduce overhead in some cases but restrict the groups that keys can belong to, leading to worse performance.

**Performance impact.** Microbenchmark 1 intentionally captures the worst-case scenario for grouping. We run a single transaction type with the topology in Figure 6a, and we extend the right branch of the graph for larger transaction sizes. Each read uniformly accesses keys at random among 10M objects. We measure throughput and latency as we increase transaction size up to 60 (equivalent to the largest transactions in the TAOBench workloads). Figures 12a and 12b show that performance for complete groups decreases dramatically as transaction size increases due to the exponential number of complete groups: for a transaction of size 15, over 16K groups have to be scored. Note that the bars for throughput and latency are omitted for complete groups for transaction sizes greater than 15 since these experiments did not finish in reasonable amount of time. In contrast, performance degradation is minimal with interchangeable groups (<5% difference compared to LRU at size 60). There are only a linear number of groups that must be scored with respect to transaction size since all keys in the right branch of this topology are interchangeable. Finally, levels offer similar performance to

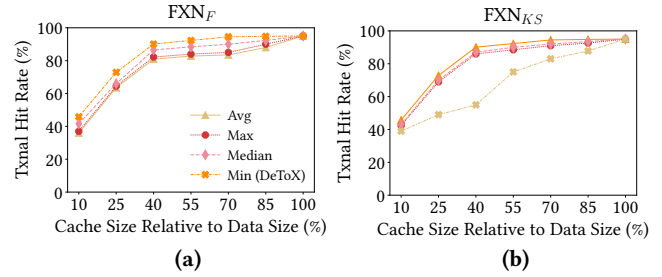

Figure 13: Scoring heuristics

LRU. Each key can only belong to one level per transaction, so larger transaction sizes do not increase overhead. The run time CPU overhead of both interchangeable groups and levels is within 5% of that of single-object algorithms for all microbenchmarks and previous benchmark workloads.

Moreover, the one-off cost of finding complete and interchangeable groups at compile time remains low: transactions of size 60 (with 100K+ groups due to worst-case topologies) require less than five minutes to process (Figure 12c). All benchmark workloads require less than 30 seconds for dependency analysis.

While dependency analysis incurs a static cost, it can lead to significant benefits compared to more basic forms of grouping (levels and T-DeToX), which ignore some or all dependency information. Microbenchmark 2 quantifies the worst-case scenarios for levels and T-DeToX. We run a single transaction type with the topology in Figure 6a in which the keys in vertices *a* and *c* are hot keys chosen from a Zipfian distribution while keys in *b* and *d* are cold keys chosen from a uniform distribution over 10M objects. Using levels causes keys in *b* and *c* to be scored together. However, keys in *b* are rarely accessed, and contaminate keys in *c*. T-DeToX makes even worse eviction decisions since it scores all keys in *a*, *b*, *c*, and *d* together. Using complete and interchangeable groups would instead cause keys in *b* and *d* to be scored together, enabling the algorithm to capture the fact that caching *c* individually reduces critical length. We find that complete and interchangeable groups significantly outperform levels (53% increase) and T-DeToX (139% increase) for THR (Figure 12d). Complete and interchangeable groups offer similar performance to LRU since these policies cache keys in *c*, which are frequently accessed.

**Memory overheads.** Metadata overhead in DeToX is low. Our algorithm stores two additional counters (total group score, individual score) per key and a global aging factor for eviction. While prefetching, DeToX stores dependency sets. On TAOBench, additional metadata takes up less than 1% of the cache space. For workloads in which prefetching is more prevalent, metadata overheads increase slightly. For example, in SmallBank, additional metadata grows to 2%. DeToX must store the dependency set associated with each transaction (1.5 keys on average).

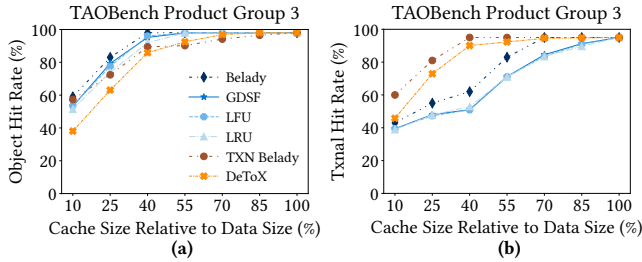

Figure 14: Object (a) and transactional (b) hit rates.

## 8.4 Scoring Heuristics

We evaluate different heuristics for calculating instance ( $F_{XNF}$ ) and aggregate scores ( $F_{XNKS}$ ). DeToX uses the *minimum* frequency of keys in a group for the instance score, and *averages* instance scores to compute an aggregate score (Section 4.2). We measure transactional hit rates for simple functions (average, maximum, median, minimum) in Figure 13 for the PG3 workload (results are similar across workloads).

For assigning key instance scores, we find that, as expected, Min provides the best performance (Figure 13a). Since we only get a transactional hit if *all* keys of a group are cached, the key with the smallest frequency should have outsized impact on the group score. The other functions discount this information and thus perform worse. However, these functions still encode the all-or-nothing property of transactions to some extent since they assign the same instance scores to all keys in a particular group. As a result, we still observe higher hit rates than single-object policies.

Average and Median are the most effective functions for calculating aggregate key score (Figure 13b). Max yields a lower hit rate since it assigns each key the score of its highest-scoring group, but this may not be the most frequent group that contains this key. Min provides markedly lower performance (up to 64% lower hit rates). Each key is assigned the score of its lowest-scoring group, so most scores converge to the lowest group score (the smallest frequency of any key). As a result, most scores are low and do not differ by much.

## 8.5 OHR versus THR

There is a tradeoff between optimizing for latency and for system load. Figure 14 shows the OHR and THR of online algorithms as well as Belady and Transactional Belady (see Appendix A). As expected, Belady outperforms other algorithms for object hit rate. Conversely, DeToX and Transactional Belady give some of the lowest object hit rates. However, these two algorithms significantly outperform the other policies for transactional hit rate (and result in better throughput and latency as shown in Section 8.2). While we focus on PG3 here, we find similar results on the other workloads (omitted due to lack of space).

The difference between OHR and THR illustrates a tradeoff between reducing I/O bandwidth and optimizing for latency.

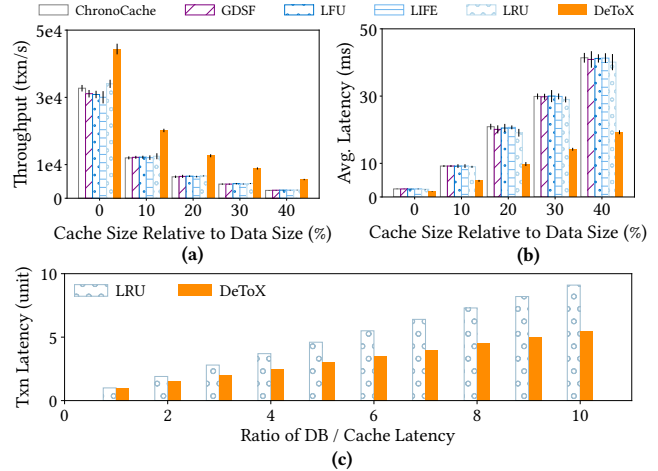

Figure 15: Network latency (a), (b) and simulation (c) results.

OHR prioritizes the absolute number of requests that can be served from cache, minimizing requests to disk. In contrast, THR focuses on the number of latency reductions for transactions, leading to lower latency and higher throughput. There are practical motivations for choosing THR as the caching objective: with increasing elasticity from cloud resources, applications often focus on latency optimization for which large wins are possible with DeToX.

## 8.6 Transactional Hit Rate

Transactional hit rate is independent of system specifics; only relative throughput and latency gains differ when cache / system latency changes. We confirm this by (1) varying this ratio (both experimentally and through simulation) and (2) evaluating DeToX with an alternative key-value store, TiKV [4].

**Network latency.** We inject latency between the shim layer and data store to simulate scenarios in which the latter is hosted in a remote cloud region. Figure 15 shows that the performance improvement with DeToX grows as network latency increases. With no additional network latency (0ms), there is a 30% increase in throughput and 29% decrease in latency between DeToX and the best single-object policy for PG3. With a WAN delay of 10ms, there is a 61% increase in throughput and 47% decrease in latency.

**Simulation results.** To illustrate the impact of cache and data store request times, we provide results for the TAOBench PG2 workload. At the 25% cache size, the THR for this workload is around 90% for DeToX and 50% for the other policies (Section 8.2). We vary request times for the cache and the data store (DB), using arbitrary units to represent latency. As we increase the ratio of DB to cache latency in Figure 15c, we find that the difference in request latency between LRU and DeToX increases from 0% to 65% as request times to the data store lengthen.

**Transactional key-value store.** We confirm that both the difference in transactional hit rate and gains in cache

Figure 16: TAOBench PG2 results on TiKV.

efficiency (3.4x) remains identical when executing atop TiKV, demonstrating that these metrics are independent of the setup chosen (Figure 16). In contrast, as TiKV exhibits higher throughput and lower latency than Postgres, throughput and latency gains fall to 19% and 15% respectively.

## 9 Related Work

**Eviction.** There is a wide range of research on single-object caching policies that consider frequency [23, 40, 41, 53, 63], recency [32, 42, 52, 70], the number of unique keys between accesses [14, 50, 57, 64, 73], the variable sizes of objects [5, 25], and combinations of these features [6, 7, 12, 13, 15, 18, 20, 28, 49, 51, 56, 77, 80, 99]. Some specialized eviction policies optimize for flash storage [74], adapt to changing workloads [17, 19, 21, 30, 31, 39, 89], or consider network bandwidth and download time for proxy caches [93]. These previous efforts do not explicitly address how caching should be optimized for parallel accesses in transactions.

PACMan [11] presents eviction algorithms targeted towards job processing based on the all-or-nothing property: for jobs that issue tasks in parallel, latency only improves if all parallel tasks are cached. Similarly, existing literature on web caching [7, 18, 91] focuses on maximizing the *page* hit rate since latency is reduced only when all parts of a page are cached. Transactional hits in DeToX are based on a similar insight. However, DeToX addresses the issue of complex, unbalanced dependency graphs and recognizes that keys can be shared across many transactions.

**Admission algorithms.** In contrast to eviction algorithms, admission policies decide what to *allow* into the cache by enforcing a threshold based on object scores. These algorithms have often been applied alongside eviction policies [7, 21, 40, 52, 62]. While we focus on eviction and prefetching in this paper, our grouping and scoring strategies can feasibly extend to admission, which we will explore in future work.

**Prefetching.** Prefetching has been applied extensively to web caching [10, 90]. Past work focuses on web page analysis [38, 55, 68, 71, 86, 95, 96], which most stand-alone caches do not support [2, 69]. Other research [24, 44, 45, 72] centers around reducing the latency of query execution using dependency analysis. These works assume that each client issues queries sequentially, so any cache hit can

improve latency. Instead, DeToX caches in order to maximize transactional hit rate. Furthermore, none of these systems provide isolation guarantees or consider how eviction policies should be modified to handle transactions.

**Cache coherence.** Previous work combining transactions and caching focuses on maintaining isolation guarantees for cache coherence [1, 54, 76, 97]. In contrast, we focus on what objects to cache for performance. DeToX ensures serializability while optimizing for transactional hit rate.

## 10 Conclusion

In this paper, we study the problem of transactional caching. Standard caching policies fail to account for the all-or-nothing property of transactions, resulting in inefficient choices for which objects to retain in cache. In light of this issue, we provide a formal framework to quantify the latency impact of caching for transactions and introduce transactional hit rate as the key metric for this setting. We then present DeToX, a novel caching system targeting at transactional workloads. DeToX maximizes transactional hit rate by centering its caching policy around scoring groups of keys together. We consider how keys are accessed in parallel through complete groups and introduce interchangeable keys as an optimization to reduce the overhead of having to score many groups at run time. We also describe levels as a technique for cases when transaction code is not available. Our implementation is lightweight and deployable on a range of existing caching systems and data stores. DeToX improves THR by up to 1.3x and cache efficiency by up to 3.4x. This work demonstrates that many applications can benefit measurably from transactional caching.

## A Appendix

We prove the optimal offline transactional caching problem is NP-Hard. We begin by providing intuition for how and why traditional optimal offline caching policies fail to translate to transactional caching.

### A.1 Transactional Belady

We straightforwardly adapt Belady’s optimal caching policy [16] to the transactional context by defining *Transactional Belady*, a caching policy that evicts keys that result in *transactional hits* furthest in the future. While this extension is intuitive, it does not offer optimal performance even for flat, uniformly-sized transactions that access equally-sized objects, as we prove below.

Consider the execution trace in Figure 17 with cache capacity of 5. All transactions access three keys, either all from set  $S_1: \{t, u, v, t', u'\}$  or set  $S_2: \{x, y, z, x', y'\}$ .  $T_1$  and  $T_2$  access only keys from the former group, while  $T_3$  and  $T_4$  access only keys from the latter.  $T_5$  and  $T_6$  access keys from  $S_1$  and overlap in  $v$ , while  $T_7, T_8, T_9$  overlap in  $x', y, z$  from  $S_2$ . Transactional

T	Keys accessed	Cache state	Optimal cache state
1	$t, u, v$	-	-
2	$t', u', v$	$t, u, v$	-
3	$x, y, z$	$t, u, v, t', u'$	-
4	$x', y', z$	$t, u, v, t', u'$	$x, y, z$
5	$t, u, v$	$t, u, v, t', u'$	$x, y, z, x', y'$
6	$t', u', v$	$t, u, v, t', u'$	$x, y, z, x', y'$
7	$x, y, z$	$t, u, v, t', u'$	$x, y, z, x', y'$
8	$x', y, z$	$t, u, v, t', u'$	$x, y, z, x', y'$
9	$x', y', z$	$t, u, v, t', u'$	$x, y, z, x', y'$

Figure 17: Non-optimality of Transactional Belady. Red keys indicate ones that lead to transactional hits.

Belady evicts keys that yield a transactional hit furthest in the future. After  $T_3$ 's execution, the algorithm evicts  $x, y, z$  as they would first yield a hit at  $T_7$  while the other keys would lead a hit at  $T_5$  and  $T_6$ . A similar reasoning leads the algorithm to evict  $x', y', z'$  after  $T_4$  executes. This strategy yields two transactional hits (for  $T_5$  and  $T_6$ ). Unfortunately, evicting  $x, y, z$  after  $T_3$  is the wrong decision. Keeping all keys of set  $S_2$  in the cache yields three transactional hits  $T_7, T_8, T_9$ . As a result, Transactional Belady achieves only two transactional hits, while an optimal caching policy would achieve three.

Transactional Belady does not account for shared keys across transactions. It caches set  $S_1$ , which is shared across two transactions, instead of keys in set  $S_2$ , which is shared across three transactions. Belady assumes that a cache hit closer in the future is always as valuable as a cache hit further out. This assumption holds when a single cached object provides a single object hit but breaks down when keys are shared across transactions. In these cases, an equal number of cached objects can produce varying numbers of transactional hits.

## A.2 Optimal Offline Transactional Caching is NP-Hard

We demonstrate that the optimal offline transactional caching problem (TxPolicy) is NP-Hard through a reduction from the variable-sized caching problem, CACHING(FAULT, OPTIONAL), introduced in [29].

We first provide intuition for our reduction. A page hit is only possible if the entire page is present in the cache, regardless of its size. The objective of CACHING(FAULT, OPTIONAL) is to minimize the number of page faults, or the number of pages accessed and missed. We convert each page of size  $X$  into a transaction without dependencies that accesses  $X$  operations. Therefore, there is only a transaction hit when the entire transaction is in the cache. This transforms CACHING(FAULT, OPTIONAL) into an easier version of TxPolicy with two simplifying assumptions: (1) all transactions will use unique keys, so that retaining a key in the cache from any single transaction provides no benefit to any other transaction, and (2) there are no logical dependencies. If an optimal offline transactional

caching policy exists, then through this reduction, we have the optimal policy for CACHING(FAULT, OPTIONAL).

We now formally describe CACHING(FAULT, OPTIONAL) from [29]. CACHING(FAULT, OPTIONAL) asks,

Given a set of pages  $p_1, \dots, p_k$  with sizes

$\text{SIZE}(p_1), \dots, \text{SIZE}(p_k)$ , request sequence  $r_1, \dots, r_m \in \{p_1, \dots, p_k\}$ , cache size  $C$ , and cost bound  $F$ , is there a replacement policy that serves  $r_1, \dots, r_m$  with cache size  $C$  and incurs a total fault cost at most  $F$ ?

A *fault* is incurred when  $r_i \notin C_i$ , where the FAULT parameter states that each fault has cost 1. The OPTIONAL parameter requires that  $\forall i > 1, C_i \subseteq \{C_{i-1} \cup r_i\}$ ; informally, the caching policy does not have to admit the most recent page.

We formally define the offline transactional caching problem, based on our formalisms from Section 3.

**Definition 10** (*Offline transactional caching policy*). An *offline transactional caching policy* is a function  $P$  that takes a sequence of transactions  $T_1, T_2, \dots, T_m$ , cache size  $n$ , and outputs a sequence of cache states  $C_1, C_2, \dots, C_m$ , with the following restrictions:

1.  $C_1 = \emptyset$ .
2.  $\forall i > 1, C_i \subseteq \{C_{i-1} \cup T_{i-1}\}$ .

TxPolicy asks,

Given a set of transactions  $T_1, \dots, T_m$ , cache size  $C$ , is there an offline transactional caching policy that serves  $T_1, \dots, T_m$  with cache size  $C$  and incurs at most  $F$  transactional misses? We define *transactional misses* as the number of  $i$  where  $T_i \not\subseteq C_i$ , or the number of transactions that cannot be served from cache.

**Theorem 1.** *The optimal offline transactional caching problem is NP-Hard.*

*Proof.* We reduce CACHING(FAULT, OPTIONAL) to TxPolicy through the following polynomial-time reductions. Each page  $p_i$  is reduced to a transaction  $T_i$ .  $\text{SIZE}(p_i)$  new tables are created per transaction, each with only one key. Let  $X$  be one such table. A read operation on the sole key of that table  $x \in X$  is inserted into the transaction  $T_i$ . There are no logical dependencies. Cache size  $C$  is preserved. The maximum fault cost  $F$  is converted to the maximum number of transactional misses. If there exists a policy solving the offline transactional caching problem, run it with these parameters. Its output is the output to the CACHING(FAULT, OPTIONAL) problem. CACHING(FAULT, OPTIONAL) is NP-Hard; therefore, the offline transactional caching problem is NP-Hard.  $\square$

## B Artifact Appendix

### Abstract

DeToX is a transactional caching system that leverages insights on transactional hit rate to improve caching performance for transactional workloads. DeToX is implemented as a shim layer that integrates with caching and database systems. In addition to DeToX, the artifact contains several other implementations. First, there is a modified version of ChronoCache, a middleware predictive query caching system, that measures transactional hit rate, integrates with Redis, and supports several benchmarks not available for the original system. There is also a modified version of Redis that supports several eviction algorithms, including DeToX's eviction algorithm and LIFE from the PACMan paper. Finally, there is a caching simulator that takes transaction traces as input and outputs hit rates for the offline Belady and Transactional Belady algorithms.

### Scope

The artifact enables others to run DeToX directly. All code used in the paper is made available.

### Contents

The artifact consists of a Github repository hosted at <https://github.com/audreycccheng/detox>. The repository is structured as follows:

- /chronocache - the codebase for ChronoCache
- /oltpbench-chronocache - the benchmarks for ChronoCache
- /redis - the modified version of Redis supporting transactional caching algorithms
- /simulator - the caching simulator for offline policies
- /sys - the transactional caching system
  - /benchmarks - the benchmarks for running DeToX
  - /src - the implementation of the DeToX shim layer

### Hosting

The artifact is hosted at <https://github.com/audreycccheng/detox> on the main branch at commit 604c9bd.

### Requirements

The following packages are required to run the codebase.

- mvn 3.8.5
- build-essential
- Java 17

For specific installation guides for each system, please see the Github repository.

# Replicating Persistent Memory Key-Value Stores with Efficient RDMA Abstraction

Qing Wang, Youyou Lu, Jing Wang, and Jiwu Shu\*

*Tsinghua University*

## Abstract

Combining persistent memory (PM) with RDMA is a promising approach to performant replicated distributed key-value stores (KVSs). However, existing replication approaches do not work well when applied to PM KVSs: 1) Using RPC induces software queuing and execution at backups, increasing request latency; 2) Using one-sided RDMA WRITE causes many streams of small PM writes, leading to severe device-level write amplification (DLWA) on PM.

In this paper, we propose ROWAN, an efficient RDMA abstraction to handle replication writes in PM KVSs; it aggregates concurrent remote writes from different servers, and lands these writes to PM in a sequential (thus low DLWA) and one-sided (thus low latency) manner. We realize ROWAN with off-the-shelf RDMA NICs. Further, we build ROWAN-KV, a log-structured PM KVS using ROWAN for replication. Evaluation shows that under write-intensive workloads, compared with PM KVSs using RPC and RDMA WRITE for replication, ROWAN-KV boosts throughput by 1.22× and 1.39× as well as lowers median PUT latency by 1.77× and 2.11×, respectively, while largely eliminating DLWA.

## 1 Introduction

Replicated distributed key-value stores (KVSs) support many applications by providing durability and high availability [28, 56, 76]. The recent commercialization of persistent memory (PM), e.g., Intel’s Optane DIMMs, enables local storage with extremely low latency (e.g., ~100ns when persisting small data [73]). When building replicated distributed KVSs with such fast storage media, network and CPU will become determinants of request latency, since replicating an object (i.e., key-value pair) involves multiple times of network communication and request queuing/execution.

RDMA, a widely-deployed network technology [34, 37, 53], is promising to mitigate the network and CPU overhead. First, RDMA delivers low latency (~2μs) due to protocol-offload RDMA NICs (RNICs) and kernel-bypass software. Second, RDMA provides one-sided WRITE and READ, allowing remote memory accesses without involvement of remote CPUs. Recent work have leveraged WRITE to replicate data in DRAM (i.e., WRITE-enabled replication) [17, 30, 31, 69]. This eliminates software queuing/execution of backups in the critical

path, thus significantly cutting the replication latency compared with RPC-enabled replication.

Yet, in the context of PM KVSs, WRITE-enabled replication approach does not work well: it induces severe device-level write amplification (DLWA) on PM. Specifically, a KVS is typically finely sharded for load balancing and fast recovery, so every server acts as backups for many shards, receiving numerous concurrent replication writes from many remote threads; besides, these replication writes are typically small (~100B) due to prevalent tiny objects in real-world workloads [24, 52]. In WRITE-enabled replication approaches (e.g., FaRM [31]), each server allocates an exclusive backup log for *every remote thread*, to accommodate remote WRITE from primaries. When adopting WRITE-enabled replication to PM KVSs, these backup logs generate a huge number of PM write streams<sup>1</sup>, which contain lots of small-sized writes. These numerous write streams lead to severe DLWA, since PM has block access granularity at media level (e.g., 256B in Optane DIMMs) and its hardware combining capacity is bounded. In our experiments, with 128B RDMA WRITE, 144 remote PM write streams cause 1.58× DLWA (§2.4). DLWA wastes limited PM write bandwidth, shortens PM lifetime, and harms PM’s persistence efficiency.

In this paper, we propose ROWAN, an efficient RDMA abstraction to handle replication writes on PM KVSs. ROWAN can aggregate numerous concurrent remote writes from different servers, and land these writes to PM *sequentially*, so as to largely eliminate DLWA. Besides, it is one-sided as RDMA WRITE, enabling backup-passive replication with low latency and high CPU efficiency. We realize ROWAN with off-the-shelf RNICs based on two observations: 1) RDMA SEND is two-sided on the control path but *one-sided on the data path*; 2) RNICs consume receive buffers *in order*. Thus, we let a control thread at the receiver side push PM-resident buffers into receive queues *in increasing address order*. Senders only need to issue SEND for remote PM writes and wait for ACKs generated by receiver-side RNICs. We leverage two RNIC hardware features, shared receive queue (SRQ) [11] and multi-packet receive queue (MP RQ) [7, 9], to merge writes from different connections and support variable-sized writes, respectively. We also streamline ROWAN’s control path by minimizing the control thread’s tasks. A ROWAN instance can

\*Jiwu Shu is the corresponding author (shujw@tsinghua.edu.cn)

<sup>1</sup>A *write stream* is a group of writes targeting contiguous addresses, e.g., writes that perform log appending.

achieve 54.5Mops/s for highly concurrent 64B remote PM writes, with almost no DLWA.

Further, we build ROWAN-KV, a PM KVS leveraging ROWAN for primary-backup replication. It adopts a log-structured approach to manage both local PM writes and remote PM writes. Specifically, each server maintains per-thread primary logs and a *single* backup log on PM. For a PUT request, a worker thread in servers generates a log entry containing the targeted object; then, it persists the log entry into its local primary log via CPU instructions and every backup’s backup log via one-sided ROWAN. For a GET request, the thread searches DRAM-resident indexes which point to objects in logs. In this way, ROWAN-KV features high performance and low DLWA: 1) Replication bypasses CPUs of backups, ensuring low latency and saving CPU cycles for foreground operations; 2) The number of PM write streams in a server is small (i.e.,  $n$  primary logs + 1 backup log, where  $n$  is local thread count), enabling efficient write combining in PM hardware and thus largely eliminating DLWA. ROWAN-KV also introduces a failover mechanism for fault tolerance and a dynamic resharding mechanism for load balancing.

We evaluate ROWAN-KV on Optane DIMMs under a cluster of 14 machines (8 clients and 6 servers). Our evaluation focuses on YCSB benchmarks [26] with object sizes from three typical Facebook KVSs workloads [24] (i.e., ZippyDB, UP2X and UDB). Compared with KVSs using RPC and WRITE for replication, ROWAN-KV boosts throughput by 1.22× and 1.39×, lowers median PUT latency by 1.77× and 2.11×, and lowers 99% latency by 1.26× and 2.06×, respectively, under write-intensive workloads. In addition, the DLWA is less than 1.032× in ROWAN-KV, while 1.54× in the WRITE-enabled KVSs. Under read-intensive workloads, they have similar performance. We also compare ROWAN-KV with two software techniques mitigating DLWA, i.e., batching and log sharing; ROWAN-KV still outperforms them.

In summary, this paper makes the following contributions:

- It demonstrates that WRITE-enabled replication can lead to severe device-level write amplification on PM KVSs.
- It introduces ROWAN abstraction and ROWAN-KV with goals of low latency and low device-level write amplification.
- It uses experiments to confirm the efficacy of ROWAN-KV.

## 2 Background and Motivation

In this section, we first provide the background on PM (§2.1) and RDMA (§2.2). Then, we show that characteristics of typical KVSs architecture and workloads together lead to high fan-in small writes for replication (§2.3). Finally, with experiments, we demonstrate that when handling these writes, WRITE-enabled replication causes severe DLWA (§2.4).

### 2.1 Persistent Memory (PM)

PM is a new kind of storage device that sits on the memory bus. Thus, PM is byte-addressable and can be accessed by CPUs via load/store instructions. In this paper, we focus on Intel’s Optane DIMM, the only available PM product.

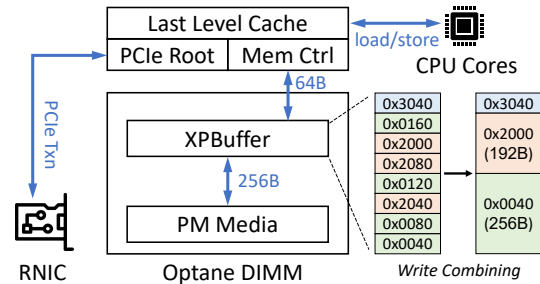

Figure 1: Architecture of Optane DIMMs and RNICs.

**PM performance.** Optane DIMMs have unique performance characteristics. In terms of bandwidth, an Optane DIMM offers about 2GB/s for writes and 6GB/s for reads, which are 1/6 and 1/3 of DRAM, respectively. In terms of latency, compared to DRAM, Optane DIMMs have similar write latency but 3× higher read latency [73]. The limited write bandwidth and high read latency of Optane DIMMs are the main design considerations for many PM systems [20, 25, 48, 49, 59, 67, 74].

**PM architecture.** Figure 1 presents the architecture of Optane DIMMs. The memory controller generates cache-line granularity (i.e., 64B) read/write requests to Optane DIMMs, but the internal PM media has a 256B access granularity (referred as *XPLine* in this paper). Such a granularity mismatch will trigger read-modify-write events, thus leading to device-level write amplification (DLWA). To mitigate DLWA, each Optane DIMM features an XPBuffer [73], which performs write combining for adjacent 64B writes, as shown in the right part of Figure 1. Yang et al. estimated that the XPBuffer in an Optane DIMM is approximately 16KB in size [73].

**Persistent modes.** There are two persistent modes for PM: ADR and eADR [36]. In ADR mode, once a store reaches the memory controller, it can survive power failure; but the CPU cache is volatile, so programmers must explicitly flush data from the CPU cache (using `clwb` or `clflushopt` instructions) or bypass the CPU cache (using `ntstore` instructions). In eADR mode, the CPU cache also belongs to the persistence domain: its data will be flushed to PM upon power failure.

### 2.2 Remote Direct Memory Access (RDMA)

RDMA is a network technology that offers high bandwidth (e.g., 100 Gbps) and low latency ( $\sim 2\mu\text{s}$ ).

**Verb types.** RDMA provides two types of verbs for network communication: *message verbs* and *memory verbs*. Message verbs, i.e., SEND and RECV, are the same as Linux socket interfaces: a SEND emits a message to a remote server that prepares receive buffers via RECV. Memory verbs include WRITE, READ and ATOMIC. These verbs can operate receivers’ memory without involving receivers’ CPUs. Due to the *one-sided* feature, memory verbs enjoy low latency and high CPU efficiency.

**Queue pair.** RDMA servers use queue pairs (QPs) for communication. A QP contains a *send queue* (SQ) and a *receive queue* (RQ). A server posts requests, including SEND, WRITE, READ, and ATOMIC, to the send queue, and posts RECV to the receive queue for accommodating incoming SEND messages. A send/receive queue is associated with a *completion queue*

	max shard size	# of backup shards (stored by one PM server)
CosmosDB	20GB [10]	200
DynamoDB	10GB [2]	400
FoundationDB	500MB [3]	8,400
Cassandra	100MB [1]	42,000
TiKV	96MB [38]	43,000

**Table 1:** A PM server hosts many backup shards for popular KVSs. We assume 3-way replication and a typical configuration of PM servers: 2 sockets, each with 3TB Optane DIMMs (6TB in total).

(CQ), which generates completion signals for posted verbs.

**Remote persistence.** When issuing a WRITE to remote PM, to ensure the data persistence, we should take two extra actions. ① Since receiver-side RNICs return acknowledgements before data in WRITE is DMA-ed to PM, we should send a READ (1B in arbitrary addresses) to flush RNIC and PCIe buffers at the receiver side [42]. These two verbs (i.e., WRITE followed by READ) can be posted in one request according to the ordering guarantee of RDMA [70]. ② We should disable *Data Direct I/O (DDIO)* [5, 32], a technology of Intel CPUs that lets RNICs directly DMA data to last level cache (LLC). In ADR mode, disabling DDIO ensures that DMA-ed data can reach persistence domain. In eADR mode, it avoids PM write amplification resulting from LLC’s near-random eviction (64B cache line vs. 256B XPLine) [42, 70].

### 2.3 High Fan-in Small Writes in KVSs

In KVSs, replication makes *high fan-in small writes* a dominant access pattern due to the following two reasons.

**1) Data sharding.** Distributed storage systems (including KVSs) typically split the entire data set into a large number of shards, and then distribute these shards across many servers [16, 50]. Each shard has multiple replicas, with one selected as *primary* and the others as *backups*. Data sharding has two advantages. First, it can improve load balancing and support dynamic data migration in a fine-grained manner. Second, it can improve availability: when a server fails, since replicas of its data are distributed to many servers, the system can perform recovery and re-replication in parallel. For example, FaRM [30] maps each server into 100 consistent hashing rings by default; in Facebook’s RocksDB clusters, each server typically hosts tens or hundreds of shards [29].

With data sharding, each server acts as backups for tens or hundreds of shards, and their primaries are distributed to many servers. This makes every server receive messages for data replication, i.e., replication writes, from many primaries residing in many other servers. We call it *high fan-in writes*.

To solidify the argument of high fan-in writes in KVSs, we analyze five widely-used replicated KVSs. As shown in Table 1, these KVSs all have a maximum shard size, from tens of megabytes (i.e., Cassandra [1] and TiKV [38]) to several gigabytes (i.e., DynamoDB [2] and CosmosDB [10]). When we deploy these KVSs on servers having terabytes of PM, each server will host a considerable number of backup shards which ranges from 200 (CosmosDB) to 43,000 (TiKV),

generating high fan-in replication writes.

The degree of fan-in is even higher in systems equipped with fast network hardware (e.g., RNIC) [30, 31, 44, 45, 61, 69]. To achieve multicore-scalable and squeeze out the raw performance of NICs, these systems run multiple threads, each independently processing requests using exclusive network connections. For example, in DrTM+H [69], every worker thread independently issues RDMA WRITE for replication. With this threading model, the degree of fan-in increases from the number of remote servers to the *number of remote threads*.

**2) Numerous small-sized objects.** Many important applications relying on KVSs generate numerous small objects, whose size is much smaller than the access granularity of PM media (e.g., 256B XPLine in Optane DIMMs). For example, in ZippyDB, the largest KVS at Facebook [15], the average size of objects is only 90.8B [24]. Moreover, the other two typical KVSs at Facebook — UP2X (a KVS for AI services) and UDB (a KVS for social graph) — have average object size of 57.25B and 153.8B, respectively [24]. Twitter exhibits a similar workload feature: the most common length of a tweet is only 33 characters [14, 52]. This paper focuses on these small objects because of their prevalence and importance.

When a KVS handles PUT requests (from clients) for these small objects, primaries emit replication writes to associated backups. These writes are small, since they typically only contain replicated objects with tiny metadata [56]. These writes are also high fan-in due to data sharding, as explained before. As a result, we can conclude that *high fan-in small writes are a dominant access pattern in the cluster of KVSs*.

### 2.4 DLWA from WRITE-enabled Replication

Recent research demonstrates that for in-memory DRAM systems, compared with RPCs, leveraging RDMA WRITE for replication can obtain significant performance gain [17, 30, 31, 69]. In such WRITE-enabled replication, primaries issue replication writes to backups’ logs via one-sided WRITE, and only need to wait for acknowledgements (ACKs) from the RNIC hardware of backups. This eliminates software queueing/execution of backups in the critical path, thus enjoying low latency (e.g., Mu [17] cuts the latency by 61%). Further, the saved CPU cycles in backups can serve requests (e.g., GET) from clients, thus improving system throughput.

In systems using WRITE-enabled replication, to handle high fan-in replication writes from many remote threads (recall §2.3), each server maintains lots of backup logs, each accommodating WRITE from an individual remote thread (which can act as primary) [31, 69]. For example, in FaRM’s evaluation with 90 machines (each running 30 worker threads) [31], there are thousands of backup logs (i.e., 89×30) in each server. Yet, when we apply WRITE-enabled replication to PM KVSs, these backup logs (which are placed in PM for durability) will cause a huge number of PM write streams, which contain lots of small writes, thus inducing severe DLWA. We conduct an experiment to demonstrate it.

**Figure 2:** DLWA with varying remote write streams.  $DLWA = \text{media bandwidth}/\text{request bandwidth}$ . Threads access PM on a remote server; each thread generates a remote write stream. In (c) and (d), 18 CPU cores in the remote server perform local sequential PM writes.

In the experiment, we launch a number of threads (on four servers), each issuing sequential RDMA WRITE to an exclusive PM-resident log in a remote server and thus generating a PM write stream. We disable DDIO in the remote server and post a READ after each WRITE to guarantee persistence. The remote server is equipped with three 256GB Optane DIMMs and a 100Gbps RNIC. We use `ipmctl` [8] to periodically read hardware counters of Optane DIMMs, calculating *request bandwidth* and *media bandwidth*, which means write bandwidth received from memory bus and write bandwidth issued to PM media, respectively. Figure 2(a) and (b) show results with 64B and 128B WRITE size (representing small replication writes, §2.3), respectively. When remote write stream count is lower than 90, DLWA is negligible. This is because the XPBuffer on Optane DIMMs can combine adjacent small writes from the same write streams into 256B internal writes (§2.1). However, the capacity of combining is bounded due to the limited size of XPBuffer. Consequently, as the number of remote write streams continues to increase, severe DLWA appears. Specifically, when remote write stream count is 144, the DLWA is 2.48 $\times$  and 1.58 $\times$  in case of 64B WRITE and 128B WRITE, respectively.

Next, we consider a more practical scenario where local PM writes exist. In the remote server, we run 18 CPU cores, each performing sequential 128B PM writes using `ntstore`. We repeat the above experiment; Figure 2(c) and (d) show the results. Without remote RDMA WRITE, local PM writes can deliver high request bandwidth (i.e., available bandwidth). As the remote write stream count increases, DLWA in Optane DIMMs reaches 2.49 $\times$  and 1.70 $\times$  in case of 64B WRITE and 128B WRITE, respectively. In addition, the available bandwidth drops from 5.2GB/s to 2.1GB/s (60%) for 64B WRITE, and from 5.4GB/s to 3.2GB/s (41%) for 128B WRITE.

DLWA on PM leads to three issues. First, it reduces available PM write bandwidth, thus degrading system performance. The wasted bandwidth could also have been used for co-located applications [33, 54, 55]. Second, it shortens the lifetime of PM which has limited write endurance [6]. Third, severe DLWA consumes a considerable number of hardware resources (e.g., XPBuffer), harming persistence efficiency.

To efficiently handle high fan-in small writes, we need a new RDMA abstraction (rather than WRITE) for PM KVSS. This abstraction should *mitigate DLWA, while achieving benefits of one-sided verbs — low latency and high CPU efficiency.*

**Figure 3:** An instance of RowAN abstraction.

### 3 RowAN Abstraction

We propose RowAN, a new RDMA abstraction to handle high fan-in small writes in PM KVSSs. In this section, we first describe RowAN’s semantic and characteristics. Then, we present how to realize RowAN using off-the-shelf RNICs.

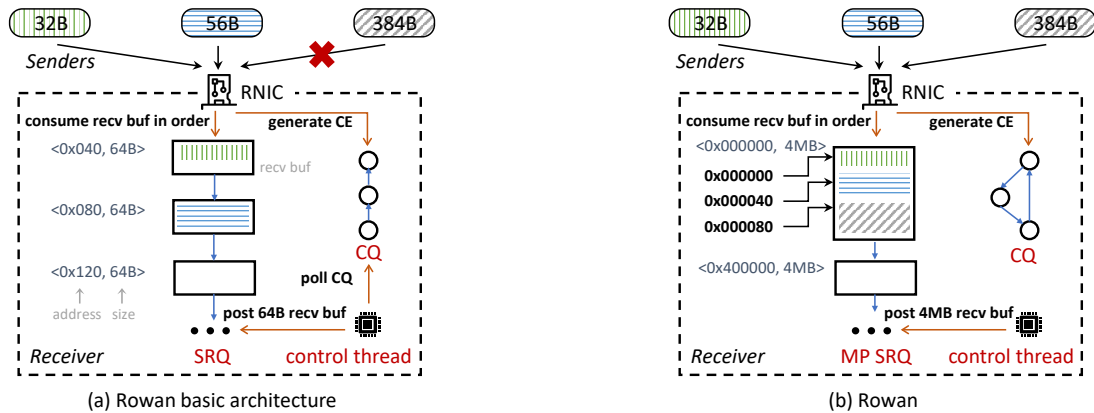

#### 3.1 RowAN Semantic

Figure 3 presents a RowAN instance. A RowAN instance is associated with one receiver and a set of senders. Senders concurrently issue writes to the receiver which has registered a large PM area. The receiver-side RNIC lands these writes to the PM area *sequentially*, and finally returns ACKs to senders.

RowAN abstraction has the following advantages. First, by translating concurrent remote small writes into a single write stream, the XPBuffer in Optane DIMMs can easily combine them into 256B XPLine writes, largely eliminating DLWA. Second, since all the data operations are performed by the receiver-side RNIC without involving receiver-side CPUs, RowAN enjoys benefits of low latency and high CPU efficiency like RDMA WRITE. In addition, compared with CPUs, RNIC ASICs can deliver extremely high throughput.

**Comparison with batching.** Batching is also an approach that can mitigate DLWA on PM: it opportunistically accumulates multiple small writes at the sender side, and then emits the batched writes to the receiver via one RDMA WRITE. However, batching induces extra latency, sapping the benefits of extremely low-latency hardware (i.e., RNICs and PM). In contrast, RowAN does not delay any write and thus ensures low latency: senders *immediately* issue writes and receiver-side RNICs *immediately* land received writes to PM. In addition, as we will show in §6, batching frequently fails to accumulate enough small writes within a short time interval in KVSSs, and RowAN outperforms batching in both latency and throughput. Our view of batching has been echoed by authors of RAMCloud — “. . . batching requires some operations to be delayed until a full batch has been collected, and **this is not acceptable in a low-latency system such as RAMCloud**” [56].

**Figure 4:** Realizing ROWAN with off-the-shelf RNICs. (a) ROWAN basic architecture using shared receive queue (SRQ). In this subfigure, the 32B write and 56B write are placed in the same XPLine. Yet, the 384B write fails to be received due to 64B receive buffers. (b) ROWAN using multi-packet shared receive queue (MP SRQ) with 64B stride. In this subfigure, three writes are placed in two XPLines of the first receive buffer. We use a completion queue (CQ) ring to eliminate CQ polling in the control thread.

## 3.2 High-Performance ROWAN

ROWAN is conceptually simple but challenging to realize using off-the-shelf RNICs. We do not want to modify RNIC hardware like StRoM [60] and PRISM [23], so as to enable ROWAN to be deployed immediately in datacenters today that are equipped with RNICs. Before describing our solution, we present a straightforward solution that has poor performance.

### 3.2.1 Straightforward Solution

A straightforward solution to realize ROWAN abstraction is combining RDMA WRITE and atomic verb FETCH\_AND\_ADD. Specifically, there is a 64-bit sequencer stored in the receiver’s memory. When performing a write, the sender first issues a FETCH\_AND\_ADD to the sequencer, reserving a PM address; then, it issues a WRITE to this address. This solution has two limitations. First, it needs two round trips, increasing the latency. Second, the poor performance of atomic verbs bottlenecks throughput: even storing the sequencer in RNICs’ device memory [68], the throughput is less than 10Mops/s.

### 3.2.2 Our Solution

Counter-intuitively, we use RDMA SEND and RECV to realize ROWAN. This is based on our two observations.

- **RDMA SEND is two-sided on the control path but one-sided on the data path.** In the control path, the receiver’s CPUs prepare receive buffers via RECV; however, in the data path, when handling SEND requests, the receiver-side RNIC performs *all* tasks, including landing SEND’s data to receive buffers and returning ACKs.
- **In a receive queue, receive buffers are consumed in order.** Every time, the receiver-side RNIC pops the *first* buffer in the associated receive queue and lands data to it.

**Key idea.** On the control path, CPUs push PM buffers into the receive queue in increasing address order; on the data path, the receiver-side RNIC consumes them in order.

**Basic architecture.** Figure 4(a) shows the basic architecture of ROWAN implementation. ROWAN uses reliable connection (RC) QPs to delegate transmission reliability to RNICs. We create a shared receive queue (SRQ) [11] which is associated

with all QPs; thus, RNICs can land data of SEND from *different remote QPs* to the same receive queue. In the receiver, we reserve a dedicated thread, namely *control thread*, to perform control-path tasks; the RNIC performs data-path tasks.

Specifically, the control thread splits the PM area into fixed-sized (e.g., 64B in Figure 4(a)) buffers, and posts these buffers (using RECV) into the SRQ in *increasing address order*. Senders encapsulate writes into SEND requests, and emit them to the receiver; each SEND is followed by a READ for persistence. When receiving a SEND (followed by a READ), the receiver-side RNIC pops the first buffer in SRQ, DMA’s the SEND’s data into the buffer, generates a completion entry (CE) to the SRQ’s CQ, and finally returns an ACK to the sender. In this way, writes from different senders can be combined into the same XPLines on PM, mitigating DLWA.

**Handling variable-sized writes.** When the size of a SEND’s data is larger than the first buffer in the SRQ, the RNIC cannot accommodate it and will trigger an error CE. For example, in Figure 4(a), with 64B receive buffers, the 384B write cannot be handled. If we use a buffer size larger than 256B for the SRQ to support relatively large writes, small writes from different senders will not be combined into the same XPLines, destroying the benefits of ROWAN abstraction.

Fortunately, current RNICs (e.g., ConnectX-4/5/6) support a new type of RQ, called *multi-packet receive queue* [7, 9] (MP RQ). In an MP RQ, each receive buffer can accommodate *multiple* SEND requests. We need to define a *stride* (e.g., 64B) for an MP RQ. When receiving a SEND, the RNIC appends the data to the receive buffer that is being used, and the start address is stride-aligned. If there is no enough space left, the RNIC pops a new receive buffer from the MP RQ to use.

Figure 4 shows ROWAN that uses MP SRQ, where we set the stride to 64B and receive buffer size to 4MB. In the figure, three writes are placed in two XPLines (i.e., 512B area) in the first receive buffer, each having a 64B-aligned start address. By using MP SRQ, ROWAN can support variable-sized writes, while combining small writes to mitigate DLWA.

There are two points worth noting when using MP SRQ:

- In ROWAN, the stride is a fixed value of 64B. We do not choose a smaller value (e.g., 32B) for two reasons. First, in the RNIC we use (i.e., ConnectX-5), the minimum supported stride value is 64B. Second, recent studies suggest that senders should pad small writes to PCIe data word (64B) granularity [70], to avoid expensive read-modify-write operations on receivers' PM. Thus, we assume the incoming small writes are already 64B granularity.
- If a SEND is larger than maximum transmission unit (MTU), it is comprised of multiple packets. The RNIC may land these packets to non-contiguous addresses. We let the upper applications (e.g., KVSs) to handle this case.

**Minimizing control-path tasks.** On ROWAN's data path, the receiver-side RNIC can deliver extremely high throughput (> 50Mops/s). On the control path, for CPU efficiency, we only want to use *one* control thread; thus, we minimize control-path tasks to make them can be easily handled by one thread.

There are two tasks performed by the control thread: posting receive buffers into the MP SRQ and polling the CQ to consume CEs. For the former, since we use large receive buffers (e.g., 4MB) by leveraging the multi-packet feature and post a batch of receive buffers at a time, this task is lightweight. For the latter, unfortunately, unlike other verbs, RECV can not be marked as un signaled, so every SEND will generate a CE at the receiver side. The control thread cannot timely consume these CEs (considering > 50Mops/s throughput), making the CQ fill and thus causing QPs in an error state. We get inspiration from eRPC [43] to address this problem. Like eRPC, we create a CQ that forms a *ring structure*, so that the RNIC can overwrite entries in the CQ ring in a round-robin manner. In this way, the control thread does not need to poll the CQ.

## 4 ROWAN-KV Design

We build ROWAN-KV, a PM KVS that uses ROWAN for primary-backup replication. It has two main design goals.

- **Low latency.** ROWAN-KV exploits one-sided ROWAN to eliminate software overhead at backups during replication.
- **Low DLWA.** ROWAN-KV adopts a log-structured approach to manage PM writes from both local CPUs and remote CPUs. For the former, every thread appends data in its local log. For the latter, ROWAN merges replication writes into a *single* backup log. Hence, Optane DIMMs only receive a small number of write streams and can efficiently combine adjacent small writes into XPLines, thus mitigating DLWA.

### 4.1 Overview

Figure 5 shows the architecture of ROWAN-KV. Servers persistently store objects (i.e., key-value pairs) in PM and use RDMA for network communication. ROWAN-KV divides the entire data set into many shards and distributes them across servers. Each shard is replicated for high availability: with the replication factor of  $k$ , it has one server as *primary* and  $k-1$  servers as *backups*. Clients issue KV requests via RPCs. **Sharding mechanism.** ROWAN-KV hashes each object's key

**Figure 5:** Architecture of ROWAN-KV. The *per-thread logs (t-logs)* and *backup log (b-log)* are divided into 4MB segments.

into a 64-bit number and lets a shard manage a continuous range in the hashed keyspace. Shard distribution is maintained by a *configuration manager (CM)* and is cached in servers and clients. ROWAN-KV uses a dynamic resharding mechanism to mitigate load imbalancing from overloaded servers (§4.6).

**Log-structured approach.** ROWAN-KV adopts a log-structured approach, where each server has three components:

- **Per-thread logs.** Each server launches a number of *worker threads* to handle requests from clients. Each worker thread maintains a per-thread log (**t-log**) in PM, which stores objects of PUT/DEL requests. We do not allocate independent logs for each shard, to reduce random PM writes.
- **Backup log.** Each server has a *single* backup log (**b-log**) in PM, which receives replication writes from primaries using a ROWAN instance. By doing so, ROWAN-KV can largely eliminate DLWA from high fan-in small writes.
- **Per-shard hash indexes.** Each server builds a DRAM-resident hash table for every shard it manages, to index objects in t-logs or the b-log. Putting indexes in DRAM can avoid random PM writes and expensive PM reads [22, 25]. The t-logs and b-log are divided into 4MB *segments*.

**Handling KV requests.** When issuing a KV request for an object, the client sends an RPC to a worker thread residing in the server that is the targeted shard's primary.

For a PUT/DEL request, the worker thread generates a log entry containing the object (only the object's key for DEL), and persistently appends the log entry to its local t-log using `ntstore` instructions (① in Figure 5). Then, the worker thread issues replication write for every backup via one-sided ROWAN, persistently appending the log entry to every backup's b-log (②). Upon receiving all ACKs from backups' RNICs, the worker thread updates the associated index to make the object (in t-logs) visible (③), and finally returns a response to the client. ROWAN-KV has a strong durability guarantee: when a client receives the response of a PUT/DEL request, its effects have been persisted on all replicas.

For a GET request, the worker thread first locates the object by searching the associated index (①). Then, it copies the object's value from t-logs (②) and replies to the client.

Figure 6: Life cycle of segments.

**Background operations.** ROWAN-KV uses three types of threads to perform background operations.

- *Control thread.* One control thread performs control-path tasks for the ROWAN instance (§3). In ROWAN-KV, it pushes free segments to the b-log via RDMA RECV, and hands used segments over to digest threads.
- *Digest threads.* There are multiple digest threads. They digest used segments from the b-log. Specifically, they parse log entries and update associated indexes.
- *Clean threads.* There are multiple clean threads. They garbage collect stale objects in segments (from worker threads or digest threads) to reclaim free PM space.

## 4.2 Log Metadata

In ROWAN-KV, t-logs and b-log are comprised of multiple segments, each storing a number of log entries. We describe segment metadata and log entry metadata, respectively.

### 4.2.1 Segment Metadata

A segment’s metadata mainly includes its *state*. At any given time, each segment is in one of four states:

- *Free.* The segment can be allocated to t-logs by worker threads, the b-log by the control thread, or clean threads.
- *Using.* The segment is being used by t-logs, the b-log, or clean threads; it has space to store new log entries.
- *Used.* It has no space to store new log entries, and some of its log entries have *not* been persisted on all replicas.
- *Committed.* It has no space to store new log entries, and all of its log entries have been persisted on all replicas.

In addition to the state, a segment has an extra metadata called *owner*, indicating which type of thread allocates it (e.g., worker threads). Each server maintains a PM array called *segment meta table* to record metadata for all its segments.

Figure 6 presents the life cycle of segments. The path for primaries is simple: a worker thread allocates a *free* segment for its t-log, and the segment becomes *using* state. Once the segment has no space, it transitions into *committed*, since the worker thread can easily ensure that all of the segment’s log entries have been persisted on all replicas. The path for backups is fairly complicated, where we should accurately distinguish between *used* segments and *committed* segments (§4.3 and §4.4). Such a distinguishment is essential for failover (§4.5).

### 4.2.2 Log Entry Metadata

A log entry contains the request type (i.e., PUT/DEL) and the targeted object (only the object’s key for DEL). It also includes three metadata fields:

- *32-bit checksum.* The checksum covers the whole log entry. Checksums eliminate persistent tails for logs: upon

Figure 7: A 2-MTU-sized log entry in the b-log.

recovery, we can identify the end of each log by calculating checksums. Besides, backups can use checksums to independently check the integrity of log entries in the b-log.

- *48-bit version.* Each shard has a version, namely *shard version*, which is maintained by its primary. Upon a PUT/DEL request, the worker thread atomically increments the associated shard version, and stores the obtained version into the log entry. Upon recovery, the version allows us to identify the most recent objects from multiple t-logs.
- *16-bit shard ID.* It indicates which shard the targeted object belongs to.

**Handling larger-than-MTU log entries.** For a log entry that is larger than MTU, backup-side RNICs may divide it into multiple packets and place them in non-contiguous addresses of the b-log (recall §3.2). To enable backups check the integrity of such a log entry, we design a simple counter-based metadata. Specifically, if a log entry is larger than MTU, we logically divide it into multiple MTU-sized blocks, and duplicate log entry metadata at the start of each block (each *checksum* field protects the individual block). Besides, we add two extra metadata to each block: 1) *cnt*: block count of the log entry, and 2) *seq*: the sequence number of the block.

Figure 7 shows a 2-MTU-sized log entry in the b-log, where its two blocks are not adjacent. The pair of  $\langle \text{shard ID} : A, \text{version} : 64 \rangle$  uniquely identifies the log entry. When scanning the two blocks (checksums match) with their *cnt* and *seq*, backups can determine the log entry’s integrity.

## 4.3 Managing the Backup Log

The control thread manages the b-log by communicating with the RNIC and digest threads. To minimize the communication overhead, the control thread performs tasks in a *batch* manner.

Specifically, when the system starts up, the control thread allocates a considerable number of free segments (e.g., 512) for the b-log, and pushes them into ROWAN’s MP SRQ via RECV. Then, it enters into a loop: 1) identifies a batch of segments (e.g., 128) that is in *used* state; 2) hands these segments over to digest threads; 3) allocates a batch of free segments and pushes them into the b-log via one RECV call. Note that a free segment transitions into the *using* state after it is allocated by the control thread (recall backup path in Figure 6).

**Identifying used segments.** The control thread adopts a simple method to identify used segments in the b-log. For every segment pushed into the b-log, its first 64 bits are set to zeros. Meanwhile, the first 64 bits in a log entry include the request type, which is non-zero. Thus, when the control thread finds that a segment has non-zero first 64 bits, it can ensure that all *previous* segments in the b-log (we call the set of segments *S* here) have been allocated by the RNIC for accommodating

log entries. However, this does not mean that segments in  $S$  are *used*, since maybe some DMA operations writing log entries in  $S$  are outstanding. Hence, we wait 2ms for all these DMA operations to complete, to guarantee that all segments in  $S$  have transitioned into *used* state. At the primary side, worker threads measure the time of each replication write: if it is more than 1ms, worker threads retry the replication write.

#### 4.4 Digest and Garbage Collection

**Digest.** Multiple digest threads process used segments in the b-log in parallel. Each digest thread manages an exclusive set of shards: it extracts log entries from used segments in order and only processes shards it manages. For a log entry, digest threads update the index of the associated shard. Besides, digest threads identify *committed* segments, and hand these segments over to clean threads.

**Identifying committed segments.** To help digest threads identify committed segments in the b-log, primaries disseminate the information of log entries to backups. Specifically, for a shard, worker threads in its primary maintain a `CommitVer`; any log entry containing a version  $\leq$  `CommitVer` has been persisted on all replicas. Every 15ms, worker threads write the  $\langle$ shard ID, `CommitVer` $\rangle$  pair into backups' b-logs via `ROWAN`.

At the backup side, digest threads maintain an array `CommitVerArray`, which contains associated `CommitVer` for each shard. When encountering a  $\langle$ shard ID, `CommitVer` $\rangle$  during parsing segments of the b-log, digest threads update `CommitVerArray`. Meanwhile, when processing a segment, digest threads generate an array `MaxVerArray` for it; for each shard, this array records the *maximum version* that digest threads have encountered in log entries. A used segment can transition into committed one, if its `MaxVerArray`  $\leq$  `CommitVerArray` (i.e., for every shard, the maximum version in `MaxVerArray`  $\leq$  `CommitVer` in `CommitVerArray`).

**Garbage collection.** Multiple clean threads garbage collect stale objects in committed segments. When memory utilization of a committed segment, i.e., the percentage of valid bytes, is lower than a pre-defined threshold (e.g., 75% in our evaluation), a clean thread cleans it. Specifically, the clean thread scans the committed segment and checks the liveness of objects in log entries (by searching indexes). For live objects, the clean thread copies associated log entries to a *using* segment and updates indexes. Finally, the committed segment transitions into *free* state for future usages.

#### 4.5 Failover

We adopt FaRM's reconfiguration-style approach [31] to handle failover but tailor it for `ROWAN-KV`. A *configuration* in `ROWAN-KV` contains 1) 64-bit term, 2) membership, i.e., the set of live servers, and 3) shard distribution. The configuration is persistently stored in a Zookeeper instance [40], and is cached in the CM, clients, and servers. `ROWAN-KV` uses leases to detect failures for servers and CM [31]. When the CM fails, `ROWAN-KV` activates a new CM using the same mechanism as FaRM [31]. When a server fails, `ROWAN-KV` performs failover

with the following three phases.

**1) Generating and committing a new configuration.** The CM generates a new configuration, where the term is incremented and the membership excludes the failed server. In the new shard distribution, the CM reassigns shards managed by the failed server to live servers, and promotes a backup to the new primary for each shard losing its primary.

Then, the CM stores the new configuration in Zookeeper and sends it to all servers. Servers cache the configuration, destroy QPs used for communicating with the failed server, and respond. From this point, servers block all requests from clients. Once the CM receives all responses, after ensuring that the lease for the failed server has expired, it sends a commit message to all servers. Now, servers can unblock requests. A server rejects requests containing terms that are lower than the one it caches. Clients will fetch the new configuration from CM upon receiving rejected responses.

**2) Promoting backup to primary.** When a backup of a shard (we call the shard  $A$  here) is promoted to the new primary, its worker threads block requests to  $A$  until digest threads build indexes for all objects of  $A$ . The new primary and backups should reach a consensus on the committed log entries. Hence, the new primary and backups process *using* and *used* segments in the b-log, collecting log entries belonging to  $A$ . These collected log entries are gathered to the new primary and then are scattered to backups. The new primary and backups store these log entries into segments. In this way, all replicas will own the same set of log entries for  $A$ . During digest, the new primary constructs a valid shard version for  $A$ , which is larger than versions in any  $A$ 's log entry.

**3) Re-replication.** The CM adds a new backup for the shard having replicas in the failed server. The new backup performs re-replication asynchronously. It first initializes an index for the shard, and then sends a message to the primary. Upon receiving the message, the primary traverses the shard's index and transmits associated log entries to the new backup.

#### 4.6 Dynamic Resharding

`ROWAN-KV` introduces a dynamic resharding mechanism to migrate hotspot shards for improving load balancing.

CM detects overloaded servers and produces new shard distribution. Specifically, for each shard, each worker thread records the number of received requests during a fixed period (i.e., 500ms), and sends the statistic data to CM. Since `ROWAN` is one-sided and thus backups are unaware of replication writes, we let worker threads in primaries record the number of received replication writes for backup shards. CM calculates the load of each server according to these statistics. If a server has a load that is higher than the average load by a threshold (i.e., 30%), CM determines that the server is *overloaded*. CM produces a new shard distribution, where the hottest shards in overloaded servers are moved to underloaded servers, with a goal of making the load of every server within 5% of the average. Then, it saves a migration list in the config-

uration, which contains a triple  $\langle$ source server, target server, shard ID $\rangle$  for each migration task. Finally, CM increments the term, writes the new configuration (including the new shard distribution) to Zookeeper, and sends it to all servers.

Next, we describe how ROWAN-KV migrates a primary shard from a *source* server to a *target* server (migrating a backup shard is much easier since it does not serve client requests). Upon receiving the new configuration, servers cache it to local memory. From this point, the source server rejects client requests for the migrated shard. Clients will fetch the new configuration from CM when receiving rejected responses, so subsequent requests to the migrated shard will be sent to the target server. Then, the source server sends a message to the target server; the message contains the shard version of the migrated shard. Upon receiving both the message and the new configuration, the targeted server starts to serve requests for the migrated shard. In this way, ROWAN-KV guarantees that only one server can serve the shard at any given time. Then, the process of data migration starts:

- In the source server, a migration thread requests free PM segments from the target server via RPCs, traverses the index of the migrated shard, and stores the associated log entries to remote segments via RDMA WRITE.
- In the target server, a migration thread scans segments written by the source server and installs log entries in the shard's index. Upon a PUT request to the migrated shard, the target server handles it as normal. Upon a GET request, the target server searches the index; if the corresponding key is not found, the target server routes the GET request to the source server since some objects have not been migrated yet. Of note, the versions in log entries resolve the conflicts between the migration thread and concurrent PUT requests.

The target server informs CM when it finishes data migration. Then, CM deletes the migration task from the migration list and writes the new configuration to Zookeeper. Finally, CM sends a message to the source server to inform it to free the index of migrated shard; the associated log entries in the source server will be removed by garbage collection.

If the migration is interrupted due to failures of the source/target server, the CM first rolls back the shard distribution in the configuration to the state before migration. Then, the CM deletes the associated task in the migration list and performs the normal failover process. In addition, the CM informs the target server (if alive) to release resources allocated for the interrupted migration task (e.g., migration thread and index).

## 4.7 Cold Start

When the entire cluster experiences a power failure, ROWAN-KV can guarantee durability of data. Upon recovery, the CM fetches the configuration from Zookeeper, and disseminates it to all servers. Each server obtains the metadata for all its segments via the segment meta table (recall §4.2.1). For a shard, its primary extracts associated log entries from *using* segments whose *owner* is worker threads; then, the primary

sends these log entries to backups, to make all replicas own the same set of log entries. Each primary builds indexes for shards it manages by processing segments, and constructs valid shard versions. If two log entries have the same targeted key, the one with the larger version is more recent. Finally, ROWAN-KV resumes unfinished migration tasks according to the migration list stored in the configuration.

## 5 Implementation

We implement ROWAN-KV in Linux hosts. ROWAN-KV is a fully user-space system: it uses *libverbs* for RDMA operations and CPU memory instructions for accessing PM.

### 5.1 Threading Model

ROWAN-KV binds each thread (i.e., worker threads, clean threads, digest threads, and control thread) to an exclusive CPU core. ROWAN-KV follows two principles:

**Minimizing inter-thread communication.** First, each worker thread handles both network I/O and KV logic; this avoids request dispatch in systems that have dedicated threads to poll network requests [56], thus enjoying high multicore scalability. Second, a thread hands over segments to other threads *in a batch manner* (§4.3) using thread-safe queues.

**Avoiding thread blocking.** To avoid blocking due to waiting for network events, worker threads adopt a coroutine-like approach to interleave work: after issuing ROWAN operations for a PUT, a worker thread saves the context of the PUT request (e.g., the targeted key); then, it polls the RDMA completion queue, getting new requests to execute. Upon receiving ACKs from backups, the worker thread restores the PUT's context and continues the remaining logic. In this way, a worker thread can concurrently handle multiple PUT requests.

### 5.2 Network Components

**RPC.** ROWAN-KV uses an RPC framework for client-server and inter-server communication (not include replication). We build the RPC framework with RDMA SEND and RECV verbs using unreliable datagram (UD) QPs. Specifically, each worker thread creates a UD QP to receive requests and send responses. When a client joins the ROWAN-KV cluster, it establishes RPC connections with a worker thread in every server. Like FaSST [44], our RPC framework currently does not support messages larger than an MTU. To reduce CPU consumption on PM reads: the RPC framework leverages RNICs' scatter-gather DMA to gather RPC headers and PM-resident objects, generating responses of GET requests.

**ROWAN.** To realize ROWAN, every worker thread builds a reliable connection (RC) QP with every remote control thread.

At the sender side, a worker thread uses the associated send queue in QPs to issue ROWAN operations. A ROWAN operation contains a SEND followed by a 1B READ for persistence (§3). SEND and READ are sent in one `ibv_post_send` call. For a worker thread, all its ROWAN QPs and RPC QP share the same CQ, so that it can be aware of ROWAN ACKs and new RPC messages by polling the CQ. We mark SEND as un signaled to eliminate a completion event. For READ, we store the context

id of the associated PUT request (§5.1) into the `wr_id` field, so that worker threads can distinguish RowAN ACKs belonging to different PUT requests when polling the CQ.

At the receiver side, a control thread manages all RowAN QPs connected to remote worker threads; these QPs share an MP SRQ. The control thread pushes PM segments to the MP SRQ via RECV. We register PM to RNICs using physical addresses [64], to remove virtual-to-physical translation tables in RNICs and thus reduce cache thrash of RNICs.

**Mitigating the impact of disabled DDIO.** We disable DDIO to ensure the RNICs can land data to PM (rather than CPU cache). However, disabling DDIO will ① cause CPU cache miss when handling RPCs and ② degrade performance of DMA operations between RNICs and memory. For ①, worker threads poll multiple RPC messages at a time, and issue prefetch instructions to them. For ②, for RDMA READ used for persistence, we set its source address to RNICs' device memory [4, 68], to eliminate a DMA write at senders. We expect that DDIO does not need to be disabled, with next-generation RNICs supporting RDMA flush extensions [12].

### 5.3 Storage Components

**PM management.** We configure Optane DIMMs in App-Direct mode, which exposes PM as a range of physical memory. RowAN-KV splits the PM space into 4MB segments and stores the segment meta table in a predefined PM area (recall §4.2.1). A DRAM-resident free list records free segments, to serve segment allocation. We add padding for each log entry, making it 64B-aligned; it can ① avoid expensive PM read-modify-writes on receiver-side RNICs [70] when performing RowAN operations, and ② avoid slow repeated writes to the same cache lines [25, 42] in logs.

**DRAM indexes.** Each per-shard index is implemented with a concurrent bucket hash table [51]. The hash table is organized into a bucket array, where each bucket contains multiple 64-bit items. An item is composed of a 16-bit tag and a 48-bit PM address: the tag is a part of a key's hash value, to filter out mismatched searches and thus reduce PM reads; the PM address points to log entries. For a key, its targeted bucket is calculated by  $hash(key) \% sizeof(bucket\ array)$ . If the targeted bucket is full when inserting a key, threads create a new free bucket and link it to the targeted bucket, forming a bucket chain. Indexes support conditional update to resolve conflicts between threads: indexes omit an update if its log entry has version that is smaller than the one indexes are pointing to.

## 6 Evaluation

### 6.1 Experimental Setup

**Environment.** We use 6 machines as servers and 8 machines as clients. Each machine is equipped with the Intel Xeon Gold 6240M CPU (18 physical/36 logical cores), 96GB DRAM, and one 100Gbps Mellanox ConnectX-5 RNIC. All machines are connected to a 100Gbps Mellanox IB switch. Each server machine owns three 256GB Optane DIMMs (ADR mode).

Unless otherwise specified, we run RowAN-KV on 6 servers.

In each server, we use 24 cores for worker threads, 5 cores for digest threads, 6 cores for clean threads, and 1 core for control thread. The control thread also manages leases, with a lease time of 10ms. The CM and Zookeeper instance (3-way replication) run on client machines. Each client machine runs multiple client threads to issue requests to servers. We set the replication factor to 3. Each server holds 48 shards.

**Workloads.** We evaluate RowAN-KV using YCSB [26] with different PUT:GET ratios: **Load A** — 100% PUT (write-only); **A** — 50% PUT and 50% GET (write-intensive); **B** — 5% PUT and 95% GET (read-intensive); **C** — 100% GET (read-only). Key distribution follows Zipfian with parameter 0.99 (default parameter in YCSB). We populate 200 million objects into KVSs before each experiment. We use three Facebook workloads [24] to generate object size: **ZippyDB** (for general data store) — 90.8B average object size; **UP2X** (for AI/ML services) — 57.25B average object size; **UDB** (for social graph) — 153.8B average object size.

**Comparing targets.** We compare RowAN-KV with four KVSs, each using a specific replication approach:

- **RPC-KV.** It uses RPC to perform replication. Each server maintains per-thread b-logs, and primaries issue replication writes via RPC. Upon receiving a replication RPC, the worker thread appends the log entry into its local b-log.
- **RWrite-KV.** It uses FaRM's approach [31] to perform replication. Each worker thread has an exclusive remote b-log at every remote server. During replication, the worker thread issues WRITE for appending log entries to its b-logs at backups. Each server stores  $(m-1)*n$  b-logs, where  $m$  is the number of servers and  $n$  is the worker thread count.
- **Batch-KV.** Batch-KV is a variant of RWrite-KV and uses WRITE for replication. Each worker thread generates large-sized WRITE requests to its remote b-logs by *batching log entries*, to mitigate DLWA. To reduce latency, worker threads immediately send batched log entries to backups once 1) the total size is larger than an XPLine, i.e., 256B, or 2)  $5\mu s$  timeout is triggered.
- **Share-KV.** It is another variant of RWrite-KV and uses WRITE for replication. Worker threads in a server share the same remote b-log at a remote server, to reduce b-log count and thus mitigate DLWA. Worker threads use local atomic increment to obtain contiguous addresses in remote b-logs.

All systems are implemented in the same codebase (including optimizations in §5), to allow us to focus on the effects of replication approaches. By default, we disable DDIO to provide one-sided persistence. For RPC-KV, DDIO is enabled. We compare RowAN-KV with two off-the-shelf KVSs in §6.7.

### 6.2 RowAN Performance

We repeat the experiment in §2.4, to show performance of RowAN abstraction. Figure 8 presents the result of one RowAN instance. RowAN can largely eliminate DLWA in case of numerous concurrent remote small writes. The DLWA is less than 1.029 $\times$  when no local PM writes exist (Figure 8(a) and

**Figure 8:** ROWAN performance.  $DLWA = \text{media bandwidth}/\text{request bandwidth}$ . A number of threads issue 64B/128B writes to a remote server’s PM via a ROWAN instance. In (c) and (d), 18 CPU cores in the remote server perform local sequential PM writes.

(b)), and less than  $1.056\times$  when local PM writes exist (Figure 8(c) and (d)). This is because ROWAN can merge remote small writes into a single write stream, enabling efficient hardware combining in Optane DIMMs’ XPBuffer.

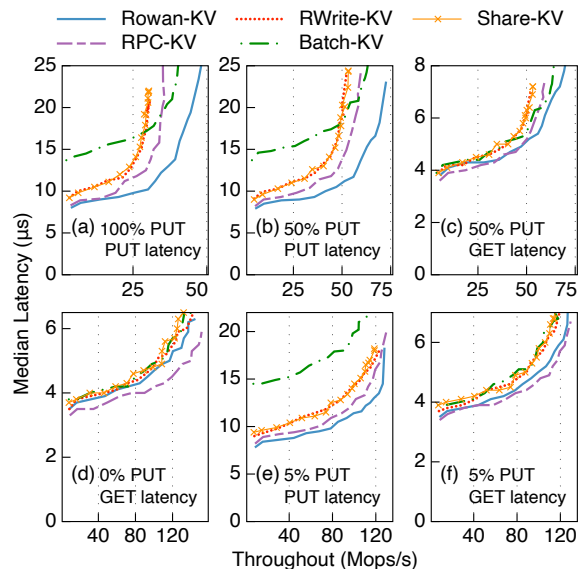

Further, we report the peak throughput of ROWAN and RDMA WRITE under these four cases, as shown in the rightmost subfigure of Figure 8. When no local PM writes exist, ROWAN can deliver 54.5 Mops/s for 64B remote PM writes and 42.2 Mops/s for 128B one, outperforming WRITE by  $1.44\times$  and  $1.43\times$ , respectively. When local PM writes appear, ROWAN outperforms WRITE by  $1.85\times/1.78\times$  for 64B/128B writes. Three causes make ROWAN performant. First, ROWAN largely eliminates DLWA, improving the available PM bandwidth. Second, on the data path of ROWAN, all PM writes are performed by the receiver-side RNIC, ensuring high throughput. Finally, on the control path, by leveraging ring CQ and MP SRQ, the control thread only performs very lightweight tasks, so it does not become the bottleneck. Of note, the bottleneck of ROWAN performance is 6GB/s PM write bandwidth in Figure 8(b)-(c), but processing capacity of RNICs in Figure 8(a). ROWAN does not achieve 75Mops/s (a maximal message rate that a 100Gbps RNIC can provide), since we disable DDIO and send an extra RDMA READ for each ROWAN operation.

### 6.3 ROWAN-KV Performance

Figure 9 shows median latency and throughput (6 servers) under YCSB workloads with ZippyDB object size. Since ROWAN-KV aims to accelerate replication, we report latency of PUT and GET separately. We increase the load generated by clients, and ensure that KVSs reach their peak throughput. We make two observations.

First, under read-only workloads (Figure 9(d)), RPC-KV has 5% higher throughput against other KVSs. This is because for KVSs using WRITE or ROWAN, DDIO is disabled, lowering RPC performance. Such performance gap can be eliminated with next-generation RNICs supporting RDMA flush extensions [12]. Under read-intensive workloads (Figure 9(e) and (f)), RPC-KV and ROWAN-KV have the similar throughput, since RPC-KV consumes CPU cycles of backups for 5% PUT requests, offsetting the benefits of DDIO. Compared with RPC-KV, ROWAN-KV has  $1.09\times$  lower median PUT latency due to elimination of backups’ software queueing, and  $1.27\times$  higher median GET latency due to disabled DDIO.

Second, under write-only and write-intensive (i.e., 50% PUT) workloads (Figure 9(a)-(c)), ROWAN-KV has the highest throughput with the lowest median latency. We compare

**Figure 9:** Median latency vs. throughput. ZippyDB object size. We report PUT latency and GET latency separately.

ROWAN-KV with the other four KVSs in turn.

With RPC-KV. ROWAN-KV achieves peak throughput of  $72.7/48.2\text{Mops/s}$  under write-intensive/write-only workloads, outperforming RPC-KV by  $1.22\times/1.37\times$ . This is because ROWAN-KV replicates log entries via *one-sided* ROWAN, saving CPU cycles that handle replication RPCs. The saved CPU cycles can be used for primaries to handle RPCs from clients. At the peak throughput of RPC-KV, ROWAN-KV has  $1.77\times/1.61\times$  lower median PUT latency under write-intensive/write-only workloads. This is because compared with RPCs, one-sided ROWAN eliminates backup-side software queueing/execution on the critical path of replication. Avoiding replication RPCs also makes ROWAN-KV reduce median GET latency by 23%. Figure 10 shows DLWA of write-only and write-intensive workloads (6 servers). For ROWAN-KV and RPC-KV, the DLWA is less than  $1.032\times$ . This is because they generate a small number of PM write streams: in each server, ROWAN-KV has 24 t-logs and 1 b-log; RPC-KV has 24 t-logs and 24 b-logs (recall we use 24 worker threads in experiments). Optane DIMMs can efficiently combine adjacent small writes of the same logs into XPLINE writes, when write stream count is not high (recall Figure 2(c) and (d)).

With RWrite-KV. Compared to RWrite-KV, ROWAN-KV yields  $1.39\times/1.61\times$  higher throughput and  $2.06\times/2.1\times$  lower median PUT latency under write-intensive/write-only work-

Figure 10: DLWA (6 servers) at peak throughput.

loads. The main culprit of RWrite-KV’s low performance is DLWA: as shown in Figure 10(a), it suffers 1.54× DLWA.

This is because RWrite-KV owns lots of logs (i.e., 24×6 in experiments) in a server to accommodate small writes, exceeding the combining capacity of Optane DIMMs: a large number of write streams are equivalent to random writes. In RWrite-KV, Optane DIMMs trigger lots of read-modify-write events, which squander a considerable number of hardware resources (e.g., XPBuffer), degrading performance of PM accesses. To demonstrate it, we measure the latency of remote persistence operations of ROWAN-KV and RWrite-KV under write-intensive workloads. Figure 11 shows the latency distribution. Remote persistence in RWrite-KV is slow (against ROWAN-KV), with 11.5μs median latency and 24μs 99% latency. Of note, although RNICs are ideally capable of providing an RTT of ~2μs, the 6.6μs median latency of ROWAN is reasonable, since 1) we disable DDIO and each ROWAN operation contains a synchronous RDMA READ, and 2) the latency is measured under high loads where RNICs suffer from DMA queuing.

Figure 11: Latency CDF.

With Batch-KV. Batch-KV boosts the throughput of RWrite-KV by 1.23×/1.35× under write-intensive/write-only workloads, since it reduces the number of WRITE and mitigates DLWA (by 12%) via batching. However, batching makes Batch-KV suffer the highest PUT latency among all KVSs: even under low loads, Batch-KV has more than 50% higher PUT latency compared with ROWAN-KV. In terms of throughput, ROWAN-KV outperforms Batch-KV by 1.13×/1.19× under write-intensive/write-only workloads. This is because Batch-KV still experiences DLWA: it frequently fails to accumulate enough small writes within 5μs timeout for two reasons: 1) All GET requests do not generate writes but consume CPU time; 2) Only writes to the same destination can be batched; yet, due to sharding of KVSs, for a server acting as primaries, the backups of its shards are distributed to *multiple* servers, greatly decreasing the batching opportunity. We also change the timeout value to 20μs, and Batch-KV delivers 9% lower throughput against ROWAN-KV, with unacceptable latency.

With Share-KV. Share-KV reduces DLWA of RWrite-KV by 26%/22% under write-intensive/write-only workloads, since it lets worker threads share the same b-logs. However, it still

	ROWAN-KV	RPC-KV	RWrite-KV	Batch-KV	Share-KV
UP2X	73.9Mops/s	61.5Mops/s	56.2Mops/s	70.3Mops/s	56.0Mops/s
UDB	62.5Mops/s	50.4Mops/s	49.9Mops/s	57.1Mops/s	50.6Mops/s

Table 2: Throughput under write-intensive workloads.

suffers sizable DLWA (1.28×~1.39×), resulting in lower performance against ROWAN-KV. This is because although worker threads in a Share-KV server generate contiguous remote addresses for WRITE, the asynchronous network makes receiver-side RNICs receive and perform these writes in an out-of-order manner. In contrast, for ROWAN-KV, leveraging ROWAN, receiver-side RNICs decide destination addresses of writes. Besides, ROWAN can merge writes from *different* servers.

**Tail latency.** Under write-intensive workloads with 50Mops/s throughput, ROWAN-KV’s 99% latency is 20.5μs, which is 1.26×, 2.11×, 1.53×, and 1.87× lower than that of RPC-KV, RWrite-KV, Batch-KV, and Share-KV, respectively.

**Performance under uniform workloads.** We evaluate ROWAN-KV using uniform key distribution. ROWAN-KV delivers 67.86Mops/s and 108.19Mops/s in cases of 50% PUT and 5% PUT, respectively, which are 6.6% and 15.5% slower than throughput of Zipfian skewed workloads (see Figure 9). ROWAN-KV has higher performance under skewed workloads for two reasons. First, in our cluster of 6 servers, due to hash-based sharding, there is no observable load imbalance across servers under skewed workloads. Second, threads enjoy much better cache locality under skewed workloads.

**Performance with UP2X/UDB object size.** Due to space limitations, here we only report the throughput under write-intensive workloads, as shown in Table 2. ROWAN-KV delivers the highest throughput via powerful ROWAN abstraction.

## 6.4 Sensitivity Analysis

We conduct experiments on sensitivity analysis using write-intensive workloads and ZippyDB object size.

**Impact of object size.** We change object size to generate varying log entry size. As shown in Figure 13(a), when log entry size is an integer multiple of XPLine size (e.g., 256B), all KVSs do not induce severe DLWA; thus, ROWAN-KV and KVSs using WRITE have the similar throughput. RPC-KV consumes CPU cycles for replication RPCs, so it has 21% lower throughput against ROWAN-KV with 1024B log entries.

**Impact of replication factor.** Figure 13(b) presents throughput with varying replication factor. As replication factor increases, performance improvement between ROWAN-KV and other KVSs increases. This is because, with higher replication factors, RPC-KV needs to consume more CPU cycles to handle a PUT request, and WRITE-enabled KVSs issue more WRITE and thus induce more DLWA. In contrast, ROWAN-KV replicates objects in a one-sided manner and merges all remote writes into a single b-log in a sequential manner.

**Impact of worker thread count.** Figure 13(c) presents throughput with different worker thread counts. We make two observations. First, when the number of threads is small (i.e., ≤ 16), RPC-KV has the lowest throughput, since the CPU

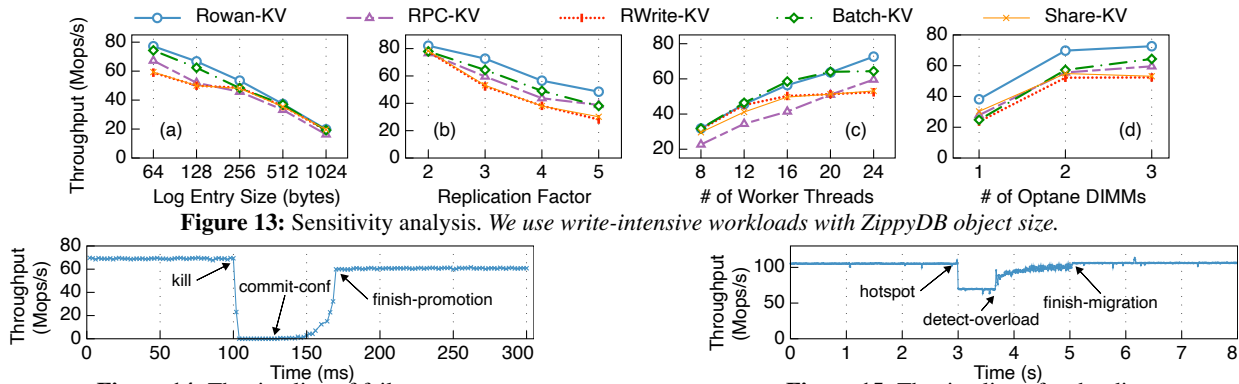

Figure 13: Sensitivity analysis. We use write-intensive workloads with ZippyDB object size.

Figure 14: The timeline of failover.

Figure 15: The timeline of resharding.

is the bottleneck. Second, RWrite-KV and its variants yield poor scalability. This is because 1) for RWrite-KV and Batch-KV, the number of b-logs is proportional to thread count, and 2) for Share-KV, RNICs are more likely to receive and perform WRITE to b-logs in an out-of-order manner in case of high thread count; thus, they suffer more severe DLWA with higher thread count. DLWA harms PM performance (recall Figure 11), thus stalling throughput. In contrast, ROWAN-KV exhibits superior throughput with different thread counts.

**Impact of PM bandwidth.** Figure 13(d) presents throughput with different number of Optane DIMMs per server. In case of one Optane DIMM, the PM bandwidth is bottleneck. Thus, RWrite-KV (which has the most severe DLWA) is outperformed by ROWAN-KV, RPC-KV, Batch-KV, and Share-KV by 1.61 $\times$ , 1.18 $\times$ , 1.05 $\times$ , and 1.28 $\times$ , respectively. In case of three Optane DIMMs, CPU becomes the bottleneck and limits throughput, and PM bandwidth is not saturated (see Figure 10). ROWAN-KV squeezes out CPU resources in two aspects: 1) it reduces CPU involvement via ROWAN’s one-sided semantic; 2) it largely eliminates DLWA, streamlining Optane DIMMs’ internal operations and thus improving persistence efficiency of worker threads.

### 6.5 Failover and Cold Start

**Failover.** We kill a server to test ROWAN-KV’s failover mechanism. We use write-intensive workloads with ZippyDB objects and ROWAN-KV runs for 50 seconds before the test. Figure 14 shows the timeline, where throughput is recorded per 2ms. The server is killed at time 100ms (i.e., `kill`). ROWAN-KV uses 26ms to commit the new configuration (i.e., `commit-conf`), which mainly includes detecting failure (8ms), writing new configuration to Zookeeper (4.3ms), and waiting for the failed server’s lease to expire (10ms). Then, ROWAN-KV consumes about 44ms to promote backups to primaries (i.e., `finish-promotion`). At this point, ROWAN-KV can serve all requests from clients.

**Cold start.** We test cold start of a ROWAN-KV instance, which contains 10 billion ZippyDB objects and thus occupies about 3TB PM space (6 servers). The time of cold start is 49.6s. Although cold start is slow, it is not common in datacenters. Periodically checkpointing DRAM-resident indexes can accelerate cold start, and we leave it for future work.

### 6.6 Dynamic Resharding

In this experiment, we evaluate ROWAN-KV’s dynamic resharding mechanism. We use read-intensive workloads with ZippyDB objects. Figure 15 presents the total throughput (6 servers) over time. At first, clients generate a uniform workload and each server has a similar CPU utilization (i.e., 90.2% ~ 90.9%). At time 3s (i.e., `hotspot`), clients shift 80% requests for server A to a shard residing on server B, to make server B have a hotspot shard and overloaded. The throughput drops by 33% due to load imbalance. At this time, server A and server B have a CPU utilization of 60.7% and 91% respectively. The average CPU utilization of the other 4 servers drops to 72.8%, since requests to overloaded server B suffer from long queueing and thus the limited number of clients cannot generate enough requests to other servers. CM detects the overload after 660ms (i.e., `detect-overload`) and produces a migration task that migrates the hotspot shard from server B to server A. The migration takes 1346ms and moves about 1.1 million objects. The throughput increases as the migration proceeds, since more GET requests to the hotspot shard can be served by server A. Finally, the system achieves a load-balanced state with steady throughput.

### 6.7 Comparison with Other Systems

We compare ROWAN-KV with two state-of-the-art replicated KVSs designed for RDMA networks:

- **Clover** [63]. Clover runs on disaggregated PM, where PM servers do not have compute resources. Clients perform GET operations via RDMA READ verbs, and perform PUT operations (including replication) using a combination of RDMA WRITE and ATOMIC.
- **HermesKV** [45]. It is a DRAM-resident KVS built on Hermes [45], a broadcast-based replication protocol. HermesKV uses RPC for all inter-server communication (including replication). We modify the code to support PM: we store objects in PM and issue `ntstore` instructions for durability; indexes are in DRAM. In addition, we let clients generate KV requests to HermesKV servers.

We use ZippyDB objects and 4KB objects to test KVSs under small writes and large writes, respectively. The key distribution follows Zipfian with parameter 0.99. The replication factor is 3 and HermesKV runs with enabled DDIO.

**Figure 16:** Comparison with Clover and HermesKV. (a) Throughput with ZippyDB objects. (b) Throughput with 4KB objects.

Figure 16(a) shows the results of small writes (ZippyDB objects). Under write-intensive workloads (i.e., 50% PUT), ROWAN-KV outperforms Clover and HermesKV by 24.5 $\times$  and 1.98 $\times$ , respectively. Two reasons contribute to Clover’s low throughput. First, due to the disaggregated architecture, every operation in Clover needs multiple network communications. Second, Clover uses RDMA ATOMIC to resolve conflicts between client threads, which leads to significant performance degradation when contention appears [35]. Using RDMA ATOMIC on PM is also considered slow due to its read-modify-write behavior [70]. HermesKV uses RPC for replication which consumes CPU cycles at backups, so it is outperformed by ROWAN-KV which uses one-sided ROWAN for replication. We measure DLWA of these KVSSs. Clover has 1.86 $\times$  DLWA and HermesKV has 2.95 $\times$  DLWA, since both of them generate a large number of random small writes on PM: for a PUT operation, Clover performs copy-on-write using WRITE and HermesKV performs in-place updates. In contrast, ROWAN-KV adopts the log-structured approach to manage objects and exploits ROWAN abstraction to minimize the number of write streams; thus, DLWA of ROWAN-KV is less than 1.032 $\times$ . Under read-intensive workloads (i.e., 5% PUT), ROWAN-KV and HermesKV have similar throughput, which far exceeds that of Clover (about 5 $\times$ ).

Figure 16(b) reports the results of large writes (4KB objects). Under write-intensive workloads, ROWAN-KV outperforms HermesKV by 1.42 $\times$  and is bottlenecked by PM write bandwidth. HermesKV can not approach the limitation of PM write bandwidth, since its backups waste lots of CPU cycles to copy/persist large objects from RPC buffers to PM. Under read-intensive workloads, ROWAN-KV and HermesKV are bottlenecked by the network bandwidth (11GB/s per server), which is much lower than PM read bandwidth (18GB/s).

## 7 Discussion

Although Intel killed Optane memory business for commercial reasons in summer 2022, we believe that ROWAN is still applicable to future byte-addressable storage devices. For example, CXL storage devices (e.g., Samsung’s Memory-Semantic SSD [13]), which are considered promising alternatives to Optane DIMMs, share similarities with Optane DIMMs: 1) limited write bandwidth; 2) byte interfaces with a block-level internal access granularity (e.g., flash page). Thus, when many remote threads concurrently access CXL storage devices with small IO size, ROWAN can still effectively mitigate DLWA and thus boost system performance.

## 8 Related Work

**PM KVSSs.** There are a host of works on PM KVSSs, but most of them are single-machine (except Clover [63]). HiKV [71] and Bullet [39] are designed before the availability of real PM devices; both of them store objects into fine-grained PM hash tables. However, real PM devices have block-level internal access granularity (e.g., 256B in Optane DIMMs). To reduce DLWA, recent PM KVSSs, including FlatStore [25], Viper [22], and Pacman [66], adopt log-structured approaches to manage objects. ROWAN-KV also uses log-structured approach for the same reason, but focuses on distributed environments where objects are sharded and replicated.

**RDMA replication.** RDMA replication can be categorized into two groups, namely *backup-active* and *backup-passive*, depending on whether backups consume CPUs on the critical path of replication. Lots of systems [20, 21, 41, 45, 65] belong to backup-active group, where backups’ CPUs need to process messages during replication. For backup-passive group [17, 31, 46, 47, 57, 62, 69, 75], primaries only need to wait for ACKs from the RNIC hardware of backups. For example, Hyperloop [47] uses RDMA WAIT and WRITE verbs to realize chain replication. ROWAN-KV belongs to the backup-passive group, so it features low latency and high CPU efficiency. Yet, traditional backup-passive approaches can lead to DLWA on PM KVSSs, driving us to design the ROWAN abstraction.

**RDMA abstraction.** Due to limited expressivity of RDMA verbs, several works propose new RDMA abstractions [18, 19, 23, 27, 60, 72]. StRoM [60] and RMC [19] allow applications to define functions on NICs. Aguilera et al. [18] and PRISM [23] propose several new RDMA verbs to support far memory data structures and distributed systems. RedN [58] makes RDMA Turing complete using self-modifying chains. All above works (except RedN) require RNIC modification or specialized hardware (e.g., SmartNICs). In contrast, ROWAN can be realized with off-the-shelf RNICs, leveraging RNIC features such as SRQ and MP RQ. Besides, ROWAN targets handling high fan-in small PM writes.

## 9 Conclusion

This paper explored how to efficiently replicate PM KVSSs using RDMA. We showed that existing approaches using RDMA WRITE cause severe device-level write amplification (DLWA) on PM. To this end, we proposed ROWAN, a one-sided RDMA abstraction that can merge numerous remote writes into a single stream. Based on ROWAN, we built ROWAN-KV, a log-structured PM KVSS; it outperforms RPC and RDMA WRITE alternatives in throughput and latency under write-intensive workloads, while achieving low DLWA.

<sup>2</sup>University of Wisconsin-Madison

## Abstract

Emerging Zoned Namespace (ZNS) SSDs, providing the coarse-grained zone abstraction, hold the potential to significantly enhance the cost-efficiency of future storage infrastructure and mitigate performance unpredictability. However, existing ZNS SSDs have a static zoned interface, making them in-adaptable to workload runtime behavior, unscalable to underlying hardware capabilities, and interfering with co-located zones. Applications either under-provision the zone resources yielding unsatisfied throughput, create over-provisioned zones and incur costs, or experience unexpected I/O latencies.

We propose eZNS, an elastic-zoned namespace interface that exposes an adaptive zone with predictable characteristics. eZNS comprises two major components: a zone arbiter that manages zone allocation and active resources on the control plane, a hierarchical I/O scheduler with read congestion control, and write admission control on the data plane. Together, eZNS enables the transparent use of a ZNS SSD and closes the gap between application requirements and zone interface properties. Our evaluations over RocksDB demonstrate that eZNS outperforms a static zoned interface by 17.7% and 80.3% in throughput and tail latency, respectively, at most.

## 1 Introduction

The NVMe Zoned Namespace (ZNS) is a newly-introduced storage interface and has received significant attention from data center and enterprise storage vendors. By dividing the SSD physical address space into logical zones, migrating from device-side implicit garbage collection (GC) to host-side explicit reclaim, and eradicating random write accesses, a ZNS SSD significantly reduces device DRAM needs, resolves the write amplification (WAF) issue, minimizes costly overprovisioning, and mitigates I/O interference. However, the performance characteristics of the ZNS interface are not well-understood. In particular, to build efficient I/O stacks over it, we should be cognizant of (1) how the underlying SSD exposes the zone interface and enforces its execution restrictions; (2) what trade-offs the device's internal mechanisms make to balance between cost and performance. For

example, the device-enforced zone placement makes the actual I/O bandwidth capacity of a zone contingent on how a ZNS SSD allocates zone blocks across channels/dies. Further, a zone is not a performance-isolated domain, and one could observe considerable I/O interference for inter-zone read and write requests. Therefore, there is a strong need to understand its idiosyncratic features and bring enough clarity to storage applications.

We perform a detailed performance characterization of a commodity ZNS SSD, investigate its device-internal mechanisms, and analyze the benefits and pitfalls under different I/O profiles in both standalone and co-located scenarios. Using carefully calibrated microbenchmarks, we examine the interaction between zones and the underlying SSD from three perspectives: zone striping, zone allocation, and zone interference. We also compare with conventional SSDs when necessary to investigate the peculiarity of a ZNS SSD. Our experiments highlight the interface's capabilities to mitigate the burden on I/O spatial and temporal management, identify constraints that would cause sub-optimal performance, and provide guidance on overcoming the limitations.

We then propose eZNS, a new interface layer, which provides a device-agnostic zoned namespace to the host system, mitigates inter-/intra-zone interference, and improves the device bandwidth by allocating active resources based on the application workload profile. eZNS is transparent to upper-layer applications and storage stacks. Specifically, eZNS comprises two components: the zone arbiter on the control plane and a tenant-cognizant I/O scheduler on the data plane. The zone arbiter maintains the device shadow view that manages zone allocations and realizes a dynamic resource allocation by a zone ballooning mechanism. It allows serving applications to max out the device capability by enabling the maximum device parallelism given the workload profile and rebalancing inactive bandwidth across namespaces. The I/O scheduler of eZNS leverages the intrinsic characteristics of ZNS, where there are no hardware-hidden internal bookkeeping operations. Read I/Os become more predictable, and one can directly harness this property to examine inter-zone interference.

Figure 1: The architecture of a conventional and ZNS SSD.

On the other hand, write I/Os share a performance domain due to the write cache architecture of the SSD, causing global congestion across all active zones. eZNS, therefore, applies a local congestion control for reads and a global admission control for writes. Our I/O schedulers mitigate the interference independently but improve overall system performance cooperatively. We demonstrate benefits in the evaluation (§5) over micro-benchmarks and RocksDB.

## 2 Background and Motivation

This section reviews the basics of NAND-based SSDs, introduces the ZNS SSD and its features, and discusses the problems with the existing zoned interface.

### 2.1 NAND-based SSDs

A NAND-based SSD combines an array of flash memory dies and is able to deliver a bandwidth of several GB/s. It comprises four main architectural components (Figure 1): (1) a host interface logic (HIL) that implements the protocol used to communicate with the host, such as SCSI [40] and recent NVMe [29]; (2) an SSD controller, enclosing an embedded processor and a flash channel controller, which is responsible for the address translation and scheduling, as well as flash memory management; (3) onboard DRAM, buffering transmitted I/O data and metadata, storing the address translation table, and providing a write cache; (4) a multi-channel subsystem that connects NAND dies via a high-bandwidth interconnect. As shown in Figure 1, a NAND *die* consists of hundreds of *erase blocks*, where each *block* contains hundreds to thousands of *pages*. Each page encloses a fixed-sized data region and a metadata area that stores ECC and other information. Flash memory supports three major operations: *read*, *program*, and *erase*. The access granularity of a read/program is a page, while the erase command is performed in units of blocks. NAND flash memory has three unique characteristics [1, 10, 12, 19, 26]: (1) no in-place update, where the whole block must be erased before updating any page in that block; (2) asymmetric performance between reads and programs; (3) limited lifetime (endurance) – each cell has a finite number of program/erase (P/E) cycles [22].

To effectively use the NAND flash and address its limitations, SSDs employ a special mapping layer called the flash translation layer (FTL). It provides three major functionalities [13, 20, 33, 52]: (1) dynamically mapping logical block addresses (LBA) to physical NAND pages addresses (PPA); (2) implementing a garbage collection (GC) mechanism to

handle the no in-place update issue and asynchronously reclaim invalid pages; (3) applying a wear-leveling technique to evenly balance the usage (or aging property) of all blocks and prolong the SSD lifespan. However, FTL brings in considerable overheads. First, the translation table requires a large amount of DRAM to store the mapping entries, e.g., 1GB for 1TB NAND capacity for 4KB data unit size. Second, when serving a user I/O, the compounding effect of GC and wear-leveling would trigger additional SSD internal writes (i.e., copying valid pages to erase the block) and lead to the WAF (Write Amplification Factor) problem. Third, the FTL does not employ performance isolation mechanisms and incurs significant interference issues under mixed I/O profiles [28, 32].

### 2.2 Zoned Namespace SSDs

ZNS SSDs, a successor to Open-Channel (OC) SSDs [6, 9], have recently been developed to overcome the aforementioned limitations of conventional SSDs. There are several commodity ZNS SSDs from various vendors [34, 37, 38, 50]. A ZNS SSD applies the same architecture as a conventional one (Figure 1) but exposes the zoned namespace interface. A namespace is a separate logical block address space, like a traditional disk partition, but managed by the NVMe device controller rather than the host software. The device may control the internal block allocation of namespaces to optimize the performance based on the device-specific architecture. In ZNS SSD, the namespace comprises multiple zones instead of blocks in the conventional one, and each namespace owns dedicated *active resources* that are used to open and write a zone.

A ZNS SSD divides the logical address space of namespaces into fixed-sized zones, where each one is a collection of erase blocks and must be written sequentially and reset explicitly. ZNS SSDs present three benefits: (1) Maintain coarse-grained mappings between zones and flash blocks and apply wear-leveling at the zone granularity, requiring much smaller internal DRAM; (2) Eliminate the device-side GC and reclaim NAND blocks via explicit zone resets by host applications, which mitigates the WAF and log-on-log [51] issues and minimizes the over-provisioning overhead; (3) Enable the placement of opened zones across different device channels and dies, providing isolated I/O bandwidth and eliminating inter-zone write interference.

A zone has six states (i.e., *empty*, *implicitly open*, *explicitly open*, *closed*, *full*, *read only*, and *offline*). State transitions are triggered by either write I/Os or zone management commands (i.e., RESET, OPEN, CLOSE, and FINISH). A zone must be opened before issuing writes, but it is capable of serving reads in any state except the *offline* state. *closed* and *open* (both implicit and explicit) are *active* states that require the device to maintain NAND metadata for incoming user write I/Os, limiting the maximum number of active zones. SSDs employ the write cache in DRAM to align the wide range of user I/O sizes to the NAND program unit and comply with the NAND-

specific requirements (timings and program order). In case of a sudden power-off failure, the device flushes uncommitted data in the cache using batteries or capacitors as an emergency power source [46, 54]. Since active zones must have a buffer backed by energy devices for at least one NAND program unit in the cache, the maximum number of active zones is also constrained by the size of the write cache.

A zone provides three I/O commands: *read*, *sequential write*, and *append*. The *append* works similarly to the nameless write [53] but improves the host I/O efficiency rather than the internal NAND page allocation. Compared with the normal write, a zone *append* command does not specify the LBA in the I/O submission request, whilst the SSD will determine it at processing time and return the address in the response. Thus, user applications can submit multiple outstanding operations simultaneously without violating the restriction of sequential writes. Random writes are disallowed on ZNS SSDs, and the zone is erased as a whole (via the RESET). A ZNS SSD delegates the FTL and GC responsibilities to user applications, where they are performed at the zone granularity, thus eliminating traditional SSD overheads.

### 2.3 Small-zone and Large-zone ZNS SSDs

Zones can be classified into two types: *physical zone* and *logical zone*. Physical zones are the smallest unit of zone allocation and consist of one or more erasure blocks on a single die. They are device-backed and offer fine-grained control over storage resources. In contrast, logical zones refer to a striped zone region consisting of multiple physical zones. They can be implemented by either the device firmware or application and provide higher bandwidth through striping. Large-zone ZNS SSDs provide coarse-grained large logical zones with a fixed striping configuration that spans multiple dies across all internal channels but offers limited flexibility for controlling device behavior from the host software. This simplifies zone allocation but exposes a small number of active zones available for allocation to applications (e.g., 14 zones [50]). As a result, large-zone SSDs are more suitable for scenarios with small numbers of tenants, where the number of active zones required is not high. In addition, the application-agnostic fixed striping configuration does not adapt to workload profiles, resulting in low bandwidth utilization. Small-zone ZNS SSDs operate under similar hardware constraints but expose finer-grained physical zones. Each zone is contained within a single die but sufficiently large to encompass at least one erasure block. Small-zone SSDs provide greater flexibility and much more active resources (e.g., 256 zones in our testbed ZNS SSD) to support more I/O streams. In addition to increased flexibility, small-zone SSDs reduce the need for application-level garbage collection, especially while managing large numbers of small objects. Recent studies also corroborate some of these points. Specifically, Bae et al. [3] advocate a zone to be as small as possible to reduce the interference caused by high zone-reclaiming latencies. ZNS+ [16]

Figure 2: The number of zone with actual write activity when running the *fill-random* workload over the RocksDB. The storage backend is ZenFS. The maximum number of active zones is 16 (red line).

also prefers small zones as it minimizes the latency of COPY operations performed frequently in its F2FS implementation.

### 2.4 The Problem: Lack of an Elastic Interface

The ZNS SSD brings in two key benefits. First, it exposes controllable garbage collection to host applications, eliminating obtrusive I/O behaviors precipitated by device internal bookkeeping I/Os. This also alleviates write amplification and reduces flash over-provisioning. Second, it only allows sequential writes within a zone and thereby mitigates certain I/O interference observed in a conventional SSD. Both prior studies [3, 8, 16, 45] and our characterizations (§3) below demonstrate these points. However, existing ZNS SSDs have one significant drawback: **the zoned interface is static and inflexible**. After a zone is allocated and initialized, its maximum performance is fixed regardless of the underlying device capability, its I/O configurations cannot adapt to runtime workload characteristics, and cross-zone I/O interference yields unpredictable I/O executions.

First, the performance profile of a zone-sized storage partition hinges on physical zone placement and stripe configuration, which should align with application requirements. Despite significant benefits from the flexibility of the user-defined logical zone, application-managed zone configuration would sustain sub-optimal performance due to the lack of knowledge of other tenants sharing the device. In addition, it imposes another burden on application developers, as with OC SSDs.

Second, it is non-trivial to develop a complete application profile that captures every aspect of I/O execution characteristics, such as read/write block size and distribution, I/O concurrency, and command interleaving degree. The existing zoned interface fails to adapt to the changing workload behavior. Users have to over-provision the zone resources when configuring a zone based on the worst-case estimation.

In Figure 2, it is shown that the RocksDB over ZenFS [7] actively writes to only a fraction of the zones it maintains in the *active* state. This leads to inefficient utilization of valuable active resources in the ZNS SSD. Similarly, file systems like BtrFS [36] and F2FS [25] support ZNS SSDs but write user data to only one zone at a time, resulting in suboptimal utilization of the available active resources. This issue is fur-

ther exacerbated when the device has multiple namespaces serving different applications. In such cases, each application only utilizes a fraction of the available bandwidth, wasting valuable active resources in the ZNS SSD.

Third, a zone is not a completely performance-isolated domain, and co-located zones interact with each other in a non-deterministic fashion. Ideally, each tenant should receive a weighted share based on the consolidation degree. Specifically, its housing application should achieve its targeted performance when the SSD is under-utilized but receive a proportional degradation when the SSD is over-subscribed. However, unlike its predecessor OC SSD, ZNS SSDs manage zone allocation and wear-leveling internally with no strong isolation support and expose an opaque view to applications, yielding unpredictable performance interference and I/O execution unfairness. Such an issue could be mitigated in a conventional SSD where FTL and GC blend and distribute blocks across channels and dies uniformly regardless of the original command flow, ensuring the attainment of the maximum bandwidth and equal utilization of channel and die.

### 3 Performance Characterization of a ZNS SSD

This section characterizes a ZNS SSD with a focus on understanding why existing ZNS interfaces are static and inflexible. We then discuss the possibilities of addressing the problem.

#### 3.1 Experimental Setup

Device HW Parameters	Specification
Capacity	3,816 GB
Channels #	16 Channels
NAND Dies #	128 Dies
NAND Page Size	16 KB
NAND Channel B/W	~600 MB/s
Physical Zone Size	96 MB
Read B/W per Physical Zone	~200 MB/s
Write B/W per Physical Zone	~40 MB/s
Maximum Active Zones #	256

Table 1: The commodity ZNS SSD specification.

**ZNS SSD and testbed.** We use a commodity ZNS SSD for characterization. Table 1 presents its hardware details. It has 40,704 physical zones, where each 96MB-size zone consists of NAND erase blocks solely on a single die, and supports a maximum of 256 open zones simultaneously. We then configure various logical zones using such fine-granular units. We also prepare a conventional SSD with an equivalent architecture for a fair comparison. Our server has two 2.50GHz E5-2680v3 Xeon processors with 256GB DDR4 DRAM, and both SSDs are connected to  $\times 4$  PCIe Gen3 slots directly.

**Workloads and performance metrics.** We use the Fio benchmark tool [15] running on the SPDK framework [43] to generate synthetic workloads. We report both per-IO average/tail latency as well as achieved bandwidth. We add a thin layer to the SPDK to implement the logical zone concept and realize different zone configurations. Given the ZNS protocol, we regulate the write workloads to sequential accesses on a

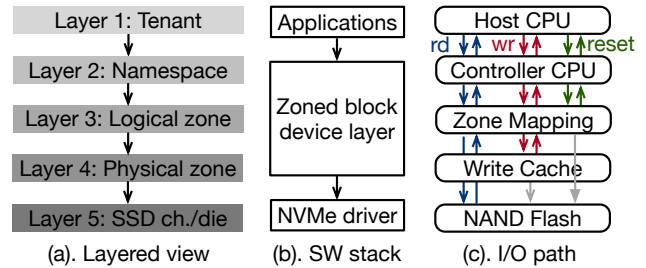

Figure 3: System model, SW stack, and I/O path of a multi-tenant ZNS SSD deployment. RD/WR=Read/Write. The write cache flushes data to the NAND flash asynchronously. Zone resets are completed after invalidating the mapping layer, where NAND blocks are erased lazily.

single logical zone in the following experiments, where read workloads are issuing random I/Os unless specified.

#### 3.2 System Model

We consider a typical system setup with a five-layered view to facilitate the understanding of a multi-tenant ZNS SSD deployment and dissect the I/O behavior (Figure 3-a). From the top-down perspective, the first layer contains a few co-located tenants, each running a storage application (e.g., blob store, F2FS, and RocksDB). Next, a tenant exclusively owns one or several namespaces based on the required capacity. A namespace provides independently configurable logical zones (layer 3), exposing a private logical block address space. By manipulating the logical zone setup, a namespace can be configured differently to meet the capacity and parallelism requirements. Within a logical zone, reads happen everywhere, while writes are only issued in an append-only manner. This is unique to a ZNS SSD and in significant contrast to a conventional SSD, which can be viewed as a fixed or statically configured SSD.

A logical zone comprises several physical zones (fourth layer). The number of physical zones per logical zone is typically fixed within a namespace. The logical-to-physical zone mapping can be arbitrary regardless of the request serving order and device occupancy. However, the logical zone must not share its physical zones with each other to conform with the ZNS protocol. At the bottom layer, a physical zone is placed on one channel/die following the device specification. The zoned block device (ZBD) layer (Figure 3-b) is the central component across the storage stack that abstracts away architectural details of a ZNS SSD. It provides three functionalities: (1) interacting with the application on namespace/logical zone management; (2) orchestrating the logical-to-physical zone mapping in consideration of the application requirement; (3) scheduling a sequence of I/O commands to maximize device utilization and avoid head-of-line blocking. Figure 3-c shows the IO path of read/write/reset requests. We carefully configure each layer when designing characterization experiments.

#### 3.3 Zone Striping

Since a logical zone is usually configured as an array of physical zones spatially, similar to RAID 0, one could apply the

Figure 4: Read bandwidth varying the stripe size for different types of zones.

Figure 5: Read/Write bandwidth varying the number of physical zones.

Figure 6: Read bandwidth under three channel overlapping (OL) allocations.

Stripe Size	Avg. Lat(us)	P99.9 Lat. (us)	B/W (MB/s)
4KB	64	76	59
8KB	71	84	108
16KB	88	103	175
32KB	163	269	190
64KB	314	619	198

Table 2: Read I/O average/P99.9 latency and bandwidth varying the stripe size on a physical zone.

striping technique to achieve higher throughput, especially for large-sized I/Os. Zone striping segments data blocks across multiple physical zones and access them concurrently. There are two configuration parameters: (1) *Stripe size* is the smallest data placement unit in a stripe, and (2) *Stripe width* defines the number of physical zones in an active state and controls the write bandwidth.

### 3.3.1 Basic Performance

When there are enough outstanding I/Os submitted to an SSD, unsurprisingly, the optimal striping efficiency is achieved when the stripe size matches the NAND operation unit (i.e., NAND page size). As shown in Table 2, the achieved per-die bandwidth increases slowly after the 16KB stripe size. In terms of latency, the access time reduction is non-linear for sizes smaller than a NAND page (16KB). When the I/O size is larger than 16KB, the average latency rises proportionally to the I/O unit because each request has to access the die multiple times sequentially. Next, we change the logical zone setup and see the efficiency of different stripe sizes. We use *N-zones* to refer to a logical zone configuration, where *N* is the number of physical zones in a striping. As shown in Figure 4, when issuing 2MB reads (which generates enough I/O to construct a full stripe I/O on each physical zone), for different zone configurations, the bandwidth over various stripe sizes shows a similar result with the single-die performance. On the other hand, a wider width that fully uses the stripe size ( $stripe\_size \times stripe\_width$ ) achieves higher bandwidth. For example, the 4KB stripe size in 8-zones achieves 37.3% higher read bandwidth than the 8KB stripe size in 4-zones. Note that the stripe size does not significantly affect the write performance as one can coalesce stripes on the same physical zone into a single device I/O and submit it at once. Instead, the stripe width determines the maximum write bandwidth.

### 3.3.2 Challenge #1: Application-agnostic Striping

When deciding the optimal stripe size and width, one should consider the application I/O profile dynamically, including

request type, size distribution, I/O size efficiency, and concurrency. However, the existing zoned interface lacks such support and hinges on users' domain knowledge during configuration. A large stripe may hurt performance if the size of sequential user I/O is smaller than the size of a full stripe. On the other hand, too small a stripe also hurts the I/O efficiency of the device; a 4KB stripe with an 8-zone or wider width significantly lags behind 8KB or larger stripes in Figure 4. A wide stripe width sustains high performance per logical zone. However, since the device has a limited amount of active resources, it will instead limit the maximum number of active logical zones and jeopardize application concurrency.

**Observation:** The use of logical zones with striping is beneficial for the application, but zone striping should be an adaptive configuration determined based on the total amount of active zones and application profiles. A ZNS SSD has to provide enough active logical zones to not only cope with application concurrency but also max out the device bandwidth by adjusting the stripe width dynamically. An ideal strip size can be the NAND page size, but it also has to be adjusted to the stripe width to provide a consistent full stripe size.

## 3.4 Zone Allocation and Placement

A ZNS SSD allocates physical zones across dies/channels, mainly taking access parallelism and wear-leveling into consideration. Upon an allocation request, the ZNS SSD traverses the die array following a certain order, and then selects the next available die to place each physical zone. Within a determined die, it chooses blocks with the least P/E cycles based on opaque wear-leveling policies.

### 3.4.1 Basic Performance

Zone allocation should be locality-aware and parallelism-aware. A larger-sized logical zone is expected to observe higher read/write bandwidth because it spreads physical zones across *different* channels and dies in a deterministic sequence and achieves more I/O parallelism. The maximum performance is obtained when I/Os access all channels and dies without blocking. We configure the stripe size to 16KB and increase the number of physical zones in a logical zone (*N*), then measure the I/O bandwidth of a single logical zone under four I/O profiles (Figure 5). The performance of 2MB reads with queue depths 1 and 2 (i.e., 2MB-RD-QD1/2MB-RD-QD2) keeps increasing until the number of physical zones approaches 20. But they max out for different reasons. The

Figure 7: Bandwidth and tail latency varying with the die overlapping ratio.

Figure 8: Read tail latency varying the write bandwidth (ZNS vs Conventional SSD)

Figure 9: Bandwidth under RD-RD and WR-WR congestion due to the die-collision.

QD2 case is bounded by the PCIe bandwidth (i.e., four Gen3 lanes or 3.2GB/s), whilst the QD1 scenario is simply limited by the application as it cannot issue enough outstanding I/Os at that queue depth. In terms of 4KB random read with 32 queue depth and 2MB sequential write, they sustain 80MB/s read and 40MB/s program bandwidth per physical die, respectively, requiring much more physical zones ( $\sim 40$  and  $80$ ) to utilize the channel or PCIe bandwidth fully.

### 3.4.2 Challenge #2: Device-agnostic Placement

An ideal allocation process should expose all of the internal I/O parallelism of a ZNS SSD to a tenant. However, the existing mechanism is opaque to housed tenants, where the global allocation pointer picks the next available die without considering the application’s prior allocation history or how it interacts with other tenants. This causes unbalanced zone placement, hurts I/O parallelism, and jeopardizes performance. We find two types of inefficient placements:

- **Channel-overlapped placement:** Concurrent zone allocations might cause overlapped zone placements across channels, limiting the maximum channel parallelism. Similarly, synchronized allocation requests might prevent placement alignment, again limiting the aggregated bandwidth. Figure 6 presents 4KB and 128KB random read bandwidth when increasing the QD for three inferior placements, where 2/4/8 physical zones contend for the same channel in a 16-zone configuration. Physical zones stay across 16 different dies that limit the maximum bandwidth. The 2-overlapped allocation outperforms the other two (i.e., 4-overlapped/8-overlapped) by  $1.7\times/2.9\times$  and  $1.7\times/2.5\times$  for 4KB and 128KB cases, respectively.
- **Die-overlapped placement:** An intra-namespace die overlapped placement limits the bandwidth and can be even more detrimental because a die can only process one operation at a time. We configure such an experiment by placing physical zones in the same die and gradually increasing the overlapping ratio. Figure 7 reports the logical zone’s sustained bandwidth and tail latency under two I/O profiles. When no physical zones share the same die, it achieves 1,128MB/s and 2,051MB/s along with 317us and 284us p99.9 tail latency for the 4KB random read and 128KB sequential read cases, respectively. With full overlap, we observe 47.2%/23.8% bandwidth drop and 87.1%/28.0% tail latency increase. Such performance degradation hap-

pens even when the overlapping ratio is lower than 25%, because both types of I/Os suffer from the head-of-line blocking issue at the overlapped dies.

**Observation:** It is challenging to infer the zone’s physical location without knowing the device’s internal specification. One may run a profiling tool in the runtime to extract the relation among different zones [3]. However, it does not eliminate the imprinted overlap at the allocation time. To maximize the I/O parallelism, one could build a device abstraction layer that (1) relies on a general allocation model of the device; (2) maintains a shadow view of the underlying physical device; (3) profiles its placement balanced level across different physical channels and dies.

## 3.5 I/O Execution under ZNS SSDs

A ZNS SSD eradicates background GC I/Os, thereby removing one form of performance non-determinism. Within a logical zone, writes happen sequentially, but reads are issued arbitrarily. When reads are congested, one would observe latency spikes under die/channel contention. If considering cross-zone cases, either *intra* or *inter* namespace, interference would be more severe than a conventional SSD because ZNS SSDs impose no physical resource partitions, and per die/channel bandwidth is narrow.

### 3.5.1 Basic Performance

Irrespective of the NAND block layout of a logical zone, its I/O access latency highly correlates with achieved bandwidth because there are no device internal I/Os that consume bandwidth and are hidden from user applications. To demonstrate this, we prepare a conventional SSD having the same hardware as the ZNS SSD and compare two SSDs under the mixed read-write scenario. We configure a logical zone for the ZNS SSD that spreads across all the channels and dies (i.e., 128-zone configuration with 16KB stripe size) to match the conventional one. The fragmented conventional SSD is 70% filled and preconditioned with 128KB random writes. Then we run eight read threads—where each issues one 128KB read I/O to all the dies uniformly random—and one write thread that performs sequential write at a fixed rate. Figure 8 reports the read/write tail latency as we increase the write bandwidth. More writes on a ZNS SSD leave less bandwidth headroom for reads and cause the latency to increase. However, for the fragmented conventional SSD, the internal GC activities make even less bandwidth available to serve

reads due to write amplification. For example, when the write bandwidth is 1,000MB/s, the p99.9 read and write latency of the conventional SSD is  $4.3\times$  and  $2.8\times$  worse than the ZNS one. In terms of the read throughput, the conventional SSD shows  $1.1\times$  and  $1.6\times$  lower throughput than the ZNS SSD at the 200MB/s and 1,000MB/s write bandwidth, respectively.

### 3.5.2 Challenge #3: Tenant-agnostic Scheduling

Existing zoned interfaces of ZNS SSDs provide little performance isolation and fairness guarantees for the inter-zone case, regardless of deployed workloads. One cannot overlook the read interference on a die because (1) an arbitrary number of zones can collide on a die, (2) the bandwidth of a single die is poor, and hence the interference becomes severe even under a very low load on the device, and (3) it causes a severe head of line blocking problem and degrades the performance of the logical zone. Since there is no internal GC in the ZNS SSD, The I/O determinism [26] proposed for the conventional SSD does not apply as well. Similar to conventional SSDs, the write cache, shared among all NAND dies, is an indispensable component of the ZNS SSD, buffering incoming writes and flushing to the NAND dies in a batch. Host applications will observe prompt write I/O completions when they are absorbed by the cache but experience considerable latency spikes when the cache overflows. This has not been an intractable issue in conventional SSDs because the device firmware blends all incoming write I/Os and constructs a single large flow spanning entire NAND dies, maintaining the cache eviction rate to the maximum device bandwidth. However, in the ZNS SSD, a write I/O must be flushed out to the designated NAND die with an inadequate program bandwidth, even with zone striping. In this situation, a heavy writer exhausts the available cache capacity and severely disturbs other short flows.

We set up two readers performing 128KB read I/O in different profiles: (1) queue depth 8 with a two-zone configuration, and (2) queue depth 2 with an eight-zone configuration. Figure 9 shows the interference between two readers in a die-collision. The QD-8 reader easily obtains 97.2% of the total bandwidth of collision dies. Note that the interference and unfair bandwidth share also occurs in the conventional one, but only when the device bandwidth is fully saturated [23, 41]. We also demonstrate the write cache congestion in Figure 9. We first populate 15 logical zones with a stripe width of 8, and each physical zone is allocated to a dedicated die. The cumulative write bandwidth of 15 zones maxes out the PCIe bandwidth (3.2GB/s), and a single zone performs at  $\sim 213.3\text{MB/s}$ . In this case, a physical zone in the logical zone receives write at a lower rate than the maximum bandwidth ( $\sim 26.7\text{MB/s}$ ), and the write cache does not overflow. Then, we add one more writer with a narrow width of 2, which also runs on dedicated dies. Write I/Os towards the narrow zone are equally fetched by the device, but it soon consumes all available cache because of the scarce bandwidth ( $\sim 85\text{MB/s}$ ) of underlying physical zones. It degrades others' bandwidth by 27.3% or

Figure 10: eZNS System Architecture.

155MB/s, and the device even fails to max out the PCIe bandwidth ( $\sim 2.4\text{GB/s}$ ).

**Observation:** When using ZNS SSDs in a multi-tenant scenario, one should first understand how different namespaces and logical zones share the channels and NAND dies of the underlying device, classify their relationships into competing and cooperative types, and employ a congestion avoidance scheme for the inter-zone scenario to achieve fairness. Since there are no device bookkeeping operations, I/O latencies represent the congestion level on colliding dies. In addition, write cache congestion needs to be addressed globally. Thus, a possible solution is to design (1) a global central arbiter that decides the bandwidth share among all active zones; (2) a per-zone I/O scheduler that orchestrates the read I/O submission based on the congestion level.

## 4 eZNS: Enabling an Adaptive Zoned NS

This section describes the design and implementation of eZNS that realizes a new and elastic zoned interface. We use the gathered insights from our characterization experiments and address the aforementioned issues.

### 4.1 eZNS Overview

eZNS stays atop the NVMe driver and provides raw block accesses. eZNS exposes the *v-zone* interface that offers runtime hardware adaptiveness, application elasticity, and tenant awareness. We carefully design eZNS and spread its functionalities across the control plane and data plane. As shown in Figure 10, it mainly consists of two components. The first is the zone arbiter that (1) maintains the device shadow view in a hardware abstraction layer (HAL) and provides the basis for other components, (2) performs serialized zone allocation avoiding overlapped placement, and (3) dynamically scales the zone hardware resources and I/O configurations via a harvesting mechanism. The second is a tenant-cognizant I/O scheduler, orchestrating read requests using a delay-based congestion control mechanism and regulating writes through a token-based admission control. In sum, eZNS addresses the three issues discussed in §3.

## 4.2 Hardware Contract and HAL

We develop eZNS based on the following hardware contract, which are met by recent ZNS SSDs with small zones: (1) a physical zone consists of one or more erasure blocks on a single die; (2) the maximum number of active physical zones is a multiple of the number of dies, and all dies hold the same number of active zones when they are fully populated (i.e., the ZNS SSD evenly distributes physical zones over dies); (3) the zone allocation mechanism follows the wear-leveling requirements, indicating that consecutive allocated zones will not overlap on a physical die until all the dies have been traversed. We need to caveat that the last contract may not always be followed in allocations if the device firmware enforces a specific policy other than round-robin across dies. However, considering the large number of chips and the wear-leveling constraint, such cases are rare. Our mechanism doesn't require being cognizant of the two-dimensional geometric physical view of SSD NAND dies and channels or maintaining an exact zone-die mapping.

eZNS maintains a shadow device view, exposing the approximate data locality for zone allocation and I/O scheduling. Our mechanism (or HAL layer) only hinges on three hardware parameters from device specifications. The first one is the *maximum number of active zones* (or MAR, maximum active resources). This is based on an observation that the MAR is generally in proportion to or a multiple of the number of physical dies on the SSD. One could estimate the number of active zones that a die could hold by deliberately controlling the zone allocation order in an offline calibration experiment (§3.4). The second parameter required is the *NAND page size* used for striping configuration. For example, 16KB is a de facto standard for most TLC NVMe drives and is well-known for system developers. The SSD shows the best efficiency when the stripe size is aligned with it (§3.3), and thereby, we choose the stripe size as a multiple or factor of the NAND page size that is closest to avoid inefficient stripe reads for sequential workloads. These two parameters reflect the device's capabilities. The third one is the *physical zone size*, deciding how a logical zone and strip groups are constructed. With such information, HAL provides a shadow view having a consistent MAR (e.g., 16) and the size of a zone (e.g., 2GB) regardless of the underlying device.

## 4.3 Serial Zone Allocator

eZNS develops a simple zone allocator that provides three guarantees: (1) it ensures that each stripe group comprises a list of consecutive and serial opened physical zones, following the firmware-enforced internal order; (2) there is no die collision within a stripe group; (3) across stripe groups, die collision could happen for writes only if available active physical zones are fully populated across all the dies. Given the above device model, the number of stripe groups colliding on a die is  $\frac{\text{Maximum \# of active zones}}{\text{Die \#}}$  at most. Channel collision would not be an issue because its bandwidth is usually higher

Figure 11: Example of eZNS *v-zone* structure.

than the aggregated program bandwidth across dies.

Our allocator works as follows. It has a per-device request queue, buffering OPEN commands (including implicit ones followed by writes) from all logical zones. Our allocator serves each logical zone request atomically. Since the completion of a zone OPEN command does not guarantee that the zone is actually allocated on a physical die, we implement a zone reservation mechanism during zone opens—flushing one data block that enforces binding a die to the zone. Writes complete immediately as the write cache of the device absorbs a single block even in high load. To expedite this process, we proactively maintain a certain amount of reserved zones in serial order and provision them to an upcoming stripe group. Upon completion of the allocation, we then update the allocation history and write it into a reserved persistent region (metadata block) following the block for reservation. Hence, we preclude interleaved allocations from concurrently opened logical zones to prevent channel-overlapped placement and facilitate allocation reordering to mitigate die overlaps (§3.4.2).

## 4.4 Zone Ballooning

*v-zone*, a specialized logical zone, can automatically scale its I/O striping configuration and hardware resources to match changing application requirements in a lightweight fashion. Figure 11 illustrates an example of a *v-zone* structure. Similar to a static logical zone, a *v-zone* contains a fixed number of physical zones. However, unlike a static logical zone, it divides physical zones into one or more stripe groups. When *v-zone* is first opened or reaches the end of a previous stripe group, it allocates a new stripe group. All physical zones in the previous stripe group must be finished when the write pointer reaches the end of the stripe group, allowing an active *v-zone* to take active resources for only one stripe group. The number of physical zones in a stripe group is determined at the time of allocation according to the *local overdrive* mechanism, which enables flexible zone striping. To comply with the standard zone interface, *v-zone* has a size that is a power of 2, and its capacity is the sum of user-available bytes in physical zones.

Similar to the virtualization memory ballooning technique [5, 39, 47], zone ballooning allows a *v-zone* to (1) expand its stripe width by leasing spares from others when other namespaces are under low active resource usage; (2) return them when it finishes the stripe group either by writing to the end of the stripe group or explicitly issuing FINISH/RESET commands from the application.

#### 4.4.1 Initial Resource Provisioning

eZNS divides all the available and opened physical zones on the ZNS SSD into two groups: *essential* and *spare*. The *essential* group contains a minimal number of active physical zones that can max out the SSD write bandwidth ( $N_{essential}$ ), whilst the rest belong to the *spare* group ( $N_{spare}$ ). Our initial resource allocation follows the equal bandwidth partition principle. We choose the write I/O bandwidth as the minimum guarantee because writing resources (or active physical zones) of a ZNS SSD are scarce. Assuming the number of namespaces that a ZNS SSD holds is  $N_{ns}$  and the maximum number of active  $v$ -zones per namespace is  $MAR_{logical}$ . A namespace takes  $\frac{N_{essential}}{N_{ns}}$  exclusive active physical zones; when a  $v$ -zone in the namespace opens a new stripe group, it receives  $\frac{N_{essential}}{N_{ns} \times MAR_{logical}}$  assured essential ones which is also the minimum stripe width. In terms of *spare* zones, similarly, eZNS equally distributes them to a namespace ( $\frac{N_{spare}}{N_{ns}}$ ) during initialization. Both a  $v$ -zone and a namespace will expand/shrink their capacity to adapt to workload demands.

#### 4.4.2 Local Overdrive: Zone Expanding

eZNS provisions available spares from the *spare* group of its namespace to boost its write I/O capability. We realize this via an internal *local overdrive* operation while opening a new stripe group. The mechanism works as follows. First, it estimates the resource usage of the namespace by analyzing its previously opened  $v$ -zones, quantified as the exponentially weighted moving average over the number of active  $v$ -zones ( $N_{ActiveZoneHistory}$ ). Second, it checks the remaining spares from the spare group ( $N_{RemainingSpare}$ ) and reaps additional spares based on  $\frac{N_{TotalSpare}}{N_{ActiveZoneHistory}}$ . Essentially, a  $v$ -zone will receive more (fewer) spares if it embodies writing activities but the namespace only opens fewer (more)  $v$ -zones. Third, the  $v$ -zone conflates the harvested spares with assured essential ones for it to open the new stripe group, and the stripe width is rounded down to the nearest power of two for efficient resource management. Note that the *local overdrive* operates in a serial and best-effort fashion. Lastly, eZNS sets the baseline stripe size to 32KB at the minimum width for the optimal I/O efficiency of the device. It then reduces the stripe size for an overdriven zone according to the stripe width, down to the minimum block size of the device. For example, if the width gets two times wider, the stripe size is reduced by half. We determine the range of stripe sizes to optimize the performance as aforementioned in §3.3. The reduced stripe size further contributes to the I/O scheduler ensuring fairness (§4.5).

#### 4.4.3 Global Overdrive: Namespace Expanding

Across the whole device, our zone ballooning mechanism further reallocates spares across namespaces based on their latest write activity. We realize this via another internal *global overdrive* operation—lend spares from the spare group to each other. Unlike *local overdrive*, global overdrive is triggered

based on the write intensity across the entire drive. Specifically, our arbiter monitors the past  $N_{essential}$  opened physical zones across all active namespaces, computes their zone utilization, and redistributes the remaining spares from inactive namespaces to active ones. In the current design, we determine an *inactive* namespace as a namespace that has no allocation history in the last  $N_{essential}$  physical zone allocations of the device, and lent spares are equally distributed across active namespaces. When an *inactive* namespace becomes active again, eZNS marks the leased spares as recall spares and leased namespaces release them to the global pool as soon as they FINISH/RESET the stripe group in  $v$ -zones. eZNS then returns them to the original namespace at the next *global overdrive* operation.

#### 4.4.4 Reclaim: Zone/Namespace Compaction

Generally, an overdriven  $v$ -zone after entering the FINISH state will return spare zones. Therefore, spare zones circulate as long as namespaces continue to write to  $v$ -zones. However, when a namespace overdrives  $v$ -zones, which becomes *inactive* without releasing them, the arbiter has to use a *reclaim* operation to take back the spares to prevent resource leakage. To ensure no slowdown on the performance path, we employ an asynchronous window-based monitoring scheme, where the arbiter bookkeeps the status of each *inactive* namespace and continuously counts how long its status is in the read-only state. If a namespace presents no write I/Os for a certain amount of time,  $T_{ReadOnly}$ , the arbiter triggers the reclaim procedure to proactively collect the spare zones. The execution cost of *reclaim* depends on the configuration within the opened stripe group. If there are committed writes on the zone, *reclaim* will trigger a zone compaction and perform a sequence of I/O reads/writes, i.e., finishing existing zones, opening a new stripe group with shrunk width, and copying data to the new one. Once the migration is done, the spare zones can be returned to the global spare pool.

The zone reclaiming indeed brings GC-like overheads back to the system. Thus, it is crucial that the system does not trigger the operation in normal conditions. In eZNS, zone reclaiming is only performed when namespaces have no write activity for two cycles of global overdrive. This is likely to happen infrequently, such as when an application undergoes a significant change in its running state. Moreover, reclaiming is triggered in a lazy fashion, executed in the background, and regulated by the scheduler to limit its performance impact. As a result, eZNS can avoid triggering zone reclaiming in normal conditions, maintaining high performance and efficiency.

### 4.5 Zone I/O Scheduler

eZNS mindfully orchestrates I/O reads/writes with the goal of providing equal read/write bandwidth shares among contending  $v$ -zones, maximizing the overall device utilization, and mitigating superfluous head-of-line blocking when different types of requests interleave. Our zone I/O scheduler com-

prises two components: congestion-avoiding read scheduler and cache-aware write admission control.

#### 4.5.1 Congestion-avoid Read Scheduler

Our design is based on the observations that (1) ZNS SSDs have no internal housekeeping operations; (2) write I/Os are sequential and synchronous. Hence, the read latency is stable and low until the die becomes congested, and it is thus possible to detect congestion directly via latency measurements.

eZNS introduces a hierarchical design that performs weighted round-robin scheduling firstly across active namespaces and then delay-based congestion control across each intra-namespace *v-zones*. By conforming to the NVMe architecture, we create per-namespace NVMe queue pairs and offload the round-robin scheduling to the device. Then, we employ a Swift-like [24] congestion control mechanism to decide the bandwidth allocation for each stripe group in the *v-zone*, where the delay is the device I/O command execution latency. As shown in Algorithm 1, during the congestion-free phase, upon a read I/O completion, we additively increase (AI) the congestion window until it approaches the maximum size (line 6). Since the congestion window (*cwnd*) is shared in the stripe group, when set to the stripe width, it indicates that there is one outstanding I/O per die in the sequential case. The SSD can max out its per-die bandwidth with a few outstanding I/Os. Thus, when the *cwnd* starts with the stripe width, it quickly ramps up to the device bandwidth capacity. Further, we limit the maximum congestion window (*cwnd*) to  $4 \times \text{strip\_width}$  to minimize the software overheads when handling excess concurrent I/Os and avoid a meaningless rapid growth of *cwnd* that would imperil the efficiency of the MD phase. When congestion happens, we reduce the congestion window multiplicatively (line 4), whose ratio depends on the latency degradation degree. All the physical zones within a stripe group share the same congestion status. It is reasonable because sequential read bandwidth will be capped by the most congested physical zone. Random reads usually will not trigger frequent *cwnd* decrements because the minimum window size is large enough to absorb them. Our congestion control works cooperatively with the reduced stripe size of the overdrive and ensures a fair share of bandwidth regardless of the width of the stripe group.

#### 4.5.2 Cache-aware Write Admission Control

Due to the non-linear write latency and the shared architecture, it is inappropriate to implement a local mechanism to mitigate the problem. Unlike the read congestion case, write congestion happens globally across all zones from all namespaces (§3.5). Therefore, eZNS monitors the global write latency and regulates writes using a token-based admission control scheme. We generate tokens periodically (ALG 1 lines 14–16) and admit write I/Os in a batch for each active *v-zone* to ensure overflow rarely happens. This requires a latency monitor to analyze the write cache eviction activity (ALG 1 lines 8–12). Here, we profile the block admission rate (defined as

---

#### Algorithm 1 Zone I/O Scheduler

```

---

the minimum delay between two consecutive write blocks) and adjust the token generation rate based on its normalized average latency. This is based on an empirical observation that the latency of the write projects its capacity share in the write cache. Hence, we equalize the latency for all write zones and calculate available tokens using the average value. Additionally, we update the available tokens based on the elapsed time from the last token refill upon a write submission. By doing so, we expect that writes are self-clocked in the congestion-less condition.

Note that (1) when read and write I/Os mix on a physical die, the total aggregate bandwidth will drop due to the NAND interference effect. However, our read scheduler and write admission control require little coordination because both modules only use the latency (gradient) as a signal to infer the current bandwidth capacity; (2) we coalesce stripes for the same physical zone within a user I/O and submit one write I/O to the device in a batch, and thus, a small stripe size does not degrade the write bandwidth.

## 5 Evaluation

We add a thin layer in the SPDK framework [43] to implement eZNS and realize the *v-zone* concept. The primary reason for choosing the SPDK approach was its ease of implementation and integration into the software stack of a storage server accessible by remote clients. Moreover, the SPDK-based design can also be used in a local system to serve virtual machines through the SPDK vhost extension. This approach allows the storage server to provide efficient and high-performance I/O operations, while remaining compatible with existing software stacks. We use the same test environment as in §3.1. Non-SPDK applications require a standard ZNS block device exposed via the kernel NVMe driver; thus, we set up eZNS as a disaggregated storage device over RDMA (NVMe-over-RDMA) and connect to it using the kernel NVMe driver.

**Micro-benchmarks:** We use FIO [15] to generate syn-

Figure 12: B/W comparison between an overdriven and three statically configured zones.

thetic workloads and allocate a separate thread for each worker when the workload writes to multiple namespaces or zones. For read workloads, we first precondition the namespace by performing sequential writes for the entire range of read I/O. Additionally, we perform a pre-calibration step to determine the die allocations in case the evaluation requires a die-level collision.

**Ported Applications:** We use RocksDB as a real-world ZNS application, to evaluate the performance of eZNS We run RocksDB over ZenFS [7] to enable the ZNS support. As eZNS complies with the standard NVMe ZNS specification, no modification is required for the application and ZenFS. We initialize the DB instance with 500M entities of 20-byte keys and 1,000-byte values.

**Default  $v$ -zone Configuration:** By default, eZNS creates four namespaces (NS1–4), each of which is allocated 32 essential and 32 spare resources. Since each namespace provides a maximum of 16 active zones, the minimum stripe width for  $v$ -zone is 2 with a stripe size of 32KB. However, eZNS can overdrive the width up to 16 with a stripe size of 4KB. For a fair comparison, we prepare a static logical zone configured with stripe width and size of 4 and 16KB, respectively; hence, it also accesses full device capability when the application populates enough active logical zones. Both a  $v$ -zone and a static logical zone comprise 16 physical zones. Different configurations are used for single-tenant evaluation (single namespace) as specified in Section 5.3.

## 5.1 Zone Ballooning

We demonstrate the efficiency of zone ballooning when handling large writes (i.e., 512KB I/O with a queue depth of one). First, within a namespace, we compare the performance be-

tween a  $v$ -zone and a static logical zone, where the number of writers is configured to 4, 8, and 16, respectively. Each writer submits a write I/O to different zones. Our *local overdrive* operation can reap more spare zones and lead to better throughput. As shown in Figure 12, the  $v$ -zone outperforms the static one by  $2.0\times$  under the 4-writer case as 4 static logical zones enable only 16 physical zones while 4  $v$ -zone overdrive the width to 8 and expand to 32 physical zones. In the 8-writer and 16-writer cases,  $v$ -zone reduces the overdrive width accordingly and utilizes the same number of physical zones (32 and 64, respectively) with the static logical zone.

To evaluate eZNS’s adaptiveness under dynamic workloads, we set up overdriven zones from different namespaces. The first three namespaces (NS1, NS2, and NS3) run two writers, while the fourth namespace (NS4) runs eight. NS1, NS2, and NS3 stop issuing writes at  $t=30s$  and resume the writing activity at  $t=80s$ . We measure the throughput and spare zone usage of four zones for a 100s profiling window (Figures 13 and 14). When the other three zones become idle, the  $v$ -zone from NS4 takes up to  $3\times$  more spare zones from other namespaces using the *global overdrive* primitive and maxes out its write bandwidth ( $\sim 2.3GB/s$ ). It can then quickly release the harvest zones when other zones start issuing writes again.

## 5.2 Zone I/O Fairness

We evaluate our I/O scheduler in various synthetic congestion scenarios by placing competing zones in the same physical die group. We compare the performance of all co-located zones when enabling and disabling our mechanism. The zone ballooning mechanism is turned off for all cases. We report per-thread bandwidth in Figure 15.

**Read-Read Fairness.** We run a sequential read of 128KB

**Figure 16: readwhilewriting workload on a single tenant configurations. Static has stripe width of 16. (S: 4KB stripe, L: 16KB stripe)**

**Figure 17: Latency of db\_bench workloads (2 overwrite, 2 randomread) on different namespaces over eZNS and static zone.**

**Figure 18: Throughput of db\_bench workloads (2 overwrite, 2 randomread) on different namespaces over eZNS and static zone.**

I/O size at two types of zones on co-located dies. To equally load the physical dies, we populate more threads for lower-width zones. For example, a zone with a width of 2 runs four threads on each stripe group, while a zone with a width 8 has only one thread. As shown in Figure 15-a, in scenario 1, when disabling our congestion control mechanism, Zone A (configured with stripe width 2 and stripe size 32KB, QD-1) and Zone B (configured with stripe width 8 and stripe size 8KB, QD-32), even holding the same sized full stripe, achieve 76MB/s and 1287MB/s, respectively. This is because the zone with the higher QD dominates on the competing die. Our scheme effectively controls the per-zone window size and ensures that each zone submits the same amount of outstanding bytes. Hence, both Zone A and Zone B sustain 290MB/s. In scenarios 2 and 3, we change the Zone A stripe configuration to <stripe width 4, stripe size 16KB, QD-1> and <stripe width 8, stripe size 8KB, QD-1>, and observe similar behavior when turning off the read congestion logic. In scenario 3, the congestion level on the die gets lowered as Zone A only submits one 128KB I/O (which was 4 and 2 in scenarios 1 and 2, respectively). Hence the read latency also becomes below the threshold, and the I/O scheduler chooses to max out the bandwidth.

**Write-Write Fairness.** We carefully create different write congestion scenarios and see how our admission control operates. The workload used is a sequential write of 512KB size. In the first scenario, we co-locate 16 regular write zones (Zone A, where each has a striping width of 8 with 8KB stripe size and submits write I/Os at 5ms intervals, sustaining 95MB/s maximum throughput) with a busy writer (Zone B, that has width 2 and 32KB stripe size, submits I/O without interval delays, achieving 85MB/s at most). Figure 15-b reports the bandwidth utilization of one regular zone (Zone A) and the busy writer (Zone B). Our admission control mechanism limits the write issuing rate of Zone B and gives more room at the write cache to the regular zone (Zone A), leading to 35.7% bandwidth improvement per thread. Next, we set up a highly-congested case by changing 16 regular zones to busy writers (scenario 2). As described in §4.5.2, our scheme equally distributes the write bandwidth share across competing zones, and Zone B receives 56.8% of the total bandwidth of 2 physical zones. The last scenario is a collision-less one at the die level where we eliminate the overlapping region among all the

write zones by populating active physical zones lesser than the number of dies. Similarly, when enabling the admission control, the bandwidth allocated for Zone B slightly decreases ( $\sim 7.2\%$ ) to avoid cache congestion, and the overall device bandwidth is increased by 24.7%.

**Read-Write Fairness.** We examine how our congestion control mechanism coordinates with the admission control when handling read/write mixed workloads. In this experiment, we set up three types of zones: (1)  $\times 16$  regular readers (Zone A), where each has a striping width of 2 and 32KB stripe size, performing 128KB random read at queue depth 32, across all physical dies; (2) 1 busy writer (Zone B), whose striping width is 2 with 32KB stripe size; (3)  $\times 16$  regular writers (Zone C), which has a striping width of 8 and 32KB stripe size each, submitting I/Os under 5ms interval. Both B and C issue 512KB large writes. Figure 15-c reports their per-thread bandwidth. When disabling our scheduler, each reader achieves 199.6MB/s but writes are jeopardized significantly, where Zone B and Zone C can only achieve 19.3% and 27.3% of their maximum bandwidth. As we gradually turn on our mechanisms, the congestion control shrinks the window size such that more bandwidth is allocated to the writes. Further, the admission control then equally partitions bandwidth among competing writing zones. As shown in the CC+AC case, zone A, B, and C can sustain 71.6%, 57.5%, and 70.1% of their maximum bandwidth capacity, respectively.

### 5.3 Application: RocksDB

To evaluate eZNS in a real-world scenario, we use RocksDB [35] over the ZenFS storage backend. In addition to the built-in utility in the RocksDB *db\_bench* tool, we port YCSB workload generators [4] for the mixed workload evaluation.

**Single-tenant performance.** First, we evaluate the performance of a single tenant using the *readwhilewriting* profile of the *db\_bench*, which runs one writer and multiple readers. This workload profile demonstrates a read/write mixed scenario. In the case of a single-tenant configuration, eZNS creates a single namespace on the device and allocates 128 essential and 128 spare resources to it. Since only two stripe widths, 8 and 16, are possible in this configuration, eZNS sets the stripe size to 16KB for the width of 8 to avoid the namespace running only on large stripe sizes. We compare the performance of eZNS over two static configurations, both

Figure 19: Read latency of YCSB workloads (A/B/C/F) on different namespaces over eZNS and static zone.

Figure 20: Throughput of YCSB workloads (A/B/C/F) on different namespaces over eZNS and static zone.

Figure 21: Comparison of Avg. Read Latency for 4KB I/Os at various depths between the host-managed zone access and eZNS.

with a stripe width of 16, but with different stripe sizes of 4KB and 16KB. Since there is only one namespace on the device, eZNS always overdrives *v-zones* to the width of 16, which is identical to the static configurations. Therefore, both the static namespace and eZNS can exploit all available bandwidth on the device. However, the I/O scheduler of eZNS helps mitigate interferences between zones and improves overall application performance. Figure 16 shows that eZNS improves the P99.9 and P99.99 read latency by 28.7% and 11.3% over the static configurations with a stripe size of 16KB and 4KB, respectively. Additionally, eZNS also improves the throughput by 11.5% and 2.5% with a stripe size of 4KB and 16KB.

**Multi-tenant Performance.** Next, we set up instances of *db\_bench* on four namespaces (A, B, C, and D), each with a different workload profile. A and B perform the *overwrite* profile, while C and D execute *randomread* concurrently. We run the benchmark for 1,800sec and report the latency and the throughput. Figure 17 shows that our I/O scheduler significantly reduces P99.9 and P99.99 read (C/D) latency by 71.1% and 20.5%, respectively. In terms of throughput, eZNS improves write (A/B) and read (C/D) throughput by 7.5% and 17.7%, respectively. Furthermore, while the read latency and throughput are improved, the write latency is either maintained at the same level or decreased compared to the static configuration because eZNS moves the spare bandwidth from read-only namespaces (C/D) to write-heavy ones (A/B).

**Mixed YCSB Workloads.** YCSB [14] is widely used to benchmark realistic workloads. In our experiments, we run YCSB workload profiles A, B, C, and F on each of the six namespaces. We exclude YCSB workload profiles D and E because they increase the number of entities in the DB instance during the benchmark. As YCSB-C (read-only) does not submit any write I/Os during the benchmark, eZNS triggers *global override* and rebalances the bandwidth to the write-most namespaces (A and F). Figure 19 shows that the I/O scheduler improves the P99.9 read latency of read-intensive workloads (YCSB B and C) and also the read-modify-write one (YCSB F) by 79.1%, 80.3%, and 76.8%, respectively. The throughput improvement from global override is up to 10.9% for the write-most workload A in Figure 20.

## 5.4 Overhead analysis

**End-to-end read latency overhead.** Since eZNS serves as an orchestration layer between the physical ZNS device and the NVMe-over-Fabrics target, there may be some overhead when the I/O load is very low. To measure this overhead, we conducted a quantitative analysis using 4KB random read I/Os and compared it with host-managed zone access, where the host directly accesses the physical device without eZNS. Figure 21 demonstrates that eZNS does not add a noticeable latency overhead for I/O depths up to 8. As the I/O depth goes over 16, up to 14.0% overhead is observed due to the I/O scheduler delaying the I/O submission. However, the scheduler provides significant advantages in real-world scenarios as shown in previous experiments.

**Memory footprint.** eZNS relies on in-memory data structures for managing *v-zone* metadata, including the logical-to-physical mapping and scheduling statistics. Additionally, it maintains a copy of the physical zone information to reduce unnecessary queries to the device, enabling faster zone allocation and deallocation. In our current implementation, the size of *v-zone* metadata is less than 1KB, and the size of physical zone information is smaller than 64 bytes. For our testbed SSD with four namespaces, each with 1TB of capacity, *v-zone* metadata and physical zone information require 2MB and 2.5MB of memory, respectively. Compared to the memory requirements of the page-mapping in conventional SSDs, the memory usage of eZNS is negligible.

## 6 Related Work

**Early ZNS Exploration.** Researchers have made initial efforts to understand the ZNS interface and integrate it into the host storage stack. Theano Stavrinou *et al.* [44] argue for a shift in research to the zone interface and discuss future directions (e.g., applying application-level information for zone management and I/O scheduling). Hojin Shin *et al.* [42] develop a performance analysis tool for a ZNS SSD and profile its parallelism, isolation, and predictability properties. Compared with our study, they didn't investigate the underlying device's internal mechanisms when realizing the zoned namespace interface and, thereby, are unable to correlate the observed performance with the ZNS SSD characteristics. ZNS+ [16] enhances the existing interface with two

new architectural primitives to optimize LFS file systems. With such support, the authors then propose copy-back-aware block allocation and hybrid segment recycling techniques. Hanyeoreum Bae *et al.* [3] prioritize I/O requests for less congested zones using an interference map, whilst updates incur significant overheads. Although revising the ZNS interface and exposing the physical allocation of zones could potentially eliminate this overhead, it may not be feasible for existing devices due to vendors' resistance to disclosing internal architecture and policies. eZNS uses a delay to determine congestion and doesn't require an allocation map. Furthermore, eZNS addresses such as read and write differences, zone striping, and bandwidth provisioning issues that were not discussed in their work. Minwoo Im *et al.* [18] improved ZenFS on small-zone SSDs by introducing read/write parallelism with a multi-threaded I/O engine and lifetime-based zone management at the application level. However, it requires adjusting the RocksDB parameters to match the device capability instead of the workload-optimized parameters. This can increase the complexity of parameter configuration, resulting in sub-optimal settings for the workload. eZNS maximizes parallelism within the thin layer, regardless of the underlying device and the application profile. It exploits the device's parallel I/O processing capability that can be executed on a single thread.

**Addressing Inefficiencies of Conventional SSDs.** Early SSD researches [2, 11, 17, 31] focused on internal parallelism and tradeoffs between concurrency, locality, bandwidth, capacity, performance, and lifetime. Modern SSDs handle random write patterns with page mapping FTL, write-cache, and superbblock concepts [49] that group blocks together. It benefits from high parallelism that transforms writes into sequential NAND programming. However, multi-tenancy workloads cause interference and high write amplification factor (WAF). ZNS SSDs eliminate garbage collection and fix WAF to one, but require careful parallelism management across zones to avoid degraded device utilization. In addition, future QLC-based ZNS SSDs may have fewer active zones due to a multi-pass programming algorithm [21]. eZNS addresses these challenges by adjusting the parallelism of each logical zone based on the number of namespace flows, providing fully dynamic parallelism and maximizing device capability while presenting an identical logical view to applications.

IODA [26] is an I/O deterministic flash array that uses the I/O determinism feature and exploits data redundancy for a strong latency predictability contract. SSDs can fail an I/O to allow predictable I/Os through proactive data reconstruction. We target the ZNS SSD, where there are no random I/Os, and GCs are user-controlled. This opens up a different design space. Although techniques addressing GC-related interference are not beneficial to GC-free ZNS SSDs, others such as Engurance Group(EG) and NVM Set can be useful to ensure physically-isolated zone allocation. eZNS can take advantage of the geometry hints via EG (or even finer-grained NVM

Sets). Unfortunately, there is no currently-available SSD that supports both ZNS and EG, but it will be an interesting direction for future work.

**Open-Channel SSDs.** These drives have no mapping layer in the controller and directly expose a set of physically contiguous blocks to applications, and leave the data placement/wear-leveling responsibilities to the host. Researchers have built several domain-specific solutions using them. For example, SDF [30] employs a hardware-software co-designed approach that exposes flash channel details and delegates I/O control-plane and data-plane tasks to host applications. LOCS [48] further improves the throughput of an LSM-tree-based KV store by optimizing the scheduling and dispatching policies, considering the characteristics of access patterns of the LevelDB. RAIL [27] designs a horizontal hot-cold separation mechanism and divides dies into two groups, where user and GC writes are scheduled to different dies, and the hot/cold ratio is dynamically adjusted based on runtime monitoring. By having full control over the device, one can implement a deterministic *v-zone* using eZNS. Despite the potential architecture, it imposes too many responsibilities on the software handling tasks that are offloadable to the device with no cost, for example, wear-leveling, physical zone-to-die mapping, etc. Another challenge arises when the system consists of heterogeneous devices resulting in the overhead of managing different H/W architectures (NAND chip capacity, channel/die configuration, etc.).

**eZNS as a firmware.** One may implement eZNS solely in the SSD using the controller and firmware. This approach can exploit internal knowledge such as NAND specification, Channel/Die structure, queue length on a die, etc. Thus, it may control the interference better and outperform the software-based implementation. However, completing eZNS in one device is not future-proof, given the disaggregated systems architecture in data centers. The software-based solution can build an eZNS-based system spanning multiple devices enabling elastic capacity scaling, load-aware allocation, high availability, and more.

## 7 Conclusion

This paper presents an in-depth study on understanding the characteristics of a commodity ZNS SSD. Then, we propose eZNS, realizing an elastic zoned view via *v-zone*, providing a flexible zone scaling interface transparent to the application that maxes out the device capability, and ensuring a fair bandwidth share between zones. We demonstrate significant performance and fairness improvements using eZNS over various scenarios.

## Acknowledgments

We would like to thank the anonymous reviewers and our shepherd, Mark Silberstein. This work was supported in part by NSF grant CNS-2212193 and ACE, one of the seven centers in JUMP 2.0, a Semiconductor Research Corporation (SRC) program sponsored by DARPA.

# SEPH: Scalable, Efficient, and Predictable Hashing on Persistent Memory

Chao Wang, Junliang Hu, Tsun-Yu Yang, Yuhong Liang, and Ming-Chang Yang  
*The Chinese University of Hong Kong*

## Abstract

With the merits of high density, non-volatility, and DRAM-scale latency/bandwidth, persistent memory (PM) brings hope to high-performance storage systems, in which hashing-based index structures receive great attention owing to the efficient query performance. Though lots of efforts have been made to rethink the hashing schemes for PM in recent years, nevertheless, based on our investigation, none of them can hit performance scalability, efficiency, and predictability with one stone, seriously limiting their practicality to time-sensitive or latency-critical applications. To this end, this paper presents SEPH, a Scalable, Efficient, and Predictable Hashing for PM. SEPH paves a new direction to build the hash table by introducing the novel Level Segment (LS) structure, a key to breaking the dilemma between efficiency and predictability standing in front of the existing hashing schemes for PM. With the LS-based hash table structure, SEPH further enables a low-overhead split to greatly suppress the resizing-incurred unpredictability, and develops a semi lock-free concurrency control that requires a nearly-minimal amount of writes to handle an item insertion for achieving ever-higher efficiency and scalability while ensuring the correctness and crash consistency. Compared to state-of-the-art hashing schemes, SEPH demonstrates higher efficiency (up to 15.4× higher throughput), better scalability (performance scales up to 48 threads), and more reliable predictability (improving the tail latency by up to 19.3×).

## 1 Introduction

Persistent memory (PM) offers storage systems the potentials of large capacity, low latency, high throughput, and instant recovery [8, 48]. The first commercial product of PM, i.e., Intel® Optane™ DC Persistent Memory Module (DCPMM) [3], is currently available on the market. As shown in Table 1, compared with DRAM, Intel® Optane™ DCPMM delivers similar write latency yet has about 2× sequential read latency and 3× sequential read latency [20, 21, 45]; besides, the read and write bandwidths of Intel® Optane™ DCPMM achieve nearly 1/3

Table 1: Performance Comparison between DRAM and PM (i.e., Intel® Optane™ DCPMM 100 Series) [45].

	DRAM	PM	PM/DRAM
Latency of Seq. Read (ns)	81	169	208.64%
Latency of Ran. Read (ns)	101	305	301.98%
Latency of Write (ns)	57	62	108.77%
Bandwidth of Read (GB/s)	105.6	37.6	35.61%
Bandwidth of Write (GB/s)	76.8	12.5	16.28%

and 1/6 of those of DRAM [20, 21, 26]. When compared with SSD, Intel® Optane™ DCPMM is even much more superior in every of these performance metrics [45]. Together with the maximal 512 GB capacity for a single module, Intel® Optane™ DCPMM is especially attractive to in-memory applications [43, 45].

Index structure is a vital component for high-performance storage systems to offer efficient queries. To rapidly deploy the well-developed indexes on PM, RECIPE [26] presents a principled approach to convert concurrent DRAM indexes, including tree-based and hashing-based indexes, into crash-consistent indexes for PM. However, to better unleash the full potentials of PM, more researches focus on developing carefully-tailored indexes for PM. For example, a series of researches develops tree-based indexes for PM especially, like NV-tree [46], FAST&FAIR [19], wB+-Tree [9], LB+-Trees [31], WORT [25], BzTree [5], and ROART [35]. However, the search operation of tree-based indexes usually performs in the complexity of  $O(\log N)$ , where  $N$  is the size of data structure, because of the hierarchical structure of trees.

By contrast, hashing-based indexes can provide constant-scale query time complexity due to the flat structures, so they are widely adopted by in-memory systems [18, 23, 29, 47]. Hashing indexes can be generally categorized into two classes: *static* and *dynamic*. Static hashing must estimate and allocate sufficient space in advance, but it suffers from hash collisions, overflows or under-utilization since the size of the hash table is hard to estimate precisely in some applications like database systems and file systems [36–38, 40]. Dynamic hashing [24], on the other hand, features in dynamically adjusting the size

of the hash table as needed by the *resizing* operation. In view of this, many delicately-designed dynamic hashing schemes are proposed for PM to achieve different optimizations, like PFHT [12], Path Hashing [49], Level Hashing [50], CCEH [36], Dash [33], and Clevel Hashing [10]. This work also focuses on the dynamic hashing schemes for PM.

Thanks to all of these efforts, the existing dynamic hashing schemes especially developed for PM have made remarkable progress on improving the overall *performance efficiency* in terms of mean throughput or mean latency. Nevertheless, surprisingly less attention has been given to the *performance predictability*, a particularly important metric in situations where the high-percentile performance would largely affect the quality of service (QoS) or the end-user experience [27, 28, 34]. In view of this, we conduct intensive experiments on a 24-core/48-thread CPU socket with six 128 GB Intel® Optane™ DCPMM to examine the in-depth performance of PM hashing schemes by utilizing different number of concurrent threads (ranging from 1 to 48). Our results (presented in §2.2) disclose that the representative hashing schemes for PM might 1) encounter the dilemma of simultaneously maintaining high *performance efficiency* and alleviating the resizing-incurred *performance unpredictability*, and 2) fall short of exhibiting good *performance scalability* under highly-concurrent queries due to their excessive writes in handling insert operations. Both seriously limit the practicality of existing PM hashing schemes to time-sensitive or latency-critical applications.

Aiming at developing a more practicable dynamic hashing scheme on PM, this paper present SEPH, a Scalable, Efficient, and Predictable Hashing for PM, to hit “three birds” with one stone. First of all, to break the dilemma between efficiency and predictability, SEPH introduces a new structure called *level segment (LS)* to build the hash table with a unique and delicate indexing mechanism (i.e., *level segment index* and *sliding bucket index*). Particularly, with the LS-based hash table structure, SEPH mitigates the inefficiency in probing items randomly, and embraces the incremental resizing (i.e., the split operation) to prevent other concurrent threads from being blocked. Second, SEPH further enables a *low-overhead split* operation to significantly suppress the resizing-incurred performance unpredictability: It not only reduces the number of KV items to be rehashed to one-third of an LS (i.e., *one-third splitting*) but even avoids the pointer dereference required to rehash a KV item for most of the time (i.e., *dereference-free rehashing*). Third, to achieve ever-higher efficiency and scalability while ensuring the correctness and crash consistency, SEPH devises a *semi lock-free mechanism* that requires a “nearly-minimal” amount of writes to handle an insertion. Our results show that SEPH performs better than the state-of-the-art hashing schemes from three perspectives. First, for efficiency, SEPH averagely achieves 2.12× higher throughput than EH-based hashing schemes, and even deliver 15.4× higher average throughput than level-based hashing schemes. Second, in terms of scalability, as the number of threads in-

creases from 24 to 48, the performance of SEPH still scales up noticeably whereas the other hashing schemes barely improve. Third, SEPH provides more reliable predictability by achieving 11.4×~19.3× lower tail latency. SEPH is implemented in C++ and is available<sup>1</sup> for public use.

The rest of this paper is organized as follows. §2 presents the background and motivation regarding this work. Next, §3 introduces the design details of SEPH. Finally, §4 demonstrates the evaluations results and §5 concludes this work.

## 2 Background and Motivation

### 2.1 Hashing Schemes for Persistent Memory

Due to various *structural designs*, different hashing schemes typically have their own way to perform the *resizing operation*, an essential but expensive operation entailing extra reads and writes to enlarge the hash table for accommodating more key-value (KV) items. The existing hashing schemes, especially developed for PM, can be generally categorized into two series: 1) **Level-based hashing**, a series that features a *multi-level structure* to enable *cost-efficient resizing*, and 2) **EH-based hashing**, a series that inherits the advantage of *incremental resizing* from Extendible Hash (EH) [13].

Figure 1: Two Series of Hashing Schemes for PM.

#### 2.1.1 Level-based Hashing

**Level Hashing.** Since memory writes in PM typically consume more time and energy than memory reads, the extra writes entailed by the resizing operation might bring a negative impact on PM in terms of both performance and endurance. Because of this reason, Level Hashing [50] introduces a new *sharing-based two-level structure* to enable a *cost-efficient resizing operation* for PM.

As illustrated in Figure 1(a), Level Hashing organizes KV items into two levels (i.e., *top level* and *bottom level*) of Bucketized Cuckoo Hashing (BCH) [14] with every bottom-level bucket shared by two consecutive top-level buckets, and thus the total number of buckets in the bottom level is just a half of that in the top level. Just like the design of BCH, Level Hashing employs a pair of hash functions (denoted as H1 and H2 in Figure 1(a)) so that any KV item can be associated with two buckets (aka *candidate buckets* [50]) in each level and can be placed in any *slot* of the candidate buckets. But in

<sup>1</sup><https://github.com/cuhk-mass/SEPH>

Level Hashing, only the top-level buckets are addressable by hash functions while a bottom-level bucket is mainly served as standby slots to keep conflicting KV items. That is, if a hash collision occurs in a top-level bucket and all slots in that bucket are used, the conflicting KV item can be stored in its corresponding standby bucket in the bottom level.

When all possible candidate buckets are full, Level Hashing cost-efficiently resizes the hash table as follows. As illustrated in Figure 1(b), the hash table is firstly “expanded” by allocating a *new top level* that is twice the size of the original top level and is with all the contents cleared with zeroes (denoted as ①); then, all the KV items in the original bottom level are “rehashed” into the newly allocated top level (denoted as ②); finally, the newly allocated top level and the original top level form a new sharing-based two-level structure. That is, with the cost-efficient resizing operation, Level Hashing doubles the total size of hash table but only rehashes and migrates KV items in one-third of buckets of the original hash table.

**Clevel Hashing.** Although Level Hashing enables a cost-efficient resizing operation, it must lock the entire hash table structure and inevitably blocks the normal hash operations (e.g., insert and search operations) from concurrent threads. To address this issue, Clevel Hashing [10], a *crash-consistent and lock-free concurrent hash table* is developed based on Level Hashing. Specifically, to avoid blocking the concurrent accesses during the resizing operation, in Clevel Hashing, the thread that triggers the resizing operation only expands the hash table for completing the insertion of KV item in the newly allocated top level, while the remaining work of rehashing is postponed and offloaded to dedicated background thread(s). As a result, in Clevel Hashing, the hash table may consist of more than two levels when it is under resizing.

### 2.1.2 EH-based Hashing

Another series of PM hashing schemes is evolved from Extendible Hashing (EH) [13], a widely-adopted hashing scheme that features the incremental resizing operation, called *split operation*, to avoid the full-table rehashing. Particularly, EH organizes KV items in *buckets* of a fixed number of *slots*, where a *directory* is maintained to index buckets based on the hashed value of a key (hereafter called the *hashed key* for simplicity). When a bucket overflows, EH performs the split operation to resize the hash table in the granularity of bucket rather than the entire hash table.

**Cacheline-Conscious Extendible Hashing (CCEH).** On the basis of EH, CCEH [36] is developed to make effective use of cachelines for better performance while guaranteeing failure-atomicity for dynamic resizing. Specifically, CCEH proposes to set the bucket size to the size of a cacheline (e.g., 64-byte) for minimizing the number of cacheline accesses for visiting a bucket. Besides, as shown in Figure 1(b), CCEH introduces an intermediate granularity named *segment*, which consists of a fixed number of buckets indexed by the same directory

entry, so that the directory can be greatly shrunk to have a higher probability of being in the CPU cache. CCEH also introduces a new way to associate KV items with segments and buckets: The most significant bits of the hashed key are used to locate a segment (denoted as *segment index*) while the least significant bits are used to index a bucket within a segment (denoted as *bucket index*). To further increase the load factor, CCEH adopts linear probing [15] so that a KV item can also be placed in the next few (e.g., four) buckets following the indexed one (by the bucket index).

When all candidate buckets (i.e., the indexed bucket and the following few that can be linearly probed) are all full for a newly-inserted KV item, CCEH resizes its hash table via the split operation (i.e., an incremental resizing operation introduced by EH) as follows: First, as illustrated in Figure 1(b), a new empty segment is dynamically allocated. Second, KV items in the collided segment are either stayed or rehashed into the newly allocated segment according to their segment and bucket indexes. Finally, after all KV items are rehashed, the directory is updated to ensure that the newly allocated segment will be indexed properly by the corresponding directory entry.

**Dynamic and Scalable Hashing (Dash).** Dash [33] further introduces several advancements to two classical hashing schemes (i.e., Extendible Hashing (EH) [13] and Linear Hashing (LH) [30]) and showcases its effectiveness on real PM product (i.e., Intel Optane DCPMM [3]).

Dash for EH (Dash-EH) inherits most of designs from CCEH [36] but aligns the bucket size with the XPLine size (i.e., 256-byte) of Intel® Optane DCPMM for better locality [33]. Moreover, Dash-EH divides every bucket into a record region (224-byte) and a metadata region (32-byte), where the former maintains pointers to KV items for supporting variable-length keys and values while the latter is dedicated to optimizing the probing and load factor. On the one hand, for every KV item, Dash-EH keeps the second least significant byte of the hashed key as a *fingerprnt* in the metadata region, so that the number of pointer dereferences, required by probing or checking the uniqueness of a KV item, can be thereby reduced; besides, Dash-EH adopts an optimistic concurrency control to avoid locking the entire segment when searching a KV item. On the other hand, Dash-EH combines a variety of techniques to increase the load factor, such as probing one more bucket, balancing the load factor of candidate buckets, allowing one movement among the indexed and linearly-probed buckets, and adding a few (e.g., two or four) *stash buckets* into each segment to accommodate conflicting KV items.

## 2.2 Motivation

Though the existing studies have made remarkable progress on advancing the hashing schemes for PM, this section will disclose that the existing two series of hashing schemes might 1) encounter the dilemma of achieving both high *performance efficiency* and high *performance predictability* simultaneously

Figure 2: Real-time Throughput and Resizing Overhead under Mixed Workload (i.e., 50% Insertion and 50% Search).

(see §2.2.1) and 2) fall short of exhibiting good *performance scalability* under highly-concurrent queries (see §2.2.2). Both seriously limit the practicality of existing PM hashing schemes to time-sensitive or latency-critical applications.

### 2.2.1 Dilemma between Efficiency and Predictability

When examining the performance of PM hashing schemes, most of the existing studies mainly focus on the overall *performance efficiency* (i.e., the average performance) yet overlook the *performance predictability* (i.e., the high-percentile performance [27, 28, 34]), which is particularly crucial to time-sensitive or latency-critical applications in practice.

To investigate both performance efficiency and performance predictability of the existing two series of PM hashing schemes, we conduct intensive experiments on a 24-core/48-thread CPU socket with six 128 GB Intel® Optane™ DCPMM configured as the *App Direct* mode. More detailed experimental setups and implementation notes can be found in §4.1. Particularly, we preload each hashing scheme with 10 millions of KV items, and then measure the real-time performance of executing 200 millions of realistic mixed workloads with 48 concurrent threads, where the workloads consist of 50% search and 50% insert operations generated by YCSB [11] under the Zipf distribution with both key and value sizes set to 16B. Figure 2 shows the real-time throughput (in terms of operations per second) and the real-time resizing overhead (in terms of the number of rehashed KV items) of the four representative PM hashing schemes presented in §2.1. The results reveal that the existing PM hashing schemes might encounter the dilemma of achieving both high efficiency and high predictability simultaneously based on the following two key observations.

**Observation 1:** *Compared with Level-based hashing schemes, EH-based hashing schemes demonstrate the strength in performance efficiency yet entail heavier resizing-incurred overhead to degrade its performance predictability.*

It can be firstly observed from Figure 2 that EH-based hashing schemes demonstrate superior performance efficiency (i.e., at least 57.48% faster in terms of average throughput) than Level-based hashing schemes. The rationale behind this can be attributed to how these hash schemes probe the candidate buckets for a query. Specifically, EH-based hashing schemes probe the candidates buckets by sequential accesses, while Level-based hashing schemes entail one random access

for each of the candidate bucket (which is inherited from BCH [14]). Given that the latency of random read is about 1.8× longer than that of sequential read on PM (according to Table 1), it turns out that EH-based hashing schemes hold the advantage in performance efficiency.

Nevertheless, since EH-based hashing schemes naturally entail heavier resizing overhead (i.e., the number of rehashed KV items) than Level-based hashing schemes, their performance predictability can be affected more considerably. It can be clearly observed that the real-time throughput of EH-based hashing schemes gets degraded severely while KV items are being rehashed at that time; additionally, the more KV items are being rehashed, the lower throughput would suffer. Moreover, it is worth noting that, though Dash-EH utilizes a variety of techniques to postpone split operations for higher load factor, it may concentrate the occurrence of split operations as an adverse effect, leaving the performance predictability of Dash-EH unimproved or even degraded. As shown in Figures 2(c) and 2(d), when compared with CCEH, Dash-EH achieves 2.16X higher average throughput but suffers 5.78% lower worst throughput (i.e., the 100th percentile throughput).

**Observation 2:** *Compared with EH-based hashing schemes, Level-based hashing schemes entail lower resizing-incurred overhead yet still fail to deliver good performance predictability due to its low performance efficiency.*

As revealed by Figure 2, thanks to the cost-efficient resizing, Level-based hashing schemes greatly alleviate the total resizing overhead than EH-based hashing schemes. Cumulatively, Level-based hashing schemes incur at least 55.45% less number of rehashed KV items than EH-based hashing schemes after handling the same amount of insert operations. It is also worthy to note that, to avoid locking the entire hash table and blocking all the other concurrent requests during the resizing (as Level Hashing does), Clevel Hashing advocates a lock-free scheme and further postpones and offloads the rehashing of KV items to dedicated background thread(s), which explains why Clevel Hashing could incur even less number of rehashed KV items than Level Hashing in the evaluation.

However, unfortunately, the effective reduction in the resizing overhead is insufficient in helping Level-based hashing schemes with delivering good performance predictability. This is because Level-based hashing schemes suffer much worse performance efficiency, not only the average but also the worst ones, when compared with EH-based hashing schemes.

Specifically, even though the worst throughput (i.e., the 100th percentile throughput) of Clevel Hashing seems to drop less from its average throughput, it is still worse than that of CCEH and Dash-EH by 47.95% and 44.87% respectively.

### 2.2.2 Limited Scalability

Apart from the efficiency and predictability, the *performance scalability* is also an important indicator that reflects how efficient a hashing scheme is in processing concurrent requests. To this end, we repeat the experiments presented in Figure 2 with a different number of concurrent threads, ranging from 1 to 48, and show the measured average throughput of different hashing schemes in Figure 3.

**Observation 3:** *The existing PM hashing schemes fall short of exhibiting good performance scalability under highly-concurrent requests due to the excessive writes in handling insert operations.*

From Figure 3(a), it can be clearly observed that none of the evaluated hashing schemes could scale up the average throughput well from 24 concurrent threads. To find out the potential bottleneck to achieve good performance scalability, we further measure the total writes of PM media introduced by different hashing schemes (by reading the hardware counters of DCPMM [45]), since the write bandwidth is one of the major weaknesses of PM (according to Table 1). The results in Figure 3(b) identify that all the evaluated hashing schemes introduce more than twice amount of writes than expected (which was estimated by multiplying the number of insert operations by the XPLine size (i.e., 256-byte)), except the lock-free Clevel Hashing.

Figure 3: Scalability of Existing PM Hashing Schemes under Mixed Workload (i.e., 50% Insertion and 50% Search).

Based on our further investigation, such excessive amount of writes can be attributed to different root causes about how the PM hashing scheme handles an insertion. Specifically, for every insert operation, lock-based hashing schemes (such as Level Hashing, CCEH and Dash-EH) require one PM write to lock and insert the KV item, and another PM write for unlocking. As for a lock-free hashing scheme (like Clevel Hashing), it always requires one additional flush to persist its metadata, before every insertion, for the sake of crash consistency. In addition, it allows multiple threads to concurrently expand the hash table for the same level, but only one expansion would succeed eventually. This results in that the other failed expansions must waste PM writes to clear the memory space.

## 3 Design of SEPH

This section presents SEPH, a hashing on PM which can hit the *scalability*, *efficiency* and *predictability* with one stone. In this section, we first present a new structure called *level segment (LS)*, a key enabler to achieve both high efficiency and predictability, and elaborate on how SEPH builds a hash table based on LS (§3.1). Then, we show how LS can further enable a *low-overhead split* to greatly suppress the performance unpredictability caused by resizing (§3.2). Finally, we put forward a *semi lock-free concurrency control* that requires a *nearly-minimal* amount of writes to handle an insertion for achieving ever-higher efficiency and scalability while ensuring the correctness and crash consistency (§3.3).

### 3.1 Level Segment based Hash Table

To resolve the dilemma between efficiency and predictability disclosed by §2.2.1, SEPH introduces a new structure called *level segment (LS)* to build the hash table by combining the respective strengths of the existing two series of PM hashing. Specifically, as we are going to see in this section, LS learns from EH-based hashing to achieve better efficiency in two ways: 1) LS limits the number of buckets that need to be randomly read for a query; and 2) LS enables the incremental resizing (i.e., the split operation) to avoid the full-table rehashing. Moreover, as we will elaborate in §3.2, LS further enables a low-overhead split operation, which is inspired by the two-level structure of Level-based hashing, to greatly harness the performance unpredictability caused by resizing.

#### 3.1.1 Structure

**Physical Segment.** To ease the dynamic memory allocation of PM space, SEPH manages the PM space as fixed-sized units called *physical segment (PS)*, which can be regarded as a “segment” in the EH-based hashing. To be more specific, a PS in SEPH also comprises a fixed number (e.g.,  $2^B$ ) of *buckets*, each bucket also consists of a fixed number of *slots*, and each slot can also accommodate one KV item. Besides, as suggested by Dash [33], SEPH also aligns the bucket size with the XPLine size (i.e., 256-byte) of Intel<sup>®</sup> Optane<sup>™</sup> DCPMM for achieving better locality.

**Level Segment.** To combine the respective strengths of the existing two series of PM hashing, SEPH further organizes PSs into a two-level structure called *level segment (LS)*, which is also the granularity for splitting. As depicted in Figure 4, given one PS at lower level (e.g., PS 0) and two PSs at higher level (e.g., PS 1 and PS 2), SEPH organizes the “left half” of lower-level PS and one higher-level PS into a LS (e.g., LS 0 which is denoted by blue-shaded region) and organizes the “right half” of the lower-level PS and another higher-level PS into the second LS (e.g., LS 1 which is denoted by green-shaded region). Moreover, within an LS, every two physically-consecutive higher-level buckets share a lower-level bucket, but SEPH gives higher priority to the lower-level

buckets for accommodating newly inserted KV items than the higher-level buckets for the sake of concurrency control (see §3.3). That is, only if all slots in a lower-level bucket of an LS are fully occupied, will a new KV item be inserted into the higher-level bucket of that LS. In view of this, when querying a KV item in an LS, SEPH also searches the lower-level candidate bucket before searching the higher-level candidate bucket for better search efficiency.

Figure 4: Level Segment based Hash Table of SEPH.

**Upward Splitting.** When the lower-level and higher-level candidate buckets are both full to a new KV item, SEPH *splits* that LS into two to enlarge the hash table in a copy-on-write (CoW) fashion (i.e., by rehashing existing KV items into newly allocated PSs). However, unlike the EH-based hashing splits horizontally, SEPH splits an LS in an “upward” and “low-overhead” fashion (see §3.2 for details). Consequently, as SEPH keeps splitting LSs to accommodate more KV items, the overall hash table will grow upwardly, since some LSs are evolved from more times of upward splitting and thereby reach higher levels than other LSs.

**Residing Level.** To precisely maintain *which level a PS currently resides*, SEPH associates every PS with an attribute called *residing level (RL)*. Taking the blue-shaded LS 0 depicted in Figure 4 as an example, the *RLs* of its higher-level PS and lower-level PS are 1 and 0, respectively.

### 3.1.2 Indexing

**Level Segment Index.** Like the EH-based hashing, SEPH also maintains a *directory* and utilizes the most significant bits to index an LS. Specifically, if the current highest residing level among all PSs is  $RL_{highest}$ , there must be  $2^{RL_{highest}}$  entries in the directory, and SEPH utilizes the first  $RL_{highest}$  most significant bits of the hashed key as the *level segment index*. Consider the example illustrated in Figure 4 where the current highest residing level  $RL_{highest}$  is 1. SEPH will associate the given KV item, whose hashed key starts with “01010”, with the LS indexed by the first directory entry (since the most significant bit in the hashed key is “0”).

**Sliding Bucket Index.** However, to facilitate the low-overhead split (introduced in §3.2), unlike the EH-based hashing that utilizes the least significant bits to index a bucket, SEPH introduces a unique *sliding bucket indexing* to index the candidate bucket in a PS for a KV item. Specifically, suppose  $RL$  denotes the *residing level* of a PS comprising  $2^B$  buckets,

SEPH uses the  $RL^{th}$  to  $(RL + B - 1)^{th}$  of the most significant bits in the hashed key (denoted as  $HashedKey[RL : RL + B - 1]$ ) to locate the candidate bucket according to the residing level  $RL$  of the PS.

Following the rule, SEPH can easily locate two candidate buckets (one in the lower-level PS and the other in the higher-level PS) in an LS for any KV item. As the example shown in Figure 4 where  $B$  is 3, given a hashed key starting with “01010”, the candidate bucket at lower level PS (e.g., PS 0 at Level 0) is the third one (e.g., Buckets  $(010)_2$ ) since  $HashedKey[0 : 2]$  is “010”, and the candidate bucket at higher level PS (i.e., PS 1 at Level 1) is the sixth one (i.e., Buckets  $(101)_2$ ) since  $HashedKey[1 : 3]$  is “101”.

## 3.2 Low-Overhead Split

To suppress the resizing-incurred performance unpredictability, SEPH proposes a *low-overhead split* operation, which not only reduces the number of KV items to be rehashed to one-third of an LS (i.e., *one-third splitting* in §3.2.1) but even avoids the pointer dereference required to rehash a KV item for most of the time (i.e., *dereference-free rehashing* in §3.2.2).

### 3.2.1 One-Third Splitting

With the novel Level Segment (LS) based hash table structure and the unique indexing mechanism (presented in §3.1), SEPH enables the *one-third splitting*, which only needs to rehash “one-third” of the KV items upon splitting an LS (i.e., the victim LS) into two new LSs as follows: ❶ Two new PSs are allocated at one level higher than the higher-level PS of the victim LS to address the hash collision; ❷ Only the KV items in the lower-level buckets (i.e., one-third) of the victim LS are rehashed into the two newly allocated PSs but the two newly allocated PSs and the KV items stayed in the original higher-level PS of the victim LS amazingly form two new LSs at one level higher, thanks to the unique level segment and sliding bucket indexes presented in §3.1; ❸ The corresponding directory entries are updated accordingly to point to the two newly formed LSs; ❹ The PM space occupied by the lower-level buckets of the victim LS is safely released.

Figure 5 depicts an example that walks through the whole process of the one-third splitting, where each PS is of 8 buckets (i.e.,  $B$  equals 3). Suppose we are going to insert a new KV item with the hashed key starting with “00011” into LS 0, but the two candidate buckets (i.e., Bucket  $(000)_2$  of PS 0 and Bucket  $(001)_2$  of PS 1) are both full. To address such hash collision, SEPH splits LS 0 by rehashing only its lower-level buckets into the two newly allocated PSs (i.e., PS 3 and PS 4) at Level 2. That is, with the unique level segment index and sliding bucket index, the KV items in Buckets  $(000)_2$  and  $(001)_2$  of PS 0 are rehashed into the newly allocated PS 3 while the KV items in Buckets  $(010)_2$  and  $(011)_2$  of PS 0 are rehashed into the newly allocated PS 4; however, there is no need to rehash any KV items in PS 1 since the two newly

allocated PSs (i.e., PS 3 and PS 4), along with the existing PS 1, amazingly form two new LSs (i.e., LS 2 and LS 3). At last, the directory entries are accordingly modified to index two newly formed LSs, and the “to-be-inserted KV item” can be eventually inserted into Bucket (011)<sub>2</sub> of PS 3 of the newly formed LS 2.

Figure 5: An Illustrative Example of One-Third Splitting.

### 3.2.2 Dereference-Free Rehashing

To support variable-length keys and values, like many representative PM hashing schemes (e.g., Clevel Hashing and Dash), SEPH keeps the pointers to KV items in slots of buckets. Consequently, to rehash a KV item (during the resize/split operation), typically, the pointer needs to be first *dereferenced* and a subsequent memory read is needed to get the content of a KV item, resulting in a considerable amount of random reads to degrade the performance on PM. In view of this, SEPH further enables the *dereference-free rehashing* that circumvents the pointer dereferences required to rehash KV items for minimizing the overhead of one-third splitting.

**Key Insight.** The main purpose of dereferencing a pointer during resizing is to locate the new candidate bucket a KV item based on the re-calculated hashed key. It means that if the new candidate bucket can be known by some means, a KV item can be directly moved into the new candidate bucket without dereferencing the pointer. Thanks to its unique sliding bucket indexing, SEPH can simply infer the new candidate bucket *if the two subsequent bits, following the current sliding bucket index of the hashed key, can be known*. This is because, during the one-third splitting, the KV items are always rehashed from the lower-level buckets of the victim LS into a newly allocated PS, which locates at two-level higher. To be more specific, for any KV items stored in the lower-level buckets of the victim LS residing at Level  $RL$ , its current sliding bucket index equals  $HashedKey[RL : RL + B - 1]$ ; since this KV item will be rehashed into a new PS located at two-level higher (i.e., Level  $RL + 2$ ), its new sliding bucket index will become  $HashedKey[RL + 2 : RL + B + 1]$ . In other words, SEPH can infer the new candidate bucket for this KV item by only requiring two extra bits, i.e., the  $(RL + B)^{th}$  and  $(RL + B + 1)^{th}$  bits in its hashed key.

**Bucket Index Foreseer.** Based on this key insight, SEPH proposes to maintain a small chunk of the hashed key, called

*bucket index foreseer* (or *foreseer* for simplicity), which contains the required “two bits” for dereference-free rehashing, along with the pointer to that KV item in the slot. In our implementation, the size of the foreseer is set to 16 bits since the modern 64-bit operating systems typically use 48 or fewer bits of pointers. As shown in Figure 6, when inserting a new KV item into a PS of  $2^5$  buckets residing at Level 0, SEPH keeps not only the pointer to this KV item but also the first two bytes of the hashed key (i.e., “00101010 10101101”) as the foreseer in the 64-bit slot. Later, when this KV item needs to be rehashed into a newly allocated PS at Level 2, since the 6<sup>th</sup> and 7<sup>th</sup> bits of the hashed key (i.e., “01”) are maintained in the foreseer, SEPH can directly move this KV item into Bucket (10101)<sub>2</sub> in the new PS without dereferencing the pointer (denoted by ❶ in Figure 6).

Figure 6: An Running Example of Bucket Index Foreseer.

Nevertheless, with the growth of the hash table, the foreseer might contain fewer and fewer “unused” bits and eventually “fail to foresee” the new sliding bucket index during the subsequent split operations. Thus, SEPH proposes to keep the number of unused bits in the foreseer more than half (i.e., 8 bits) at most times by updating the foreseer in the background (denoted by ❷ in Figure 6). To this end, SEPH maintains another bit called *stale flag* in the slot to indicate the staleness of the foreseer. If the unused bits of the foreseer will be less than half of its size after a dereferente-free rehashing, SEPH sets the stale flag to 1 and submits a job to a dedicated thread, which can update the foreseer and reset the stale flag, via an atomic operation without consistency issue, in the background. Notably, if all the unused bits in a foreseer have really been used up without being timely updated, SEPH alternatively updates the foreseer right away in the foreground before rehashing the KV item.

It is also worth mentioning that the foreseer can also be utilized as the “tag” in Clevel Hashing [10] or “fingerprint” in Dash [33] to avoid unnecessary dereferences of pointers during bucket probing. This is because the foreseer will get updated timely to contain bits, which are neither LS nor sliding bucket indexes, so that it is particularly effective in telling whether a KV item exists in a bucket.

### 3.3 Semi Lock-Free Concurrency Control

As discussed in §2.2.2, the existing PM hashing schemes introduce an excessive amount of writes to handle an insertion. This not only brings considerable degradation to efficiency, but even largely limits the scalability especially under highly-concurrent and insert-intensive scenarios. To

achieve ever-higher efficiency and scalability, SEPH proposes a *semi lock-free concurrency control* that requires a nearly-minimal amount of writes to handle an insertion. §3.3.1 and §3.3.2 shall first introduce the design concept and the correctness challenges of the semi lock-free concurrency control, respectively. Then, §3.3.3 elaborates on how to conduct different hash operations while guaranteeing the correctness and crash consistency in depth.

### 3.3.1 Design Concept

Thanks to its atomicity, the compare-and-swap (CAS) primitive [4] has been widely adopted by many existing lock-free data structure and algorithm designs to allow concurrent operations without explicitly managing locks [22, 32, 39, 41]. The CAS primitive “compares” the stored content of a word in memory with a given value and, only if they match, “swaps” the content of that word with the given value; meanwhile, a Boolean value is returned to indicate whether the swap takes place or not. Notably, the execution of the CAS primitive is guaranteed to be atomic in the sense that the content of the memory word is either completely swapped or stays unchanged in an “all-or-nothing” fashion. Since SEPH sets the slot size to the word size (e.g., 8 bytes) (see §3.2.2), we can also leverage the CAS primitive to realize lock-free operations for the avoidance of excessive amounts of writes to PM due to the lock manipulation. However, in view of the fact that the split operation occurs relatively infrequent but could complicate the correctness guarantee of other frequent hash operations (i.e., insert/update/delete/search operations) [10], we propose to prudently apply the lock only to the split operation. That is, SEPH puts forward a *semi lock-free concurrency control* in which only the (infrequent) split operation needs to acquire the lock for splitting an LS, while other (frequent) hash operations (i.e., insert/update/delete/search operations) are all lock-free even when the involved LSs are under splitting.

### 3.3.2 Correctness Challenges

Guaranteeing the correctness of concurrent executions is one of the most critical challenges when designing lock-free data structures or algorithms. However, even though the CAS primitive can guarantee the atomicity of manipulating a slot, according to [10], performing hash operations in a lock-free manner may still lead to two correctness problems, i.e., *duplicate items* and *loss of items*.

**1) Duplicate Items.** The correctness problem of *duplicate items* is that concurrent lock-free insertions may place multiple KV items with the same key into different slots of the hash table. This may violate the correctness of subsequent update/delete/search operations, since the update or delete operation may only take place in one slot while the search operation may access other duplicate slots that are unmodified.

**2) Loss of Items.** The correctness problem of *loss of items* is that the modifications to the hash table (made by insert/update/delete operations) may be lost when the hash

table is under resizing concurrently. This is possible since the concurrent modifications may be left behind (i.e., not rehashed) by the resizing, making those non-rehashed modifications “invisible” to the subsequent operations incorrectly.

### 3.3.3 Operation Details

**Lock-Free Insert.** In SEPH, the insertion operation is designed to be *lock-free* for the avoidance of the concurrency control overhead in manipulating locks. In order to address the correctness problem of *duplicate items* (see §3.3.2) caused by concurrent insertions, SEPH regulates the order of empty slot allocation in the two candidate buckets to accommodate newly inserted KV items based on the following two rules of thumb: 1) The slots in the lower-level candidate bucket must be first used up before using the slots in the high-level candidate bucket. 2) In a candidate bucket, the slots must always be allocated from the first one to the last one, where no empty slots can exist before any allocated slots and no deleted slots can be re-allocated. In summary, together with the two rules and the atomicity of CAS primitive, SEPH guarantees that concurrent insertions to the same LS will always compete for not only the same candidate bucket (rule 1) but also for the same empty slot in that bucket (rule 2) so that the correctness problem of duplicate items can be nicely avoided.

Algorithm 1 elaborates the lock-free insert operation in detail. First, it looks up the directory to find out the corresponding LS for the to-be-inserted KV item (Line 2) and performs a uniqueness check to ensure that in the two candidate buckets of that LS, there are no existing KV items holding the same key as the to-be-inserted KV item (Lines 3–9). Specifically, the uniqueness check employs the atomic load instruction [2, 10, 17] to atomically fetch every allocated slot one after the other for examination (Line 5) and rejects an insertion request if its key matches the key of any allocated slots in the LS (Lines 8–9). Please note that the atomic instructions will not always lead to direct accesses to PM, since these requests can also be served in the cache [2].

Then, it starts to compete for the empty slot in the two candidate buckets based on our rules for the empty slot allocation (Lines 10–21). That is, the lower-level bucket is used before using the high-level bucket (rule 1) and the slots in a bucket are allocated from the first one to the last one (rule 2), so that all the concurrent insertions to the same LS will be regulated to always compete for the same empty slot. Especially, the CAS primitive is utilized to atomically check a slot is empty (by *comparing* the content of slot with an “empty” value) and fill in the slot (by *swapping* the content of slot with the pointer to the to-be-inserted KV item) (Line 12). Thanks to the atomicity of CAS primitive, even if there are concurrent insertions competing for the same empty slot, only one thread can successfully fill in it; then, the only “CAS-succeeded” thread utilizes the `c1wb` [2] and `mfence` instructions [2] to persist the filled slot into PM [7, 10, 33, 36] (Lines 13–15). Meanwhile, all the other “CAS-failed” concurrent threads must check every slot they failed to fill in, since those slot(s)

---

**Algorithm 1: LOCK-FREE INSERT**

---

**Input:** *kv*: the pointer to the to-be-inserted KV item  
**Output:** the result of insertion (*SUCCESS* or *FAIL*)

```
1  RETRY;  
2  Look up the directory to find out the LS for kv;  
   // uniqueness check  
3  for bucket in [LS -> PSlower, LS -> PShigher] do  
4    foreach slot in bucket do  
5      slot' ← ATOMIC LOAD(slot);  
6      if slot' has a set split mark then  
7        goto RETRY;  
8      if kv and slot' have the same key then  
9        return FAIL;  
   // CAS insert  
10 for bucket in [LS -> PSlower, LS -> PShigher] do  
11  foreach slot in bucket do  
12    resultCAS ← CAS(&slot, empty, kv);  
13    if resultCAS is successful then  
14      Persist slot into PM;  
15      return SUCCESS;  
16    else  
17      slot' ← ATOMIC LOAD(slot);  
18      if slot' has a set split mark then  
19        goto RETRY;  
20      if kv and slot' have the same key then  
21        return FAIL;  
   // split (both cand. buckets are full)  
22 Perform LOCK-BASED ONE-THIRD SPLIT() to split LS;  
23 goto RETRY;
```

---

may be inserted with KV items with the same key (Lines 16–21). If so, the insertion must be rejected to avoid duplicate items (Lines 20–21); otherwise, the CAS-failed thread(s) will continue to compete for the next empty slot iteratively.

Finally, if all the slots in the two candidate buckets are used up, the thread needs to trigger the one-third split operation (see Algorithm 2) to split the *LS* (Line 22), followed by retrying the insertion in a lock-free way (Line 23).

**Lock-Based One-Third Split.** In SEPH, the one-third split operation is *lock-based*. That is, an *LS* could only be split by one of the concurrent threads successfully. Even so, SEPH may still be threatened by the correctness problem of *loss of items* introduced in §3.3.2. Particularly, as the one-third split operation is rehashing the KV items from the lower-level PS of an *LS* into newly allocated PSs, some other concurrent lock-free /deletion operations may be making changes to that lower-level PS (since their lower-level candidate buckets are still not full), leaving some of these modifications not rehashed correctly. To resolve this correctness problem, SEPH devises a lightweight mechanism that allows a split operation to timely notify other concurrent lock-free operations of the rehashing status of every slot. Specifically, SEPH reserves a one-bit “split mark” in every slot, and the split mark will only be set atomically once the split operation has started to process it. It ensures that other concurrent lock-free operations can avoid

---

**Algorithm 2: LOCK-BASED ONE-THIRD SPLIT**

---

**Input:** *LS*: the *LS* that needs to be split

```
1  if TRY ACQUIRE LOCK(LS) == SUCCESS then  
2    Allocate two new PSs for one-third splitting;  
3    foreach bucket in LS -> PSlower do  
4      foreach slot in bucket do  
5        do // CAS Loop  
6          slot' ← ATOMIC LOAD(slot);  
7          slot'm ← slot' | split mark;  
8          resultCAS ← CAS(&slot, slot', slot'm);  
9          while resultCAS is not successful;  
10         if slot is not an empty or deleted slot then  
11           Perform DEREFERENCE-FREE REHASH() to  
             rehash slot into the two new PSs;  
12         Persist the two new PSs into PM;  
13         Form two new LSs and update the directory;
```

---

making changes to slots with a set split mark for the avoidance of loss of items, since the “compare” of CAS primitive will fail due to the set split mark bit.

As shown in Algorithm 2, the one-third split operation in SEPH needs to first acquire the lock for splitting any *LS* (Line 1), and only the thread successfully acquired the lock can rehash KV items from the lower-level PS of the to-be-split *LS* to the two newly allocated PSs (Lines 2–13). Especially, for every slot (including empty slots), the split operation shall first exploit the CAS loop [17] to ensure the split mark can be successfully set even in the presence of the concurrent operations (Lines 5–9). Then, the *dereference-free rehashing* (see §3.2.2) is employed to rehash the KV item if it exists (Lines 10–11). Finally, only after all the slots have been set with the split mark and all the KV items have been successfully rehashed and persisted into PM (Lines 12), should the directory entry be updated to index the two newly formed *LS*s (Line 13). It is the key step to ensure that no other concurrent operations can access the slots in the two newly allocated PSs when the splitting is still taking place. Notably, there is no need to release the split lock after splitting, because the split *LS* would become stale and any other concurrent threads should not split it again. Besides, we adapt the epoch-based reclamation [16] to recycle the stale PS only after no other concurrent lock-free readers are using it [33].

With the split marks, the problem of loss of items can be avoided as follows. Particularly, if the insertion ends with a CAS success, it implies that the concurrent split operation has not yet set the split mark for that slot and will rehash the inserted KV item later. Otherwise, if the insertion ends with a CAS failure because of a set split mark, it means that a concurrent split operation has already started to process this slot by first setting the split mark with the atomic CAS primitive (i.e., Line 8 in Algorithm 2). Thus, SEPH shall retry the entire insert operation to avoid leaving an insertion of KV item behind the concurrent split operation (i.e., Lines 18–19 in Algorithm 1). It is also worthy to note that during the uniqueness check, if a slot with a set split mark is found,

SEPH shall also retry the entire insert operation to avoid accessing stale KV items (i.e., Lines 6–7 in Algorithm 1); in addition, both two candidate buckets shall be examined, since the higher-level candidate bucket may have become the lower-level candidate bucket due to concurrent splits.

Notably, the problem of duplicate items can also be avoided even if an insertion ends with a CAS success but has time overlap with a split operation to the same LS. Let's first discuss the situation that the insertion can successfully fill in a slot in the "lower-level" candidate bucket of the LS. In this scenario, the split operation must be not over yet (since the split mark of this slot has not been set) and all the other concurrent insertions with the same key must fail to compete for the same slot in the same lower-level candidate bucket (thanks to the atomicity of CAS primitive). Next, let's discuss the other situation where the insertion can successfully fill in a slot in the "higher-level" candidate bucket (denoted as  $b$ ) of the LS (i.e., the corresponding lower-level candidate bucket is already full). In this scenario, the split operation may still be in the process or may have been completed by the time that slot is filled in. Specifically, if the split operation is not over yet, all the other concurrent insertions with the same key must compete in the same higher-level candidate bucket  $b$  but fail eventually. If the split operation is complete already, all the other concurrent same-key insertions launched before the split completion must compete in the same high-level candidate bucket  $b$  but fail eventually; meanwhile, since the higher-level candidate bucket  $b$  has become the lower-level candidate bucket in the new LS after the split completion (see §3.2.1), all the other concurrent same-key insertions with the same key launched after the split completion shall first compete in the same candidate bucket  $b$  (based on the rule 1 of empty slot allocation) but fail eventually.

**Lock-Free Update/Delete.** With the help of CAS primitive, in SEPH, the update and delete operations are also designed to be *lock-free*. To locate the KV item for update or deletion in the candidate buckets, the atomic load instruction is utilized (similar to how the uniqueness check is performed in the lock-free insertion). Then, if the slot with the desired key can be found, SEPH takes advantage of the atomicity of the CAS primitive to update the slot so that only one current thread can successfully modify it at a time. However, if the CAS primitive fails due to a set split mark in the slot, SEPH shall retry the entire update/delete operation to avoid leaving modifications to slots that have been processed by a concurrent split operation for the avoidance of loss of items.

On the other hand, based on the rules of thumb for empty slot allocation, no empty slots can exist before any allocated slots and no deleted slots can be re-allocated. Thus, in SEPH, the delete operation is realized in a way very similar to the update operation. The only difference is that the deletion replaces the desired slot with a "tombstone" instead of the updated KV item. In our implementation, we consider a slot that has all 1s for its pointer to KV item as a tombstone slot.

By doing so, a tombstone slot can be easily identified and more importantly, we can still exploit the split mark and the CAS primitive to avoid losing deletions in slots that have been processed by a concurrent split operation (as how we avoid losing updates).

**Lock-Free Search.** Since SEPH takes advantage of the atomicity of CAS primitive to modify a slot and utilizes the atomic load instruction to atomically read a slot, the search operation can be easily realized as *lock-free*. However, to avoid reading stale KV items, SEPH shall retry the search operation if any slot with split mark is accessed (as what we do in the uniqueness check of insertion).

### 3.3.4 Persistence for CAS

The compare-and-swap (CAS) atomic instruction [4] achieves the synchronization in multithreading; however, since the processor cache is typically volatile, a thread might access data that have not been persisted yet, resulting in data inconsistency in the presence of crashes. In our current implementation of SEPH, we utilize the *persistent single-word compare-and-swap (PSwCAS)* [42] primitive that can address this problem by adding a dirty bit on each 8-byte word operated by the CAS instruction. Specifically, the PSwCAS primitive requires that 1) the CAS instruction always stores a word of data with the dirty bit set; and 2) a thread must first persist the required word into PM if the word is set with the dirty bit, followed by clearing the dirty bit to mark the word as persistent.

Notably, the extended asynchronous DRAM refresh (eADR), a new feature supported by Intel<sup>®</sup> Optane<sup>™</sup> DCPMM 200 series and 3rd Xeon<sup>®</sup> Scalable processors, ensures that CPU caches are also included in the power fail protected domain [44]. That is, with the eADR technique, the CAS primitive can be used directly with the data consistency guarantee even in the presence of crashes [1]. Thus, we envision that SEPH shall be greatly benefited by the eADR feature to deliver even superior performance.

### 3.3.5 Crash Consistency

No inconsistency will occur in SEPH against crashes for the following reasons: 1) The insertion/update/deletion can be done atomically and their crash consistency can be guaranteed by the PSwCAS. 2) The split operation is protected by the lock and is conducted in a copy-on-write (CoW) manner, so the split operation is an all-or-nothing process; moreover, an unfinished split operation (which is broke off by the occurrence of crash) can also be identified (by examining the split locks of LS) and correctly redone. 3) The crash consistency for the directory can be secured by the directory recovery algorithm proposed in CCEH [36].

## 4 Performance Evaluation

### 4.1 Experimental setup

**Environment.** All experiments are conducted on a 24-core/48-thread Intel Xeon Platinum 8260 2.40 GHz CPU socket with

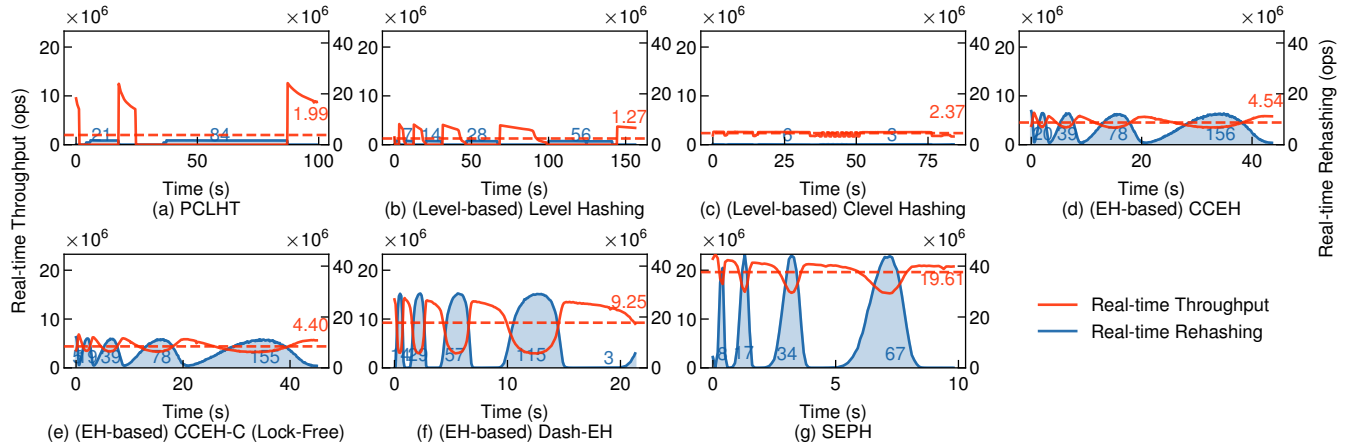

Figure 7: Real-time Throughput and Resizing Overhead of Insertion.

six 32 GB DRAM and six 128 GB Intel<sup>®</sup> Optane<sup>™</sup> DCPMM 100 series configured as the *App Direct* mode. The operating system is 64-bit Ubuntu Server 22.04 with Linux kernel version 5.15, and Persistent Memory Development Kit (PMDK) version is 1.11. All the codes are implemented in C++ and compiled using GCC 11.2 with all optimizations enabled.

**Evaluated Hashing Schemes.** We evaluate the following hashing schemes especially developed for PM, and adopt parameter settings suggested by their original papers for achieving the best performance on Intel<sup>®</sup> Optane<sup>™</sup> DCPMM 100 series.

- **PCLHT:** PCLHT is a search-optimized hashing scheme adopting a linked list based cache-efficient hash table converted by RECIPE [26].
- **Level1:** Level Hashing [50] is the origin of Level-based hashing schemes (see §2.1.1). It uses 128-byte buckets (i.e., two cachelines).
- **Clevel1:** Clevel Hashing [10] is an extension of Level Hashing with lock-free concurrency control (see §2.1.1). It uses 64-byte buckets (i.e., one cacheline) and employs one dedicated background thread to perform the resizing.
- **CCEH/CCEH-C:** CCEH [36] is developed based on Extendible Hashing (EH) [13] with effective use of cachelines for better performance (see §2.1.2). It uses 16 KB segments and 64-byte buckets (i.e., one cacheline) with a probing distance of 4. CCEH-C is a variant of CCEH that conducts the split operation in a CoW way to support lock-free search [36].
- **Dash:** Dash-EH [33] is an enhanced version of CCEH [36] with several technique advancements (see §2.1.2). It uses 16 KB segments and 256-byte buckets (i.e., an XPLine) with two additional stash buckets.
- **SEPH:** This is our proposed hashing scheme. To compress two PS pointers into one 8-byte word, we implement a segment allocator that supports atomic aligned segment allocation and crash consistency for SEPH. Besides, we set the size of a PS to 16 KB (which is also the segment size of CCEH and Dash used in the evaluation), and thus, the total size of an LS is 24 KB. Moreover, SEPH employs one dedicated background thread to update the bucket index foreseer.

For the sake of fairness, since the more recent PM hashing schemes (e.g., Clevel Hashing, Dash, and our proposal) support variable-length keys and values, all the evaluated hashing schemes are unified to only keep the pointers to KV items in slots. Besides, the length of a persistent pointer in PMDK is 16 bytes (i.e., 8 bytes for the base address of a PM pool and 8 bytes for the offset in pool), which cannot be operated by the CAS atomic instruction. To resolve this issue, Clevel Hashing [10] proposes to only maintain the offset in the PM pool as an 8-byte persistent pointer, since the base address of a PM pool will be fixed once the pool is mapped. We also apply this offset-only pointer to all the evaluated hashing schemes.

**Benchmark.** For the micro-benchmarks used in §4.2, we first warm up the hash table with 10 millions of KV items, followed by executing a total number of 200 millions of operations unless otherwise stated. Particularly, workloads composed of a single type of operations are evaluated in §4.2.1~§4.2.3 and workloads mixed with multiple types of operations are used in §4.2.4, where all these workloads are generated by YCSB [11] in Zipf distribution with 0.99 skewness. As for the macro-benchmarks presented in §4.3, we use the real-world workloads from YCSB [11]. Particularly, in the load phase, we populate 64 millions of KV items, following Clevel Hashing [10]; then, the standard YCSB workloads A, B, C, D, and F are conducted with 48 threads. Notably, the standard YCSB workload E is not evaluated since none of the hashing schemes optimizes the range query performance. Besides, the lengths of key and value are both set to 16 bytes since it is widely used [6], and the KV items are pre-generated before the testing as [33].

## 4.2 Micro Benchmark

### 4.2.1 Performance Efficiency and Predictability

To analyze the advantages of SEPH, we first focus on the insertion performance. Figure 7 plots the real-time insertion throughput of different hash tables under 48 threads. It can be clearly observed that SEPH outperforms all the other schemes

in terms of performance efficiency. Specifically, SEPH outperforms Dash, CCEH, and CCEH-C by 2.12 $\times$ , 4.31 $\times$ , and 4.46 $\times$  for average insertion throughput respectively, and achieves at least 8.27 $\times$  higher average throughput compared with Level-based hashing schemes and PCLHT.

As for the performance predictability, SEPH demonstrates the most superior worst-case real-time throughput (i.e., the minimal real-time throughput) than all the other evaluated hashing schemes, as revealed by Figure 7. Specifically, the minimal real-time throughput of SEPH is higher than that of Clevel, CCEH, CCEH-C, and Dash by 9.34 $\times$ , 4.40 $\times$ , 4.74 $\times$  and 5.23 $\times$  respectively, while PCLHT and Level Hashing even suffer zero real-time throughput because their full-table resizing are conducted in a blocking manner. Moreover, it is also worth noting that the minimal real-time throughput of SEPH is even higher than the maximal real-time throughput of all the other evaluated hashing schemes by from 1.06 $\times$  to 5.76 $\times$ . This reveals that SEPH achieves remarkable performance predictability by delivering an excellent worst-case real-time throughput under the insertion-intensive workload.

The tail latency of different percentiles is another perspective to show the performance by reflecting the response time. A design with good performance predictability requires a low bound of the latency on high percentiles (i.e., tail latency). Figure 8 shows the evaluation of the insertion latency at different percentiles. In general, SEPH significantly cuts down the 100th-percentile insertion latency compared with PCLHT/Level-based hashing schemes (by 3 ~ 4 orders of magnitude) and is superior to all the EH-based hashing schemes on every percentile of insertion latency. Especially, it can be noticed that in contrast to EH-based hashing schemes (i.e., CCEH, CCEH-C and Dash) that have a sharp raising of insertion latency at the 99.9th percentile, the insertion latency of SEPH rises at the 99.99th percentile. The rationale behind this is that SEPH triggers a less number of split operations than EH-based hashing schemes, since the size of LS in SEPH (i.e., 24 KB) is larger than the segment size (i.e., 16 KB) of EH-based hashing schemes. Despite this, SEPH still achieves 9.75 $\times$  ~ 11.36 $\times$  lower latency at both 99.99th and 99.999th percentiles than EH-based hashing schemes; Also, the 100th-percentile latency of SEPH is lower than that of EH-based hashing schemes by from 3.62 $\times$  to 5.86 $\times$  because SEPH offloads the directory doubling to the background thread.

Figure 8: Latency at Different Percentiles.

Figures 9(a) and 9(b) further disclose the key reasons behind the improvements in performance efficiency and predictability

achieved by SEPH. On the one hand, thanks to the one-third splitting and the dereference-free rehasing, SEPH introduces 8.11 ~ 43.78 $\times$  less time for resizing than all the other evaluated hashing schemes as shown in Figure 9(a). On the other hand, Figure 9(b) validates the efficacy of the semi-lock-free concurrency control in minimizing the PM writes. Specifically, SEPH significantly reduces the PM writes by 2 ~ 3.33 $\times$  and nearly approaches the expected, optimal amount of PM writes.

Figure 9: Resizing Time, Total Bytes Written, and Load Factor.

**Load Factor.** Figure 9(c) further depicts the result of average load factors. Considering that Dash leverages non-trivial memory PM (i.e., 12.5%) to store the metadata to improve the performance, the calculation of the load factor of Dash excludes this amount of memory. The average load factor of Level Hashing and Dash are both up to 59% because they adopt multiple optimizations such as one movement, balancing load, stash buckets, etc. The average load factor of SEPH is 50%, which is because SEPH does not adopt the optimization that improves the load factor at the expense of introducing more operational overhead. On the other hand, our design shows higher load factor compared to CCEH and CCEH-C (both 39%) since SEPH can accommodate more KV items in a bucket (i.e., 32 for SEPH).

#### 4.2.2 Performance Breakdown

To investigate how the key techniques of SEPH introduced in §3.2 and §3.3 contribute to the overall performance improvement, Figure 10 shows the experiment results of inserting 200 millions of KV items using 48 threads on different variants of SEPH (see Table 2 for their detailed configurations).

Table 2: Configuration of Different SEPH Variants.

SEPH Variants	Semi Lock-Free	One-Third Splitting	Dereference-Free Rehasing
SEPH-Base	×	×	×
SEPH-S	✓	×	×
SEPH-SO	✓	✓	×
SEPH-SOD	✓	✓	✓

First of all, SEPH-Base is considered as a baseline design of SEPH which only keeps the level segment based hash table of SEPH (presented in §3.1) but does not equip with any low-overhead split techniques (proposed in §3.2) and even adopts the lock-based scheme of Dash [33]. It can be clearly observed from Figure 10(a) that compared with SEPH-Base, SEPH-S (which adopts only the proposed semi lock-free concurrency control) significantly lifts up the average

and highest throughputs by 56.72% and 70.20% respectively. The rationale behind this is that the proposed semi lock-free concurrency control effectively avoids the PM writes required to manipulate locks (as validated by Figure 10(b)), resulting in better performance efficiency and scalability. Secondly, compared with SEPH-S, SEPH-SO further demonstrates the efficacy of the proposed one-third splitting in raising the worst-case throughput by 71.46% and reducing the total resizing time by 51.04% (as shown in Figure 10(c)). Finally, compared with SEPH-SO, SEPH-SOD (i.e., the complete design of SEPH) ultimately shows how the proposed dereference-free rehashing can amazingly minimize the total resizing overhead by 92.50%, resulting in a further improvement in the worst-case throughput (i.e., performance predictability) by 55.85%.

Figure 10: Breakdown of Different SEPH Variants.

### 4.2.3 Performance Scalability

**Insertion.** Figure 11(a) shows the insertion throughput under different number of threads. SEPH speeds up the insertion performance by  $2.2\times$  under 48 threads and by  $2\times$  under the other thread numbers compared with Dash. The main reason is that the write bandwidth of PM is considered a common bottleneck, and SEPH completes the insertions with less consumption of write bandwidth. By contrast, PCLHT and Level Hashing show poor scalability owing to the blocking resizing, while the low scalability of Clevel Hashing is due to the high consumption of read/write bandwidth for the full lock-free design.

Figure 11: Scalability.

**Update and Deletion.** Figures 11(b) and 11(c) present the update and deletion performance of various hashing schemes under different numbers of thread. Although SEPH shows similar performance on update operations with Dash when the number of the threads is less than 16, SEPH outperforms Dash

by 30% at 24 threads and 39% at 48 threads, demonstrating higher performance scalability. This is because the lock-free design of SEPH provides a more scalable update performance by reducing a write for the lock to avoid hitting the limit of the write bandwidth at lower concurrent scenarios. To test the scalability of delete operations, we run 10 millions of delete operations to delete all the pre-loaded 10 millions of KV items. As shown in Figure 11(c), SEPH also surpasses all the other designs at 48 threads in delivering high performance scalability of deletion, thanks to the reduction in PM write achieved by the semi lock-free concurrency control.

**Search.** As shown in Figure 11(d), Dash, SEPH and PCLHT show good scalability on search performance, thanks to the low-overhead search operations of these designs and the high bandwidth of PM read (compared with write bandwidth). The search throughput of SEPH is 9.1% lower than that of Dash with 48 threads because SEPH needs to access two candidate buckets by two random reads, yet Dash accesses two candidate buckets by two sequential reads.

### 4.2.4 Mixed Workload

In order to evaluate the performance behavior of the different hashing schemes under the realistic mixed workload, we conduct the experiments with the mixed requests of different search/insertion ratio generated by YCSB in the zipfian distribution (0.99 skewness).

Figure 12 shows the real-time throughput of different hashing schemes with different mixed workloads under 48 threads. SEPH performs the mostly-highest and the least-fluctuated performance in these workloads, which demonstrates SEPH can achieve good performance efficiency and good performance predictability at the same time under the evaluated workloads mixed with different percentages of search operations (denoted as “S”) and insert operations (denoted as “I”).

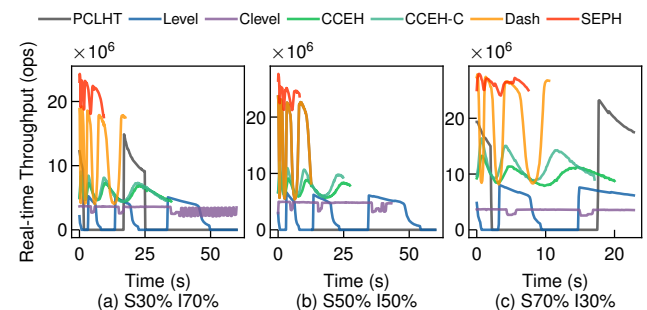

Figure 12: Real-Time Performance under YCSB Workloads with Different Search/Insert Ratio (%).

Figure 13 shows the results of the scalability of the hash tables under different mixed workloads. It can be observed that SEPH delivers better performance scalability than any other evaluated hashing schemes, even under the workload mixed with a high percentage of insertions (i.e., 70% of insert operations and 30% of search operations shown in Figure 13(a)). This is because the proposed semi lock-free

concurrency control entails a nearly-minimal amount of PM writes to handle an insertion operation.

Figure 13: Performance Scalability under YCSB Workloads with Different Search/Insert Ratio (%).

### 4.3 Macro Benchmark

Figure 14 shows the performance results of executing the standard YCSB workloads in terms of the minimal, average, and maximal throughputs. First of all, under the workload Load (100% insertion) shown in Figure 14(a), SEPH performs  $2.63\times \sim 19.59\times$  higher average throughput and at least  $4.52\times$  higher minimal throughput than any other evaluated hashing schemes. This demonstrates SEPH can deliver the most superior performance efficiency and predictability under the insertion-intensive workload, with the help of the proposed low-overhead splitting and semi lock-free concurrency control.

However, under the workload C (100% search) shown in Figure 14(d), the average throughput of SEPH is 12.83% lower than that of Dash, since SEPH is not optimized for search operations (as discussed in §4.2.3). But it is encouraging to see that with the increasing of update operations, the performance gap between the average throughputs of SEPH and Dash reduces and even reverses, because the proposed semi lock-free concurrency control avoids the PM writes to manipulate locks for update operations. Particularly, under the workload B (95% search & 5% update) and the workload F (95% search & 5% read-modify-write (RMW)), the average throughput of SEPH only falls behind that of Dash by 10.9% and 5.6%, as shown in Figures 14(c) and 14(f), respectively. On the contrary, under the workload A (50% search & 50% update), the average throughput of SEPH overtakes that of Dash by 6.9% as in Figure 14(f).

More importantly, under the workload D (95% search & 5% insertion) shown in Figure 14(e), even though SEPH does not achieve the best average throughput (due to the high portion of search operations) among all the evaluated hashing schemes, SEPH demonstrates the best performance predictability (i.e., improving the minimal throughput by at least 39.50%). This reveals the value of the proposed low-overhead splitting in reducing the resizing overhead, even if there are only 5% of insertions. Figure 15 further shows the operation latency of the evaluated hashing schemes at different percentiles under the workload D. It can be observed that SEPH outperforms

Figure 14: The Minimal, Average, and Maximal Throughputs under Standard YCSB Workloads.

EH-based designs by at least  $11\times$  and  $1.82\times$  for the 99.999th and 100th percentile latency respectively; additionally, SEPH greatly surpasses Level-based designs and PCLHT by at least  $2792\times$  for the 100th percentile latency.

Figure 15: Latency at Different Percentiles (Workload D).

## 5 Conclusion

This paper presents SEPH, a Scalable, Efficient, and Predictable Hashing for PM. To break the dilemma between efficiency and predictability, SEPH introduces a new structure called level segment (LS) to build the hash table with a unique indexing mechanism. SEPH further enables a low-overhead split operation to significantly suppress the resizing-incurred performance unpredictability, and puts forward a semi lock-free concurrency control that requires a nearly-minimal amount of writes to handle an insertion operation for achieving ever-higher efficiency and scalability while ensuring the correctness and crash consistency. Our results reveal that SEPH achieves higher efficiency, better scalability, and more reliable predictability when compared with state-of-the-art hashing schemes for PM.

## Abstract

Serverless platforms essentially face a tradeoff between container startup time and provisioned concurrency (i.e., cached instances), which is further exaggerated by the frequent need for remote container initialization. This paper presents MITOSIS, an operating system primitive that provides fast remote fork, which exploits a deep codesign of the OS kernel with RDMA. By leveraging the fast remote read capability of RDMA and partial state transfer across serverless containers, MITOSIS bridges the performance gap between local and remote container initialization. MITOSIS is the first to fork over 10,000 new containers from one instance across multiple machines within a second, while allowing the new containers to efficiently transfer the pre-materialized states of the forked one. We have implemented MITOSIS on Linux and integrated it with FN, a popular serverless platform. Under load spikes in real-world serverless workloads, MITOSIS reduces the function tail latency by 89% with orders of magnitude lower memory usage. For serverless workflow that requires state transfer, MITOSIS improves its execution time by 86%.

## 1 Introduction

Serverless computing is an emerging cloud computing paradigm supported by major cloud providers, including AWS Lambda [23], Azure Functions [91], Google Serverless [44], Alibaba Serverless Application Engine [30] and Huawei Cloud Functions [58]. One of its key promises is *auto-scaling*—users only provide serverless functions, and serverless platforms automatically allocate computing resources (e.g., containers<sup>1</sup>) to execute them. Auto-scaling makes serverless computing economical: the platform only bills when functions are executed (no charge for idle time).

However, *coldstart* (i.e., launching a container from scratch for each function) is a key challenge for fast auto-scaling, as the start time (over 100 ms) can be orders of magnitude higher than the execution time for ephemeral serverless functions [37, 94, 121]. Accelerating coldstart has become a hot topic in both academia and industry [41, 122, 94, 17, 102, 37, 20]. Most of them resort to a form of ‘warmstart’ by *provisioned*

<sup>1</sup>We focus on executing serverless functions with containers in this paper, which is widely adopted by existing platforms [122, 123, 54, 64].

**Figure 1.** The timelines of call frequency (top) and sufficient resource provisioning (bottom) for two serverless functions in a real-world trace from Azure Functions [102].

concurrency, e.g., launching a container from a cached one. However, they require non-trivial resources when scaling functions to a distributed setting, e.g., each machine should deploy many cached containers.

Unfortunately, scaling functions to multiple machines is common because a single machine has a limited function capacity to handle the timely load spikes. Consider the functions sampled from real-world traces of Azure Functions [102]. The request frequency of function 9a3e4e can surge to over 150 K calls per minute, increased by 33,000 $\times$  within one minute (see the top of Figure 1). To avoid stalling numerous newly arriving function calls, the platform should immediately launch sufficient containers across multiple machines (see the bottom part of Figure 1). Due to the unpredictable nature of the serverless workload, it is challenging for the platform to decide the number of cached instances for the warmstart. Hence, there is ‘no free lunch’ for such resources: commercial platforms require users to reserve and pay for them to achieve better performance (i.e., lower response time), e.g., AWS Lambda Provisioned Concurrency [12].

Even worse, dependent functions that run in separate containers cannot directly transfer states. Instead, they must resort to message passing or cloud storage for state transfer, which introduces data serialization/de-serialization, memory copy and storage stack overheads. Recent reports have shown that these may count up to 95% of the function execution

time [71, 53]. Unfortunately, transferring states between functions is common in serverless workflows—a mechanism to compose functions into more complex applications [4, 2]. Though recent research [71] bypasses these overheads for local state transfer (i.e., functions that run on the same machine) by co-locating local functions in the same container, it is still unclear how to do so in a remote setting.

We argue that *remote fork* (forking containers across machines like a local fork) is a promising primitive to enable both efficient function launching and fast function state sharing. First, the fork mechanism has been shown efficient in both performance and resource usage for launching containers on a single machine: one cached container is sufficient to start numerous containers with 1 ms time [17, 37, 36]. By extending the fork mechanism to remote, one active container is sufficient to start numerous containers efficiently on all the machines, achieving *no provisioned concurrency* in a distributed setting. Second, remote fork provides transparent intermediate state sharing between remote functions: the code in the container created by the fork can access the pre-materialized states of the forked container transparently bypassing message passing or cloud storage.

However, state-of-the-art systems can only achieve a conservative remote fork with Checkpoint/Restore techniques (C/R) [7, 117]. Our analysis reveals that they are not efficient for serverless computing, i.e., even slower than coldstart due to the costs of checkpointing the memory of parent container into files, transferring the files through the network and accessing the files through a distributed file system (§3). Even though we have utilized modern interconnects (i.e., RDMA) to reduce these costs, the software overhead of checkpointing and distributed file accesses still make C/R underutilize the low latency and high throughput of RDMA.

We present MITOSIS, an operating system primitive that provides a fast *remote fork* by deeply co-designing with RDMA. The key insight is that the OS can directly access the physical memory on remote machines via RDMA-capable NICs (RNICs) [115], which is extremely fast thanks to bypassing remote OS and remote CPU. Therefore, we can realize remote fork by imitating local fork through mapping a child container’s virtual memory to its parent container’s physical memory without checkpointing the memory. The child container can directly read the parent memory in a copy-on-write fashion using RNIC, bypassing the software stacks (e.g., distributed file system) introduced by traditional C/R.

Leveraging RDMA for remote fork with kernel poses several new challenges (§4.1): (1) fast and scalable RDMA-capable connection establishment, (2) efficient access control of the parent container’s physical memory and (3) efficient parent container lifecycle management at scale. MITOSIS addresses these challenges by (1) retrofitting advanced RDMA feature (i.e., DCT [1]), (2) proposing a new connection-based memory access control method designed for remote fork and (3) co-designing container lifecycle management with the

help of serverless platform. We also introduce techniques including generalized lean container [94] to reduce containerization overhead for the remote fork. In summary, we show that remote fork can be made efficient, feasible and practical on commodity RNICs for serverless computing.

We implemented MITOSIS on Linux with its core functionalities written in Rust as a loadable kernel module. It can remote-fork 10,000 containers on 5 machines within 0.86 second. MITOSIS is fully compatible with mainstream containers (e.g., runC [13]), making integration with existing container-based serverless platforms seamlessly. To demonstrate the efficiency and efficacy, we integrated MITOSIS with Fn [123], a popular open-source serverless platform. Under load spikes in real-world serverless workloads, MITOSIS reduces the 99<sup>th</sup> percentile latency of the spiked function by 89% with orders of magnitude lower memory usage. For a real-world serverless workflow (i.e., FINRA [14]) that requires state transfer, MITOSIS reduces its execution time by 86%.

**Contributions.** We highlight the contributions as follows:

- **Problem:** An analysis of the performance-resource provisioning trade-off of existing container startup techniques, and the costs of state transfer between functions (§2).
- **MITOSIS:** An RDMA-co-designed OS remote fork that quickly launches containers on remote machines without provisioned concurrency and enables efficient function state transfer (§4–5).
- **Demonstration:** An implementation on Linux integrated with Fn (§6) and evaluations on both microbenchmarks and real-world serverless applications demonstrate the efficacy of MITOSIS (§7). MITOSIS is publicly available at <https://github.com/ProjectMitosOS>.

## 2 Background and Motivation

### 2.1 Serverless computing and container

Serverless computing is a popular programming paradigm. It abstracts resource management from the developers: they only need to write the application as *functions* in a popular programming language (e.g., Python), upload these *functions* (as container images) to the platform, and specify how to call them. The platform can *auto-scale* according to function requests by dynamically spawning a container [54, 123, 59, 94, 22, 30, 91, 44, 22, 70]<sup>2</sup> to handle each call. The spawned containers will also be automatically reclaimed after functions return, making serverless economical: the developers only pay for the in-used containers.

Container is a popular host for executing functions. It not only packages the application’s dependencies into a single image that eases the function deployment, but also provides lightweight isolation through Linux’s `cgroups` and `namespaces`, which is necessary to run applications in a multi-tenancy environment. Unfortunately, enabling container

<sup>2</sup>Serverless platform may use virtual machines to run functions, which is not the focus of this paper.

**Table 1:** A comparison of startup techniques for autoscaling  $n$  concurrent invocations of one function to  $m$  machines. Local means the resources for the startup are provisioned on the function execution machine. The function is a simple python program that prints ‘hello world’.

	<b>Coldstart</b> [9, 119]	<b>Caching</b> [63, 123, 94, 102, 122]	<b>Fork</b> [37, 17, 36]	<b>Checkpoint/Restore</b> [120, 37, 117, 20]	<b>Remote fork</b> MITOSIS
<b>Local startup performance</b>	Very slow (100 ms)	Very fast (< 1 ms)	Fast (1 ms)	Medium (5 ms)	Fast (1 ms)
<b>Remote startup performance</b>	Very slow (1,000 ms)	N/A	N/A	Slow (24 ms)	Fast (3 ms)
<b>Overall resource provisioning</b>	$O(1)$	$O(n)$	$O(m)$	$O(1)$	$O(1)$

introduces additional function startup costs and state transferring costs due to container bootstrap and segregated function address spaces, respectively.

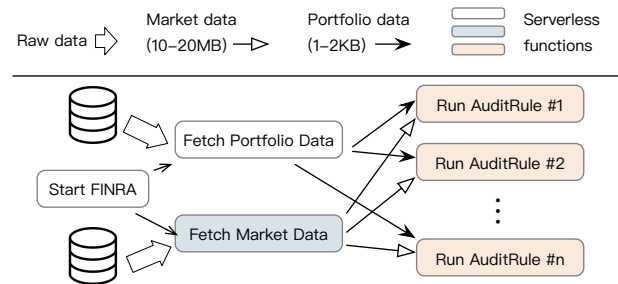

## 2.2 Startup and resource provisioning costs

**Coldstart performance cost.** Starting a container from scratch, commonly named as ‘coldstart’, is notoriously slow. The startup includes pulling the container image, setting up the container configurations and initializing the function language runtime. All the above steps are costly, which take even more than hundreds of milliseconds [37, 94]. As a result, coldstart may dominate the end-to-end latency of ephemeral serverless functions [37, 94, 119, 33]. For example, Lambda@Edge reports that 67% of its functions run in less than 20 ms [33]. In comparison, starting a Hello-world python container with runC [13]—a state-of-the-art container runtime—takes 167 ms and 1783 ms when the container image is stored locally and remotely, respectively (see Table 1).

**Warmstart resource cost due to provisioned concurrency.** A wealth of researches focus on reducing the startup time of coldstart with ‘warmstart’ techniques [94, 17, 37, 102, 113, 42, 119, 131, 106]. However, they must pay more resource provisioning cost (see Table 1):

**Caching** [63, 64, 123, 41, 122, 94, 17, 102]. By caching finished containers (e.g., via Docker pause [8]) instead of reclaiming them, future functions can reuse cached ones (e.g., via Docker unpause) with nearly no startup cost (less than 1 ms). However, Caching consumes large in-memory resources: the resource provisioned—number of the cached instances ( $O(n)$ ) should match the number of concurrent functions ( $n$ ), because a paused container can only unpause for one function. Given the unpredictability of the number of function invocations (e.g., load spikes in Figure 1), it is challenging for the developers or the platform to decide how many cached instances are required. Thus, Caching inevitably faces the trade-off between fast startup and low resource provisioning, resulting in huge cache misses.

**Fork** [37, 17, 36]. A cached container (*parent*) can call the fork system call (instead of unpause) to start new containers (*children*). Since fork can be called multiple times, each machine only requires one cached instance to fork new containers. Thus, fork reduces resource provisioned of Caching—cached containers from  $O(n)$  to  $O(m)$ , where  $m$  is the number of machines that require function startup. However, it is

**Figure 2.** The workflow graph of a real-world serverless application, Financial Industry Regulatory Authority, FINRA [14].

still proportional to the number of machines ( $m$ ) since fork cannot generalize to a distributed setting.

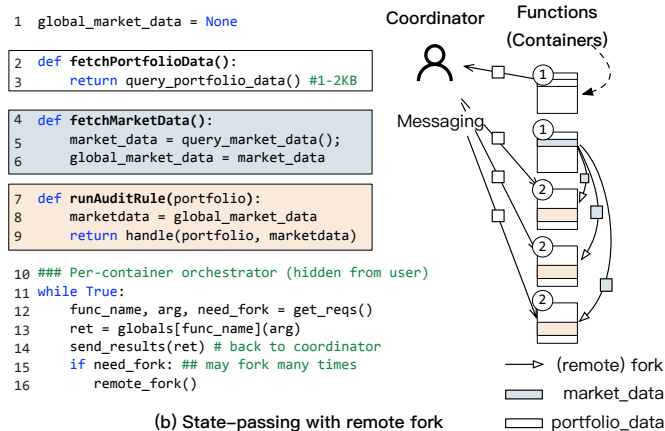

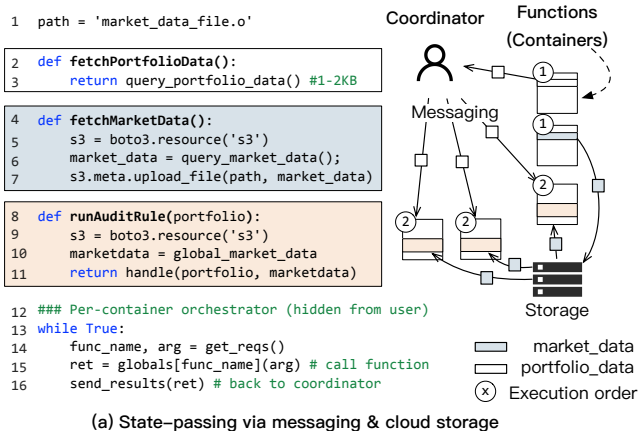

**Checkpoint/Restore (C/R)** [120, 37, 117]. C/R starts containers from container checkpoints stored in a file. It only needs  $O(1)$  resource (the file) to warmstart, because the file can be transferred through the network if necessary. Though being optimal in resource usage, C/R is orders of magnitude slower than Caching and fork. We analyze it in §3 in detail.

## 2.3 (Remote) state transfer cost

Transferring states between functions is common in serverless workflows [36, 17, 95, 64, 4, 2]. A workflow is a graph describing the producer-consumer relationships between functions. Consider the real-world example FINRA [14] shown in Figure 2. It is a financial application that validates trades according to the trade (Portfolio) and market (Market) data. Upstream functions (the ones that produce states, i.e., `fetchPortfolioData` and `fetchMarketData` first read data from external sources. Afterward, they transfer the results to many downstream functions (the one that consumes states), i.e., `runAuditRules` to process them concurrently for a better performance.

Functions run in different containers can only transfer states either by copying them through the network via message passing or exchanging them at a cloud storage service. Figure 3 (a) shows a simplified code for running FINRA on AWS Lambda. For small states transfers (less than 32KB, e.g., Portfolio), Lambda piggybacks the states in messages exchanged between the coordinator and the function containers [131]. For large ones (Market), functions must exchange them with S3—Lambda’s cloud storage service.

Transferring states via messages and cloud storage inevitably faces the overheads of data serialization, memory

**Figure 3.** (a) A simplified code of FINRA (see Figure 2) on existing serverless platforms. (b) A simplified code of using (remote) fork to transfer states between FINRA functions. `globals` records a mapping between function name and its pointer.

copies, and cloud storage stacks, causing up to a 1,000X slow-down [53, 71]. To cope with the issue, existing work proposes serverless-optimized messaging primitives [17] or specialized storage systems [110, 69, 96], but none of the mentioned overhead is completely eliminated [71]. Faastlane [71] co-locates functions in the same container with *threads* so that it can bypass these overheads with shared memory accesses. However, threads cannot generalize to a distributed setting. Faastlane fallbacks to message passing if the upstream and downstream functions are on different machines. SPRIGHT [97] achieves a similar effect by retrofitting eBPF. However, they don’t support efficient data sharing across nodes.

### 3 Remote Fork for Serverless Computing

We show the following two benefits of *remote fork* to address the issues mentioned in the previous section.

**Efficient (remote) function launching.** When generalizing the FORK primitive to a remote setting, a single *parent* container is sufficient to launch subsequent *child*<sup>3</sup> containers across the cluster, similar to C/R (see Table 1). We believe  $O(1)$  resource provisioning is desirable for the developers/tenants since they only need to specify whether they need resource for warmstart, instead of how many (e.g., the number of machines for forking or cached instances [12] for Caching).

**Fast and transparent (remote) state transfer.** The FORK primitive essentially bridges the address spaces of parent and child containers. The transferred states are pre-materialized in the parent memory, so the child can seamlessly access them with shared memory abstraction with no data serialization, zero-copy (for read-only accesses<sup>4</sup>) and cloud storage costs. Meanwhile, the *copy-on-write* semantic in the FORK primitive avoids the costly memory coherence protocol in traditional distributed shared memory systems [75, 57].

<sup>3</sup>We may also call the kernel/machine hosting the parent/child container as *parent/child* in this paper without losing generality.

<sup>4</sup>In the case of the traditional fork. MITOSIS further optimizes with one-sided RDMA (§4), allowing zero-copy even for read-write accesses.

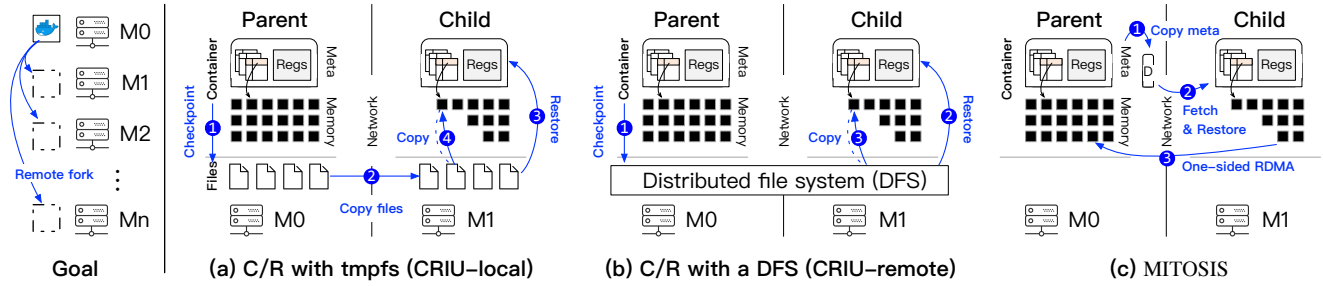

**Figure 4.** Analysis of using C/R for remote fork. **Setup:** CRIU-local: CRIU with a local file system (e.g., *tmpfs*), which uses RDMA to transfer files between machines. CRIU-remote: CRIU with an RDMA-accelerated distributed file system (e.g., *Ceph* [89]).

Figure 3 (b) presents a concrete example of using fork to transfer market data in FINRA (see Figure 2). In this setup, all functions are packaged in the same container, which has an orchestrator dispatching function requests to user-implemented functions (lines 11–14).<sup>5</sup> We further assume the coordinator issuing requests to the orchestrators is fork-aware (§6.1): based on the function dependencies in the workflow graph (e.g., Figure 2), it will request the orchestrator to fork children if necessary (line 12). After the orchestrator finishes `fetchMarketData` (line 13), it forks (lines 15–16) to run downstream functions (`runAuditRule`), which can directly access the `global_market_data` pre-materialized by the parent (line 8).

**Challenge: remote fork efficiency.** To the best of our knowledge, existing containers can only remote fork with a C/R-based approach [108, 32]. To fork a child, the parent first *checkpoints* its states (e.g., register values and memory pages) by copying them to a file, and then *transfers* the file to the child—either using a remote file copy—see *CRIU-local* in Figure 5 (a), or a distributed file system (see *CRIU-remote* in Figure 5 (b)). After receiving the file, the child *restores* the parent’s execution by loading the container states from the checkpointed file. Note that C/R may load some states (i.e., memory pages) on-demand for better performance [120].

<sup>5</sup>This setup is common in serverless platforms [70, 71, 2].

**Figure 5.** An overview of different approaches to achieve ultra-fast remote fork, including (a) C/R with a local filesystem (e.g., tmpfs), (b) C/R with a fast distributed filesystem (e.g., Ceph [5]), and (c) MITOSIS.

Unfortunately, the C/R-based remote fork is not efficient enough for serverless computing. Figure 4 (a) shows the execution time of serverless functions on a remote machine using CRIU [7]—the state-of-the-art C/R on Linux (with careful optimizations, see §7 for details) to realize CRIU-local and CRIU-remote. The synthetic function randomly touches the entire parent’s memory. We observe that C/R-based remote fork can even be  $2.7 \times$  slower than coldstart if it accesses 1 GB remote memory. We attribute it to one or more of the following aspects.

**Checkpoint container memory.** CRIU takes 9 ms (resp. 518 ms) and 15.5 ms (resp. 590 ms) to checkpoint 1 MB (resp. 1 GB) memory of the parent container using local or distributed file systems, respectively. The overhead is dominated by copying the memory to the files: unlike the local fork, the child’s OS resides on another machine and thus, lacks direct memory access capability to the parent’s memory pages.

**Copy checkpointed file.** For CRIU-local, transferring the entire file from the parent to the child takes 11–734 ms for 1 MB–1 GB image (compared to the 0.61–570 ms execution time), respectively. The whole file copy is typically unnecessary since serverless functions typically access a partial state of the parent container [120] (see also Figure 16 (b)).

**Additional restore software overhead.** CRIU-remote enables on-demand file transfer<sup>6</sup>: it only reads the required remote file pages during page faults. However, the execution time is  $1.3\text{--}3.1 \times$  longer than CRIU-local because each page fault requires a DFS request to read the page: the DFS latency (100  $\mu$ s) is much higher than local file accesses. More importantly, the latency is much higher than one network round-trip time (3  $\mu$ s) due to the software overhead.

## 4 The MITOSIS Operating System Primitive

**Opportunity: kernel-space RDMA.** Remote Direct Memory Access (RDMA) is a fast networking feature widely deployed in data-centers [115, 47, 43]. Though commonly used in the user-space, RDMA further gives the kernel the ability to read/write the *physical memory* of remote machines [115]

<sup>6</sup>CRIU lazy migration [6] also supports on-demand transfer. However, it is not optimized for RDMA and is orders of magnitude slower than our evaluated CRIU-remote (210 vs. 42 ms) for the python hello function.

**Figure 6.** The MITOSIS architecture.

bypassing remote CPUs (i.e., one-sided RDMA READ), with low latency (e.g., 2  $\mu$ s) and high bandwidth (400 Gbps).

**Approach: imitate fork with RDMA.** MITOSIS achieves an efficient remote fork by imitating the local fork with RDMA. Figure 5 (c) shows an overview. First, we copy the parent’s metadata (e.g., page table) to a condensed descriptor (§5.1) to fork a child (1). Note that unlike C/R, we don’t copy the parent’s memory pages to the descriptor. The descriptor is then copied to the child via RDMA to recover the parent’s metadata, similar to `copy_process` in the local fork (2). During execution, we configure the child’s remote memory accesses to trigger page faults, and the kernel will read the remote pages accordingly. The fault handler is triggered naturally in an on-demand pattern, which avoids transferring the entire container state. Meanwhile, MITOSIS directly uses one-sided RDMA READ to read the remote physical memory (3), bypassing all the software overheads.

**Architecture.** We target a decentralized architecture—each machine can fork from others and vice versa. Note that we do not require dedicated resources (e.g., pinned memory) to fork containers, thus, non-serverless applications can co-run with MITOSIS. We realize MITOSIS by adding four components to the kernel (see Figure 6): The *fork orchestrator* rehearsals the remote fork execution (§5.1 and 5.2). The *network daemon* manages a scalable RDMA connection pool (§5.3) for communicating between kernels. We extend OS’s *virtual memory subsystems* to utilize the remote memory with RDMA (§5.4). Finally, *fallback daemon* provides RPC handlers to restore rare remote memory accesses that cannot utilize RDMA.

**Security model.** We preserve the security model of containers, i.e., the OS and hardware (RNIC) are trustworthy while malicious containers (functions) may exist.

## 4.1 Challenges and approaches

**Efficient and scalable RDMA connection setup.** Though RDMA is fast (e.g.,  $2\ \mu\text{s}$ ), it is traditionally only supported in the connection-oriented transport (RC) [35, 83, 126, 125, 105, 127, 124], where connection establishment is much slower (e.g., 4 ms [11] with a limited 700 connections/second throughput). Caching connections to other machines can mitigate the issue, but it is impractical when RDMA-capable clusters have scaled to more than 10,000 nodes [43].

We retrofit DCT [1], an underutilized but widely supported advanced RDMA feature with fast and scalable connection setups to carry out communications between kernels (§5.3).

**Efficient remote physical memory control.** MITOSIS exposes the parent’s physical memory to the children for the fastest remote fork. However, this approach introduces consistency problems in corner cases. If the OS changes a parent’s virtual–physical mappings [77, 80, 78, 79] (e.g., swap [78]), the children will read an incorrect page. User-space RDMA can use memory registration (MR) [93] for the access control. However, MR has non-trivial registration overheads [49]. Further, kernel-space RDMA has limited support for MR—it only supports MR on RCQP (with FRMR [90]).

We propose a registration-free memory control method (§5.4) that transforms RNIC’s memory checks to connection permission checks. We further make the checks efficient by utilizing DCT’s scalable connection setup feature.

**Parent container lifecycle management.** For correctness, we must ensure a forked container (parent) is alive until all its successors (including children forked from the children) finish. A naive approach is letting each machine track the lifecycles of the successors of its hosting parents. However, it would pose significant management burdens: a parent’s successors may span multiple machines, forming a distributed *fork tree*. Meanwhile, each machine may have multiple trees. Consequently, each machine needs extensive communications with the others following paths in the trees to ensure a parent can be safely reclaimed.

To this end, we onload the lifecycle management to the serverless platform (§6.3). The observation is that serverless coordinators (nodes that invoke functions via fork) naturally maintain the runtime information of the forked containers. Thus, they can trivially decide when to reclaim parents.

## 5 Design and Implementation

For simplicity, we first assume one-hop fork (i.e., no cascading) and then extend to multi-hops fork (see §5.5).

**API.** We decouple the fork into two phases (see Figure 7): The user can first call `fork_prepare` to generate the parent’s metadata (called *descriptor*) related to remote fork. The descriptor is globally identified by the local unique `handle_id` and `key` (generated and returned by the prepared call) and the parent machine’s RDMA address. Given the identifier,

```
// Prepare the container descriptor at the parent machine
status_t fork_prepare(uint64_t *handle_id, uint64_t *key);

// Resume from a parent descriptor at the child machine
status_t fork_resume(char *addr, uint64_t handle_id, uint64_t key);
```

Figure 7. The major MITOSIS remote fork system calls.

users can start a child via `fork_resume` at another machine (can be the same as the parent, i.e., local fork).

Compared to the traditional one-stage fork system call, a two-phase fork API (prepare and resume)—similar to `pause` and `unpause` in Caching is more flexible for serverless computing. For example, after preparing and recording the parent’s identifier at the coordinator, it can later start children without communicating with the parent machine.

**Visibility of the parent’s data structures.** By default, MITOSIS exposes all the parent’s data structures—including virtual memory and file descriptors, to the child after `fork_prepare`. MITOSIS could introduce APIs to let the application limit the scope of the exposure, but currently, we find it unnecessary: parents must trust the children since they are from the same application.

### 5.1 Fork prepare

`fork_prepare` will generate a local in-memory data structure (*container descriptor*) capturing the parent states, which contains (1) cgroup configurations and namespace flags—for containerization, (2) CPU register values—for recovering the execution states, (3) page table and virtual memory areas (VMAs)—for restoring the virtual memory, and (4) opened file information—for recovering the I/O. We follow local fork (e.g., Linux’s `copy_process()`) to capture (1)–(3) and CRIU [7] for (4). Since deciding when to reclaim a descriptor is challenging, we always keep the prepared parents (and their descriptors) alive unless the serverless platform explicitly frees them (i.e., via `fork_reclaim`).

Though the descriptor plays a similar role as C/R checkpointed file, we emphasize one key difference: the descriptor only stores the page table, not the memory pages. As a result, it is orders of magnitude smaller (KB vs. MB) and orders of magnitude faster to generate and transfer.

### 5.2 Fork resume

`fork_resume` resumes the parent’s execution state by fetching the parent descriptor and then restoring from it. We now describe how to make the above two steps fast. For now, we assume the child OS has established network connections capable of issuing RPCs and one-sided RDMA to the parent. The next section describes the connection setup.

**Fast descriptor fetch with one-sided RDMA.** A straightforward implementation of fetching the descriptor is using RPC. However, RPC’s memory copy overhead is non-trivial (see Figure 18), as the descriptor of a moderate-sized container may consume several KBs. The ideal fetch is using one one-sided RDMA READ, which requires (1) storing the parent’s

descriptor into a consecutive memory area and (2) informing the child’s OS of the memory’s address and size in advance.

The first requirement can be trivially achieved by serializing the descriptor into a well-format message. Data serialization has little cost (sub-millisecond) due to the simple data structure of descriptor. For the second requirement, a naive solution is to encode the memory information in the descriptor identifier (e.g., `handler_id`) that is directly passed to the resume system call. However, this approach is insecure because a malicious user could pass a malformed ID, causing the child to read and use a malformed descriptor. We adopt a simple solution to remedy this: MITOSIS will send an authentication RPC to query the descriptor memory information with the descriptor identifier. If the authentication passes, the parent will send back the descriptor’s stored address and payload so that the child can directly read it with one-sided RDMA. We chose a simple design because the overhead of an additional RPC (several bytes) is typically negligible: reading the descriptor (several KBs) will dominate the fetch time.

**Fast restore with generalized lean containers.** With the fetched descriptor, child OS uses the following two steps to resume a child to the parent’s execution states: (1) Containerization: set the `cgroups` and `namespaces` to match the parent’s setup; (2) Switch: replace the caller’s CPU registers, page table, and I/O descriptors with the parent’s. The switch is efficient (finishes in sub-milliseconds): it just imitates the local fork—e.g., unmapping the caller’s current memory mapping and mapping the child’s virtual memory to the parents by copying parent’s page table to the child. On the other hand, containerization can take tens of milliseconds due to the cost of setting `cgroups` and `namespaces`.

Fortunately, fast containerization has been well-studied [94, 17, 27, 112]. For instance, SOCK [94] introduces *lean container*, which is a special container having the minimal configurations necessary for serverless computing. It further uses pooling to hide the cost of container bootstrap, reducing its time from tens of milliseconds to a few milliseconds. We generalize SOCK’s lean container to a distributed setting to accelerate the containerization of the remote fork. Specifically, before resuming a remote parent, we will use SOCK to create an empty lean container that satisfies the parent’s isolation requirements. Afterward, the empty container calls MITOSIS to resume execution. Since the container has been properly configured with SOCK, we can skip the costly containerization.

### 5.3 Network daemon

The network daemon aims to reduce the costs of creating RDMA connections (commonly called *RCQP*) on the critical path of the remote fork. Meanwhile, it also avoids caching RCQPs connected to all the servers to save memory.

**Solution: Retrofit advanced RDMA transport (DCT).** The essential requirement behind the goal is that we need QP to be connectionless. RDMA does provide a connectionless

**Figure 8.** A comparison of a client (CL) using two RCQPs and DCQP to communicate with two machines (M1 and M2).

transport—unreliable datagram (UD), but it only supports messaging, so we can just use it for RPC.

We find dynamic connected transport (DCT) [1]—a less studied but widely supported RDMA feature suits remote fork well. DCT preserves the functionality of RC and further provides a connectionless illusion: a single DCQP can communicate with different nodes. The target node only needs to create a *DC target*, which is identified by the node’s RDMA address and a 12B *DC key*.<sup>7</sup> After knowing the keys, a child node can send one-sided RDMA requests to the corresponding targets without connection—the hardware will piggyback the connection with data processing and is extremely fast (within  $1\mu\text{s}$  [11, 67]), as shown in Figure 8.

Based on DCT, the network daemon manages a small kernel-space DCQP pool for handling RDMA requests from children. Typically, one DCQP per-CPU is sufficient to utilize RDMA [11]. However, using DCT alone is insufficient because the child needs to know the DCT key in advance to communicate with the parent. Therefore, we also implement a kernel-space FaSST RPC [67] to bootstrap DCT. FaSST is a UD-based RPC that supports connectionless. With RPC, we piggyback the DCT key associated with the parent in the RPC request to query the parent’s descriptor. To save CPU resources, we only deploy two kernel threads to handle RPCs, which is sufficient for our workloads (see Figure 13 (b)).

**Discussion on DCT overheads.** DCT has known performance issue due to extra reconnection messages. Compared with RC, it causes up to 55.3% performance degradations for small (32B) one-sided RDMA READs [67]. Nevertheless, the reconnection has no effect on the large (e.g., more than 1 KB) transfer because transferring data dominates the time [11]. Since the workload pattern of MITOSIS is dominated by large transfers, e.g., reading remote pages in 4KB granularity, we empirically found no influence from this issue.

### 5.4 RDMA-Aware virtual memory management

For resume efficiency, we directly set the page table entries (PTE) of the children’s mapped pages to the parent’s physical addresses (PA) during the resume phase. However, the original OS is unaware of the remote PA in the PTE. Thus, we dedicate a remote bit in the PTE for distinction. In particular, the OS will set the remote bit to be 1 and clear the present bit of the PTE during the switch process at the resume phase. Afterward, child’s remote page access will trap in the kernel

<sup>7</sup>The key consists of a 4 B NIC-generated number and 8 B user-passed key.

**Table 2:** A summary of page fault handling related to remote fork at the child categorized by whether the virtual address (VA) is mapped to remote and whether the remote physical address (PA) is stored.

Example	VA mapped	Parent PA in PTE	Method
Stack grows	No	No	Local
Code in .text	Yes	Yes	RDMA
Mapped file	Yes	No	RPC

after the switch. Consequently, MITOSIS can handle them in the RDMA-aware page fault handler. Note that we don't change the table entry data structure: we utilize an ignored PTE bit (i.e., one in [58 : 52] [60]) for the remote bit.

**RDMA-aware page fault handler.** Table 2 summarizes how we handle different faults related to remote fork. If the fault page has not mapped to the parent, e.g., stack grows, we handle it locally like a normal page fault. Otherwise, we check whether the fault virtual address (VA) has a mapped remote PA. If so, we use one-sided RDMA to read the remote page to a local page. Most child pages can be restored via RDMA because serverless function typically touches a subset of the previous run [120, 37]. In case of a missed mapping, we fallback to RPC.

**Fallback daemon.** Each node hosts a fallback daemon that spawns kernel threads to handle children's paging requests, which contains the parent identifier and the requested virtual address. The fallback logic is simple: After checking the validity of the request, the daemon thread will load the page on behalf of the parent. If the load succeeds, we will send the result back to the child.

**Connection-based memory access control and isolation.** Direct exposing the parent's physical memory improves the remote fork speed. Nevertheless, we need to reject accesses to mapped pages that no longer belong to a parent and properly isolate accesses to different containers. Since we expose the memory via one-sided RDMA in a CPU-bypassing way, we can only leverage RNIC for the control.

MITOSIS proposes a connection-based memory access control method. Specifically, we assign different RDMA connections to different portions of the parent's virtual memory area (VMA), e.g., one connection per VMA. If a mapped physical page no longer belongs to a parent, we will destroy the connection related to the page's VMA. Consequently, the child's access to the page will be rejected by the RNIC. The connections are all managed in the kernel to prevent malicious users from accessing the wrong remote container memory.

To make connection-based access control practical, each connection must be efficient in creation and storage. Fortunately, the DCQP satisfies these requirements well. At the child-side, each connection (DC key) only consumes 12B—different DC connections can share the same DCQP. Meanwhile, the parent-side DC target consumes 144B. Note that creating DCQPs and targets also has overheads. Yet, they are

**Figure 9.** An illustration of the extended virtual memory subsystems to map children's virtual addresses to remote memory. The memory space is divided into a list of virtual memory area (VMA)s, each managed by a `vm_area_struct`. DC target pool and DCT keys are used by connection-based memory access control.

logically independent of the parent's memory. Therefore, we use pooling to amortize their creation time (several ms).

Figure 9 shows the DCT-based access control in action. Upon fork preparation, MITOSIS assigns one DC target—selected from a target pool—to each parent VMA. The pool is initialized during boot time and is periodically filled in the background. The DC keys of these targets are piggybacked in the parent's descriptor so that the children can record them in their VMA during resume. Upon reading a parent's page, the child will use the key corresponding to the page's VMA to issue the RDMA request. With this scheme, if the parent wants to reject accesses to this page, it can destroy the corresponding DC target.

Connection-based control has false positives: after destroying a VMA's assigned target, all remote accesses to it are rejected. Assigning DC targets in a more fine-grained way (e.g., multiple targets per VMA) can mitigate the issue at the cost of increased memory usage. We found it is unnecessary because VA-PA changes are rare at the parent. For example, swap never happens if the OS has sufficient memory.

**Security analysis.** Compared with normal containers, MITOSIS additionally exposes its physical memory to remote machines via RDMA. Nevertheless, since remote containers must leverage their kernels to read the exposed memory, a malicious container cannot read others states as long as its kernel is not compromised. Besides this, the inherent security issues of RDMA [111, 99, 128] may also endanger MITOSIS. While such security threats are out of the scope of our work, it is possible to integrate orthogonal solutions [111, 99, 128, 115] to improve the security of MITOSIS.

**Optimizations: prefetching and caching.** Even with RDMA, reading remote pages is still much slower than local memory accesses [35] (3  $\mu$ s vs. 100 ns). Thus, we apply two standard optimizations: *Prefetching* prefetches adjacent remote pages upon page faults. Empirically, we found a prefetch size of one is sufficient to improve the performance of remote fork at a small cost to the runtime memory (see Figure 15). Thus, MITOSIS only prefetches one adjacent page by default. *Caching* caches the finished children's page table (and the read pages) in the kernel. A later child forking the same parent can then reuse the page table in a copy-on-write way to avoid reading

**Figure 10.** An illustration of multi-hops remote fork.

the touched pages again. This is essentially a combination of local-remote fork. To avoid extra memory cost, we only keep the cached page table for a short period (usually several seconds) to cope with load spikes (e.g., see Figure 1).

### 5.5 Supporting multi-hops remote fork

MITOSIS supports multi-hops fork: a child can be forked again with its children possibly on the third machine. It is similar to one-hop fork except that we need to further track the ownership of remote pages in a fine-grained way. As shown in Figure 10, the pages behind `data[1]` and `data[0]` resides on two different machines. A naive approach would be maintaining a map to track the owner of each virtual page. However, it would consume non-trivial storage overhead. To reduce memory usage, MITOSIS encodes the owner in the PTE: we dedicate 4 bits in the PTE’s ignored bits to encode the remote page machine—supporting a maximum of 15-hops remote fork (up to 15 ancestors)

## 6 Bringing MITOSIS to Serverless Computing

This section describes how we apply MITOSIS to FN [123]—a popular open source serverless platform. Though we focus on FN, we believe our methodology can also apply to other serverless platforms (e.g., OpenWhisk [122]) because they follow a similar system architecture (see Figure 11).

**Basic FN.** Figure 11 shows an overview of FN. It handles the function request that is either an invocation of a single function, or an execution of a serverless workflow (e.g., see Figure 2). A dedicated *coordinator* is responsible for scheduling the executions of these requests. The function code must be packed to a container and uploaded to a Docker registry [34] managed by the platform.

To handle the invocation of a single function, the coordinator will direct the request to an *invoker* chosen from a pool of servers. After receiving the request, the invoker spawns a container with Caching to accelerate startups to execute the function. Note that FN hides the mapping of request to user-function (e.g., 12–16 in Figure 3 (a)) with function development kit (FDK): i.e., the user only needs to provide the code for the function, not the code that dispatches the requests to the function. Thanks to this abstraction, we can extend FDK to add the fork capabilities.

To execute a workflow, the coordinator will first decompose the workflow into single-function calls (one

**Figure 11.** Integrating MITOSIS to FN. The gray boxes are our added (or extended) components.

for each workflow graph node), then schedule them based on the dependency relationship. In particular, the coordinator will only execute a downstream function (e.g., `defrunAuditRule` in Figure 2) after all its upstream functions (`fetchPortfolioData` and `fetchMarketData`) finish.

### 6.1 Fork-aware serverless platform

Being aware of MITOSIS, the platform can leverage parents that have prepared themselves via `fork_prepare` (we term them as *seeds* in this paper) to accelerate function startup and state transfer. Besides, it is also responsible for reclaiming the seeds. Based on the use cases, we further categorize seeds into two classes. 1) For seeds that are used for boosting function startups, the frequency of reclamation is low. Hence, we name them *long-lived* seeds and use a coarse-grained reclamation scheme (§6.2). 2) For seeds that are used for state transfer, they only live during the lifecycle of a serverless workflow. We name them *short-lived* seeds and use a fine-grained fork tree-based mechanism to free them (§6.3).

The steps to accelerate FN with MITOSIS are: (1) Extend the FN coordinator to send `prepare/resume` requests to the invoker to fork containers if necessary and (2) Instrument FDK so that it can recognize the new (fork) requests from the coordinator (e.g., line 12–16 in Figure 3 (b)). Since the extensions to the FDK are trivial, we focus on describing the extensions to the coordinator.

**Fork-aware coordinator.** For a single function call, the coordinator first looks up an available (long-lived) seed. The locations of seeds are stored at a *seed store*. If one seed is available, it sends a `fork resume` request to the invoker. Otherwise, we fallback to the vanilla function startup mechanism.

During workflow execution, the coordinator dynamically creates short-lived based on state transfer relationship. Specifically, it will tell the invoker to call `fork_prepare` if it executes an upstream function in the workflow. The prepared results are piggybacked in the reply of the function. Afterward, the coordinator can use `fork_resume` to start downstream functions, which transparently inherit the pre-materialized results of the upstream one.

Note that one function may have multiple upstream functions (e.g., `run AuditRule` in Figure 2). For such cases, we require the user to specify which function to fork by annotating the workflow graph or fuse the upstream functions.

## 6.2 Long-lived seed management

**Deployment.** We deploy long-lived seeds as cached containers because they naturally load the function’s working set into the memory. If the invoker decides to cache a container, it will call `fork_prepare` to generate a seed. Note that we must also adjust FN’s cache policy to be fork-aware. For example, FN always caches a container if it experiences a coldstart, which is unnecessary considering MITOSIS because the fork can accelerate startups more resource-efficiently. Therefore, we only cache the first container facing coldstart across the platform. Moreover, we also detect whether a container is a multi-hop one, i.e., forked from a long-lived seed. We don’t cache such containers as they are short-lived seeds.

**Seed store.** To find the seed information, we record a mapping between function name and the corresponding seed’s RDMA address, the `handle_id` and `key` (the latter two are returned by `fork_prepare`) at the coordinator. We also record the time when the seed was deployed, which is necessary to prevent the coordinator forking from a near-expired cache instance. The seed store can be co-located with the coordinator or implemented as a distributed key-value store.

**Reclamation.** Similar to Caching, the long-lived seeds are reclaimed by timeout. Unlike Caching, seeds can have a much longer keep-alive time (e.g., 10 minutes vs. 1 minute) since they consume orders of magnitude smaller memory. The coordinators can renew the seed if it doesn’t live long enough for the forked function.

## 6.3 Fork tree and short-lived seed management

**Fork tree granularity and structure.** Each serverless workflow has a dedicated fork tree stored and maintained at the coordinator executing it. The upper-layer nodes in the tree correspond to the upstream functions (parents) in the workflow and the lower-layer nodes represent the downstream functions (children). Each node encodes the container IDs and locations, which is sufficient for the coordinator to reclaim the corresponding seed.

**Fork tree construction and destroy.** The construction of the fork tree is straightforward: After the coordinator forks a new child from a short-lived seed, it will add the seed to the tree. When all functions in the tree finish, MITOSIS will reclaim all the nodes except for the root node: the root node can be a long-lived seed and MITOSIS will not reclaim it.

**Fault tolerance.** The fork tree should be fault-tolerant to prevent memory leakage caused by dangling seeds. Replicating the tree with common replication protocols (e.g., Paxos [74]) can tolerate the failure, but adds non-trivial overheads during the workflow execution. Observing that serverless functions have a maximum lifetime (e.g., 15 minutes in AWS Lambda [3]), we use a simple timeout-based mechanism to tolerate the failures. Specifically, invokers will periodically garbage collect short-lived seeds if they run beyond the func-

tion’s maximum allowed runtime.

## 6.4 Limitation

First, fork still needs a long-lived seed to quickly bootstrap others. If no seed is available, we can leverage existing approaches that optimize coldstart (e.g., FaasNET [119]) to first start one. Second, fork only enables a read-only state transfer. Yet, it is sufficient for serverless workflow—the dominant function composition method. Finally, fork cannot transfer states between multiple upstream functions. Thus, MITOSIS must fuse these upstream functions into one or fallback to messaging (see `Portfolio` in Figure 3) for such cases. We are addressing this limitation by further introducing a *remote merge* primitive to complement the remote fork.

## 7 Evaluation

**Experimental setup.** We conduct all our experiments on a local cluster with 24 machines. Each machine has two 12-core Intel Xeon E5-2650 v4 processors and 128GB of DRAM. 16 machines are connected to two Mellanox SB7890 100Gbps switches with two 100 Gbps ConnectX-4 MCX455A Infini-Band RNICs. We use them as invokers to execute the serverless functions. Nodes without RDMA are left as coordinators.

**Comparing targets.** The evaluating setups of MITOSIS and its baselines are listed as follows. Note that we apply our generalized lean container (§5.2) to all the systems to hide the cost of containerization.

1. **Caching** is the de facto warmstart technique that provides a near-optimal function startup.
2. **CRIU-local** leverages CRIU [7] to implement remote fork (see Figure 5 (a)) and stores all files in an in-memory local filesystem (`tmpfs`). The file is transferred via our optimized transfer library with one-sided RDMA. We also apply existing on-demand restore optimization [120].
3. **CRIU-remote** leverages CRIU and a distributed file system for the remote fork (see Figure 5 (b)). We use Ceph [89]—a state-of-the-art production DFS that embraces RDMA. We also apply optimizations from CRIU-local: in-memory storage and on-demand restore.
4. **FaasNET** [119] optimizes the container image pulling of coldstart with function trees. We evaluate an optimal setup of FaasNET (for performance) that pre-provisions the images at all the invokers.<sup>8</sup>
5. **MITOSIS** is configured with on-demand execution and reads all pages from remote with a prefetch size of one.
6. **MITOSIS+cache** is the version of MITOSIS that always caches and shares the fetched pages among children. It essentially fallbacks to the local fork.

<sup>8</sup>The setup has been confirmed by the FaasNET authors.

**Figure 12.** (a) End-to-end latency comparisons of MITOSIS and baselines. (b) Analyses of different phases using microbenchmarks. Note that the working set of the execution is smaller than the prepare and startup because child only touches a subset of the parent’s memory.

**Functions evaluated.** We chose functions from representative serverless benchmarks (i.e., ServerlessBench [131], FunctionBench [68], and SeBS [31]), which cover a wide range of scenarios, including simple function (*hello/H*—print ‘Hello world’), file processing (*compression/CO*—compress a file), web requests (*json/J*—(de)serialize json data, *pyaes/P*—encrypt messages, *chameleon/CH*—generate HTML pages), image processing (*image/I*—apply image processing algorithms to an image), graph processing (*pagerank/PR*—execute the pagerank algorithm on a graph) and machine learning (*recognition/R*—image recognition using ResNet). These functions are written in python—the dominant serverless language [33]. Besides, we also use a synthetic *micro-function* that touches a variant portion of the memory to analyze the overhead introduced by MITOSIS. It is written in C to minimize the language runtime overhead interference.

### 7.1 End-to-end latency and memory consumption

Figure 12 shows the results of end-to-end latency: the left sub-figure is the time of different phases of the functions during remote fork, and the right is each phase’s result on micro-function. The function request is sent by a single client. To rule out the impact of disk accesses, we put all the function’s related files (e.g., images used by *image/I*) in tmpfs.

**Prepare time.** The prepare time is the time for the parent to prepare a remote fork. For CRIU-local and CRIU-remote, it is the time to checkpoint a container. For variants of MITOSIS, it is the `fork_prepare` time. Caching and FaasNET do not have this phase because they do not support fork.

MITOSIS is orders of magnitude faster in preparation than CRIU-local and CRIU-remote. On average, it reduces the prepare time by 94%. For example, MITOSIS prepared a 467 MB *recognition/R* container in 11 ms, while CRIU-local

and CRIU-remote took 223 ms and 253 ms, respectively. The variants of CRIU are bottlenecked by copying the container state from the memory to the filesystems.

**Startup time.** We measure the startup time as the time between an invoker receiving the function request and the time the first line of the function executes. As shown in the middle of Figure 12, caching is the fastest (0.5 ms) because starting a cached container only requires a simple unpauses operation. MITOSIS comes next, it can start all the functions within 6 ms. It is up to 99%, 94%, and 97% (from 98%, 86%, and 77%) faster than CRIU-local, CRIU-remote, and FaasNET, respectively. The startup time of MITOSIS is dominated by the generalized lean container setup time since reading the descriptor with RDMA is extremely fast with our fast descriptor fetch protocol.

The startup of CRIU-local is dominated by copying the entire file (shown in Figure 12 (b)). Using CRIU-remote avoids transferring the file, but the overhead of communicating with the DFS meta server (from 23–90 ms) is still non-trivial. Compared to CRIU-remote, MITOSIS can directly read the container metadata (descriptor) from the remote machine’s kernel. Finally, the startup cost of FaasNET (coldstart) is dominated by the runtime initialization of the function, as we skipped the image pull process of it. The overhead depends on the application characteristics. For example, *recognition/R* requires loading a ResNet model from PyTorch, which takes 875 ms. Other techniques can skip the loading process since the model has been loaded in the parents or the cached containers.

Note that the results of CRIU-remote and FaasNET are not significantly higher in the startup microbenchmark (Figure 12 (b)). For CRIU-remote, it is because the time (40ms) is relatively small compared to CRIU-local (>191ms for working-set larger than 256MB). For FaasNET, we use a native lan-

Figure 13. (a) Peak throughput comparisons of MITOSIS and baselines. (b) Bottleneck analysis of MITOSIS using a single parent seed.

Figure 14. The per-function memory usage (in MB) for each technique before running (hatched) and during runtime (colored).

guage in the microbenchmark (C), so it doesn’t suffer from the runtime initialization and library loading costs of the application functions in Figure 12 (a).

**Execution time.** For function execution, MITOSIS is up to  $2.24\times$ ,  $1.46\times$  and  $1.14\times$  (from  $1.04\times$ ,  $1.04\times$ , and  $1.02\times$ ) slower than Caching, CRIU-local and FaasNET, respectively, except for *hello/H*. The overhead is mainly due to page faults and reading remote memory, which is proportional to the function working set (see Figure 12 (b)). Consequently, the overhead is most significant in *recognition/R* that reads 321 MB of the parent memory: MITOSIS is  $2.24\times$  (477 vs. 213 ms) and  $1.46\times$  (477 vs. 326 ms) slower than Caching and CRIU-local, respectively. CRIU-local is faster since it reads files from the local memory (tmpfs). To remedy this, MITOSIS+cache reduces the number of remote memory accesses by reading from the local cached copies of the remote pages. It improves performance by up to 17%, making MITOSIS close to or better than CRIU-local and FaasNET during execution. Note that Caching is always optimal (i.e., faster than FaasNET and CRIU-local) because it has no page fault overhead. Finally, MITOSIS is up to  $3.02\times$  (from  $1.02\times$ ) faster than CRIU-remote thanks to bypassing DFS for reading remote pages.

**Memory consumption.** Figure 14 reports the amortized per-machine memory consumed for each function categorized by provisioned memory (before running) and runtime memory. An ideal serverless platform should use minimal provisioned memory for each function. On average, MITOSIS only consumes 6.5% of the provisioned memory (one cached instance across 16 machines) while Caching requires at least 16 instances. CRIU-local/remote consumes a slightly lower memory (77% on average) than MITOSIS, because it reuses

the local OS’s shared libraries to prevent storing them in the checkpointed files. This works at the cost of requiring storing all the function’s required libraries on all the machines, otherwise the restored container will fail. For the same reason, MITOSIS consumes a slightly larger runtime memory (8% on average) than CRIU-remote. Yet, its runtime memory is smaller than CRIU-local because the CRIU-local will read the entire file before it can execute the function.

## 7.2 Bottleneck analysis and throughput comparisons

**Bottleneck analysis.** Using a single seed function is ideal for resource usage. However, the parent-side network bandwidth (RDMA) and two RPC threads can become the bottleneck. Meanwhile, MITOSIS is also bottlenecked by the aggregated client-side CPU resources processing the function logic. The peak client-side performance for each function is the peak throughput of running functions with Caching.

Figure 13 (b) analyzes the impact of the above factors. We utilize all 16 invokers to achieve the peak throughput. For H, CO, J, and R, RDMA is the bottleneck. For example, *recognition/R* touches 321 MB of the parent’s memory, so the RDMA (200 Gbps) can only serve (ideal) 80 forks/sec. Thus, MITOSIS achieves 69 reqs/sec and is lower than Caching (960 reqs/sec). In contrast, if the children CPU is the bottleneck, MITOSIS is similar to Caching (P, CH, I, and PR). For example, Caching can only execute 384 reqs/sec for *pagerank/PR*. In comparison, RDMA can handle an ideal 544 PR forks/sec (the working set is 47 MB). Thus, MITOSIS can achieve a slightly lower throughput (249 reqs/sec). Finally, the RPC would never become the bottleneck: two kernel threads can handle up to 1.1 million reqs/sec, which is always faster than RDMA for working set from 1 MB to 1 GB.

**Throughput comparison.** Figure 13 (a) further compares the peak throughput of different approaches. Note that we exclude the prepare phase of CRIU—otherwise, it will be bottlenecked by this phase. MITOSIS is up to  $8.0\times$  (from  $2.1\times$ ) faster than CRIU-local, thanks to avoiding the whole file during the restore phase. Compared with CRIU-remote, MITOSIS is also up to  $20.4\times$  (from  $2.1\times$ ) faster except for R (69 vs. 81): CRIU-remote reads a smaller amount of remote memory because it reuses local copies of the shared libraries. R has the largest working set, so it is mostly affected by the network. For the others, MITOSIS is faster as it bypasses the overhead of DFS.

**Figure 15.** Effects of the number of pages prefetched per-fault on (a) execution time (in ms) and (b) memory consumption (in MB).

**Figure 16.** Effects of COW to latencies on (a) the micro-function (with a 64 MB parent working set) and (b) serverless functions.

We omit the comparison between MITOSIS and Caching, which has been studied in the bottleneck analysis.

### 7.3 Effects of prefetching

We next explore how the prefetch number affects MITOSIS in Figure 15 (a). As we can see, prefetching can significantly improve the execution time of functions: prefetching 1, 2, and 6 pages improve the average time by 10%, 16%, and 18% (up to 30%, 50%, and 50%), respectively. More importantly, a small prefetch size (6) can achieve a near-identical performance as the optimal, i.e., no remote access, (MITOSIS+cache). Note that for small prefetch size the cost to the throughput is negligible, so we omit the results.

Prefetching has additional runtime memory consumption: as shown in Figure 15 (b), prefetching 1, 2, and 6 consumes average  $1.1\times$ ,  $1.3\times$ , and  $1.5\times$  (up to  $1.15\times$ ,  $1.6\times$ , and  $2.5\times$ ) more memory than no prefetching. Therefore, we currently adopt a prefetch size of 1 to reduce runtime memory usage.

### 7.4 Effects of copy-on-write (COW)

MITOSIS reads the child’s pages in an on-demand way (copy-on-write). This section presents the benefits and costs of COW

**Figure 17.** Effects of COW to peak thpt on (a) the micro-function (with a 64 MB parent working set) and (b) serverless functions.

**Figure 18.** Effects of optimizations applied by MITOSIS.

compared to a non-COW design—the child will read all the parent’s memory before executing the functions.

**Latency.** Figure 16 reports the latency results. The benefit of COW in latency depends on the amount of the parent’s memory touched by the child (touch ratio): the cross points in the microbenchmark are 60% and 90% when the prefetch size is 1 and 2, respectively. For larger prefetch size, the cross point is close to 100%. Non-COW has a longer startup time due to extra remote memory reading, but it is more efficient in reading pages with RDMA because it can batch multiple paging requests [66]. Nevertheless, serverless functions typically have a moderate touch ratio (i.e.,  $< 67\%$ ). Therefore, COW has averages of 8.7% (from 0.6% to 44%) and 3.7% (from -5% to 31%) lower latency than Non-COW when the prefetch size is 1 and 2, respectively.

**Throughput.** Figure 17 further reports the throughput results. Unlike latency, COW is always faster in throughput (except for 100% touch ratio) because non-COW will issue more RDMA requests. Consequently, COW is  $1.03\times$ – $10.2\times$  faster than Non-COW on serverless functions.

### 7.5 Effects of optimizations

Due to space limitation, Figure 18 briefly shows the effects of optimizations introduced in §5 on the end-to-end fork time using a short function (*json*/J) and a long function (*recognition*/R). First, generalized lean container (+GL) reduced a fixed offset of the latency (100 ms) to all the functions compared with a baseline of using runC [13]. Compared with RPC, fast descriptor fetch with one-sided RDMA (+FD) further contributes 10% and 25% latency reduction for both

**Figure 19.** (a) The latency CDF, (b) average latency, and (c) memory consumption timelines on image processing (I) under spikes.

**Figure 20.** (a) The state-transfer performance between two functions and (b) performance of FINRA.

functions. The improvement is more obvious for R because its descriptor is much larger (1.3 MB vs. 31 KB). Using DCT instead of RC reduced a 10–20 ms to the functions, and directly exposing the physical memory with RDMA instead of copying them (+no copy) further reduced the fork time by 12% and 20% for J and R, respectively. Finally, prefetching (+prefetch) shortens the time by 9% and 15%.

## 7.6 State-transfer performance

**Microbenchmark.** We use the data-transfer testcase (5) in ServerlessBench [131] to compare different approaches to transfer states between two remote functions. As shown in Figure 20 (a), MITOSIS is up to 1.4–5× faster than Fn, which leverages Redis to transfer data between functions, when transferring 1 MB–1 GB data. Note that we exclude the data (de)serialization overhead (by skipping the phase) and coldstart overhead (by pre-warming the containers) in Fn. Otherwise, the gap between Fn and MITOSIS would become larger. Compared to CRIU-local/remote, MITOSIS is faster thanks to the design for a fast remote fork (see §7.1).

**Application: FINRA.** We next present the performance of MITOSIS on FINRA [14], whose workflow graph is shown in Figure 2. We manually fuse the `fetchPortfolioData` and `fetchMarketData` into one function to fully leverage remote fork for MITOSIS and CRIU variants. For FN, functions use Redis to transfer states. Figure 20 (b) reports the end-to-end latency w.r.t the number of instances of `runAuditRule`, where FINRA spawns about 200 instances [10]. We select the market data from seven stocks, resulting in a total 6 MB states transferred between functions.

As we can see, MITOSIS is 84–86%, 47–66% and 71–83% faster than the baseline Fn, CRIU-local and CRIU-remote, respectively. Note that we have pre-warmed Fn to prevent the effects of coldstart—which is unnecessary for MITOSIS. Fn is bottlenecked by Redis (27 ms) and data serialization and

de-serialization (600 ms). MITOSIS has no such overhead and it further makes state transfer between machines optimal via RDMA. Moreover, MITOSIS can scale to a distributed setting with little COST [88]—it can outperform a single-function sequentially processing all the rules (Single-function). This is because MITOSIS can concurrently run functions across machines with minimal cost transferring data between them.

## 7.7 Performance under load spikes

Finally, we evaluate the performance of MITOSIS under load spike using *imageI* on the real-world traces (660323 [102]). Figure 19 (a) summarizes the latency CDFs. The 99<sup>th</sup> percentile latency of FN+MITOSIS is 73.64% and 89.08% smaller than FN+FaasNET and FN, respectively, thanks to avoiding the coldstart with remote fork. Nevertheless, its median latency is 1.85× longer than FaasNET (799 ms vs. 430 ms), because FaasNET leverages Caching and has a 65.1% cache hit during spikes. However, Caching incurs non-trivial memory consumption: Fn (and Fn+FaasNET) will cache a container for 30 seconds if it is a coldstart, resulting in a significant amount of memory usage (see Figure 19 (c)). In comparison, MITOSIS only caches a single seed and saves orders of magnitude memory during the idle time. For example, at time 2.3 min, MITOSIS only consumes 29 MB memory per-machine, which is 3% and 2% of Fn (914 MB) and Fn+FaasNET (1,199 MB), respectively.

## 8 Discussion

**Seed placement and selection policies.** We currently choose a random placement policy. A better policy may further consider network topology and system-wide load balance. Meanwhile, we simply choose the first container experiencing coldstart as the long-lived seed, yet, a better selection policy should further consider the status of the running container. For instance, recent works have discovered that containers may need multiple invocations to warm up properly [28, 107], e.g., to JIT a function written in a managed language. Therefore, choosing a properly warm-up container as the seed can significantly improve the function performance after the fork. As these policies are orthogonal to MITOSIS, we plan to investigate them in the future.

**Frequency and cost of fallbacks.** The frequency of fallbacks can significantly impact the performance of remote forks. During our experiment, we encountered no fallbacks

because the parent (cached container) had loaded all the children’s memory. However, fallbacks can happen in corner cases (e.g., swapping). The per-page overhead is  $22\times$  (65 vs.  $3\mu\text{s}$ ) due to the cost of RPC and loading the page from disk (SSD). Currently, one fallback handler can process 16 K paging requests per second, so it will not become a bottleneck.

**The benefits of implementing MITOSIS in the kernel.** We choose to implement MITOSIS in the kernel for performance considerations. First, a user-space solution cannot directly access the physical memory of the container, so it pays the checkpointing overhead (see §3). Moreover, the kernel can establish RDMA connections more efficiently (see KR-Core [11]), and the kernel-space page fault handler is much faster than the user-space fault handler.

## 9 Related Work

**Optimizing serverless computing.** MITOSIS continues the line of research on optimizing serverless computing, including but not limited to accelerating function startups [94, 17, 106, 37, 117, 101, 119], state transfer [110, 69, 96, 71, 17, 86], stateful serverless functions [132, 63], transactions [84], improving the cost-efficiency [134, 42, 100, 76, 98, 40, 38], and others [109, 133, 65, 36, 64, 15, 114, 85, 130, 136]. While most of these works are orthogonal to MITOSIS, we believe they can also benefit from our work. In particular, we propose using the remote fork abstraction to simultaneously accelerate function startups and state transfer, which is critical to all serverless applications. We also compare our work extensively to its closest related approaches in §2. Moreover, while the implementation of Linux fork may not be optimal in some scenarios [129, 24, 135], it has been shown to be suitable for serverless functions [17, 37]. Thus, we generalize the fork abstraction to accelerate functions running across machines.

**Checkpoint and restore (C/R).** C/R has been investigated by OSes for a long time [39, 82]. e.g., KeyKOS [51], EROS [104], Aurora [116] and others [52, 72, 7, 137, 118, 21, 26, 48]. Aurora [116] leverages C/R to realizing efficient single level store, it introduces techniques including system shadowing for efficient incremental checkpointing. MITOSIS eliminates checkpointing in the context of remote fork via OS-RDMA co-design. VAS-CRIU [118] also noticed the overhead of C/R introduced by filesystems. It leverages multiple independent address spaces (MVAS) [50] to bypass the filesystem for C/R on a single machine. We further use kernel-space RDMA to build a global distributed address space and scale fast C/R to a distributed setting.

**Remote fork (migrations).** Besides using C/R for remote fork [108, 32], MITOSIS is also inspired by works on virtual machine fork (SnowFlock [73]) and migrations [18, 29, 45, 56, 55, 92, 81], just to name a few. For example, the MITOSIS container descriptor is inspired by the VM descriptor used in SnowFlock, which only captures the critical metadata used for instantiating a child container at the remote side. We further

consider the opportunities and challenges when embracing RDMA for remote fork in the context of serverless computing. We believe our techniques can benefit existing works not utilizing RDMA.

**RDMA-based remote paging and RDMA multicast.** Reading pages from remote hosts via RDMA is not a so new technique in modern OSes [19, 46, 16, 87, 103]. For example, Infiniswap [46] leverages RDMA to build a fast swap device for memory disaggregation. Remote regions [16] proposes a remote file-like abstraction to simplify exposing an application’s memory with RDMA. MITOSIS further builds efficient remote fork by reading remote pages in a “copy-on-write” fashion with RDMA.

MITOSIS exhibits a pull-based RDMA multicast communication pattern, where multiple children pull from the same parent’s memory during load spikes. Push-based RDMA multicast has been extensively studied in the literature [25, 61, 62]. For example, RDMC [25] proposes a binomial pipeline protocol where a sender can efficiently push data to a group of nodes using RDMA. We believe MITOSIS can further benefit from research on pull-based RDMA multicast.

## 10 Conclusion

We present MITOSIS, a new OS primitive designed for fast remote fork by co-designing with RDMA. MITOSIS possesses two key attributes for serverless computing. (1) Startup efficiency: MITOSIS is orders of magnitude faster than coldstart while consuming orders of magnitude fewer resources than warmstart (with comparable performance). (2) State transfer efficiency: functions can directly access pre-materialized states from the forked function. Extensive evaluation using real-world serverless applications confirmed the efficacy and efficiency of MITOSIS on commodity RDMA-capable clusters. While we focus on serverless computing in this paper, we believe MITOSIS also shines with other tasks, e.g., container migrations.

## Acknowledgment

We sincerely thank our shepherd Christopher Rossbach and the anonymous reviewers, whose reviews and suggestions greatly strengthened our work. We also thank Wentai Li, Qingyuan Liu, Zhiyuan Dong, Dong Du, Nian Liu, Sijie Shen, and Xiating Xie for their valuable feedback. # Johnny Cache: the End of DRAM Cache Conflicts (in Tiered Main Memory Systems)

Baptiste Lepers  
*University of Neuchâtel*

Willy Zwaenepoel  
*University of Sydney*

## Abstract

We demonstrate that hardware management of a tiered memory system offers better performance for many applications than current methods of software management. Hardware management treats the fast tier as a cache on the slower tier. The advantages are that caching can be done at cache line granularity and that data appears in fast memory as soon as it is accessed. The potential for cache conflicts has, however, led previous works to conclude these hardware methods generally perform poorly.

In this paper we show that low-overhead conflict avoidance techniques eliminate conflicts almost entirely and thereby address the above limitation. We explore two techniques. The static technique tries to avoid conflicts between pages at page allocation time. The dynamic technique relies on monitoring memory accesses to distinguish between hot and cold pages. It uses this information to avoid conflicts between hot pages, both at page allocation time and by dynamic remapping at runtime.

We have implemented these techniques in the Linux kernel on an Intel Optane machine in a system called Johnny Cache (JC). We use HPC applications, key-value stores and databases to compare JC to the default Linux tiered memory management implementation and to HeMem, a state-of-the-art software management approach.

Our measurements show that JC outperforms Linux and HeMem for most applications, in some cases by up to 5×. A surprising conclusion of this paper is that a cache can provide close-to-optimal performance by minimizing conflicts purely at page allocation time, without any access monitoring or dynamic page remapping.

## 1 Introduction

Tiered memory systems combine DRAM with a slower, but more abundant, storage tier (SSD, PMEM, CXL memory extension modules [8], ...). Most systems rely on a software daemon that monitors accesses to the data. Frequently accessed

data is migrated to DRAM, while less frequently accessed data is migrated to the slower tier [1, 9, 11, 14, 20, 23, 25]. Tiered memory systems have also been implemented purely in hardware, using DRAM as an "L4" cache that sits between the CPU and the slower tier [13].

Previous work has argued that hardware implementations of tiered systems are inefficient because the hardware lacks a high-level view of the application requirements and because caching strategies have to be kept simple to be executed in hardware. For instance, in tiered DRAM+PMEM systems, software daemons have been shown to outperform the "memory mode" of Intel CPUs (in "memory mode", the CPU uses DRAM as a directly-mapped cache for PMEM) [20].

This paper is based on the observation that the previously mentioned limitations of hardware caching are not fundamental and can be addressed at the operating system level. In particular, we demonstrate that the poor performance observed in earlier hardware-based systems is due to cache conflicts resulting from Linux's page allocation policy, and that simple improvements to the page allocation policy can reduce cache conflicts with little or no overhead.

Linux's page allocation does not take into consideration the location of pages in hardware caches. As a consequence, Linux suffers from the birthday paradox: the DRAM cache is large, but many pages tend to map to a subset of the available cache locations. We propose the following simple static page allocation policy to reduce conflicts: we allocate a new page such that its physical address maps to a cache slot with the fewest pages currently mapped to it. For example, if we have a cache with 2 million slots and 4 million pages to be allocated, we allocate 2 pages to each slot. The static policy has no noticeable overhead, but it vastly reduces conflicts.

We also investigate a dynamic policy that takes into account the access frequency of pages, distinguishing between hot and cold pages. The dynamic policy allocates a new page to the cache slot with the lowest access frequency and reacts to workload changes by dynamically remapping pages when it detects conflicts. Surprisingly, we find that in many workloads the static policy already results in few conflicts, and the

overheads of the dynamic policy offset the benefits of any further gains in conflict reduction.

We compare our conflict avoidance policies to software migration, as proposed by, among others, HeMem [20]. With software migration, access frequency is monitored as well, producing the same set of hot and cold pages and incurring the same monitoring overhead as our dynamic approach. Software migration, however, uses this information for an entirely different purpose, namely to migrate hot pages from slow to fast memory, and vice versa for cold pages, unlike our dynamic policy which uses it to reduce conflicts.

We have implemented the static and dynamic policies at the kernel level in a subsystem named Johnny Cache (JC), and we refer to these systems as JC-static and JC-dyn, respectively. We have evaluated these systems on a tiered DRAM+PMEM system against the Linux page allocation mechanism and against HeMem, a state-of-the-art software-based page migration system [20]. JC outperforms Linux and HeMem for the vast majority of applications, in some cases by up to  $5\times$ . We document these results in more detail in the paper and also discuss the limitations of a cache-based approach. In addition, we find that JC-static often suffices to obtain good performance. Methods involving profiling such as HeMem and JC-dyn suffer from profiling and migration overheads and the inability to detect hot pages in some workloads. In contrast, avoiding conflicts in the DRAM cache at allocation time, as done by JC-static, is robust and sufficient to achieve near-optimal performance for most workloads.

In summary, the paper makes the following contributions:

- The observation that hardware-managed DRAM caches can be made efficient by minor modifications to the operating system page allocation algorithms.
- The idea of placing conflict avoidance as a first principle of page management in tiered memory systems, instead of relying on migration of data.
- The design, implementation and evaluation of page placement policies that outperform state-of-the-art page migration systems.

The rest of the paper is organized as follows. Section 2 explains how tiered-main memory systems are managed in software and in hardware. Section 3 presents the design of our policies, Section 4 presents their implementation, and Section 5 their evaluation. Section 6 provides further discussion of the strengths and weaknesses of various approaches. Section 7 presents related work and Section 8 concludes.

## 2 Tiered main memory systems

In this section, we give an overview of existing software- and hardware-managed tiered memory systems, and we compare their overheads.

### 2.1 Software-based migration

In software-managed tiered memory systems, the operating system chooses which pages are allocated in DRAM and which pages are allocated in the slower tier. The kernel usually allocates as many pages in DRAM as possible and, when DRAM is full, subsequent pages are allocated in the slow tier. A daemon is in charge of migrating frequently accessed pages (hot pages) from the slow tier to DRAM, and infrequently accessed pages (cold pages) from DRAM to the slow tier. The techniques vary but aim at inferring the set of hot pages with high accuracy and low overhead. For instance, HeMem [20] uses the hardware performance unit of Intel CPUs to track memory accesses and migrates pages between DRAM and PMEM using DMA to minimize CPU overheads.

Software-based migration gives the operating system full control over page placement, but it comes with some downsides. First, data migrations are costly because they can only happen at page granularity (4KB or 2MB), and each migration requires modifying the page table, modifying the kernel VMA metadata and flushing the TLBs. Migrations may also cause latency spikes in write-heavy applications because pages have to be write-protected while being migrated. Second, since access frequency is collected on a per-page basis, for applications that mix hot and cold data in the same page, DRAM may need to be used for cold data to allow fast access to hot data in the same page. Finally, page migrations happen asynchronously: data may be accessed for a while in the slow tier before being migrated to DRAM. As a consequence, the performance of software-based migration is heavily dependent on the fast and accurate detection and migration of the working set. To do so, memory access must be sampled with high frequency, a costly proposition.

### 2.2 Hardware caching

In hardware, the CPU uses DRAM as a cache for the slow tier. In existing implementations [13], the DRAM is configured as a 1-way cache, indexed by physical address. Unlike software-based approaches, hardware caches are synchronous: all accessed data is cached in DRAM. In this section, we describe the implementation of the "memory mode" of Intel processors for tiered DRAM+PMEM systems.

When looking for a physical address  $W$ , the memory controller first checks if  $W$  is in the DRAM cache (at location " $W \bmod \text{cachesize}$ "). If  $W$  is not present in DRAM,  $W$  is fetched from PMEM, copied to the DRAM cache and to the CPU cache (see Figure 1(a)).

A conflict occurs when  $W$  maps to a cache slot that is already occupied by  $X$ , in which case  $X$  must first be removed from the cache. In the best case,  $X$  is clean, and the cost is equal to that of a PMEM read. If  $X$  is dirty, then  $X$  must be written back to PMEM before  $W$  can be loaded in the cache, making the cost the sum of a PMEM write and a PMEM

Figure 1: Caching in memory mode. (a) In the best case data found in PMEM is cached in DRAM and in the CPU caches, and in the (b) worst case the caching may result in evictions, causing up to two writebacks to PMEM.

read. A worst-case scenario can arise as described in Figure 1(b). In addition to the writeback of *X*, a dirty line *Y* may be evicted from the CPU cache, resulting in a writeback of *Y* to the DRAM cache, which itself may result in a writeback of another dirty line *Z* to PMEM (the DRAM cache is not inclusive).

Regardless of the precise sequence of events, conflicts are expensive. Table 1 compares the latency of performing 8B random reads or random writes in DRAM, in PMEM, and in the worst-case scenario presented in Figure 1(b). Reading from PMEM (in AppDirect mode) is  $3.2\times$  slower than reading from DRAM, and writing is  $4.4\times$  slower. A read causing two writebacks to PMEM is  $9.7\times$  slower than a read from DRAM, and a write causing two writebacks is  $7.2\times$  slower than a write to DRAM. (Causing two writebacks to PMEM is not exactly equivalent to performing two writes to PMEM, which would be  $8.8\times$  slower, because the CPU overlaps the evictions with other processing done by the application, resulting in slightly more in-CPU parallelism).

Memory mode thus performs suboptimally when frequently accessed data conflicts in the cache. If, however, conflicts can be avoided, then memory mode offers several advantages over software migration. First, caching avoids costly whole-page migration as well as virtual memory operations. Second, caches operate at the cache line level, while software migration can only migrate data at the page granularity. Therefore, they avoid wasting DRAM space if hot and cold data are located in the same page. Finally, caching is synchronous: hot data appears in DRAM on the first access.

Read in DRAM	96ns
Plain read from PMEM	305ns
Write in DRAM	130ns
Plain write from PMEM	578ns
Read/Write causing 2 writebacks	938ns

Table 1: Latency of memory access in various scenarios.

## 2.3 Comparison

Table 2 summarizes the costs of migrating data vs. caching data. These costs show that caching data in DRAM is *a priori* a more parsimonious solution: data is cached at cache line granularity (vs. page granularity), caching data requires no kernel metadata updates, and no memory profiling is necessary to infer which pages to cache.

## 3 Design

Our design is based on the idea that a DRAM cache is efficient, as long as conflicts in the cache are rare. Conflicts happen when two data items are mapped to the same cache location. Conflicts become problematic if the data items are accessed in turn. We have designed two policies that aim at minimizing conflicts in the cache. The hardware caches data at cache line granularity, but the kernel can only allocate data at page granularity, so our policies try to minimize conflicts between pages.

**Static policy:** The static policy minimizes the number of allocated pages that map to the same DRAM cache location. Assuming a DRAM cache that can store  $D$  pages, the static policy allocates the first  $D$  pages so that they map to different cache locations. The next  $D$  pages are allocated so that they possibly conflict with a single other page, and so on.

**Dynamic policy:** The dynamic policy samples memory accesses to compute the heat of every page and every cache location. When a new page is allocated, the kernel maps it to the coldest available location.

A conflict avoidance daemon monitors for conflicts between hot pages at the same cache location. When two pages, mapped to the same DRAM cache location, are both frequently accessed, one of the pages is remapped to a different cache location.

**Rationale:** The main advantage of the static policy is that it requires no monitoring of memory accesses, and so it runs with no overhead. The intuition behind the static policy is that minimizing the number of pages that overlap in the cache reduces significantly the likelihood of conflicts between hot data items. Indeed, in most workloads, at most of a few GBs of data is hot, even in workloads whose memory footprint vastly exceeds the available DRAM. Minimizing overlaps makes conflicts between hot pages unlikely. For instance, let's consider an application that allocates data twice the available DRAM size, 5% of which is hot. The static policy allocates

	Software migration	Hardware caching
Granularity	Page Size (4KB, 2MB)	64B
Cost of migrating/caching	Page copy from PMEM to DRAM Page copy from DRAM to PMEM 2 page table updates 2 VMA updates TLB flush	<i>Best case</i> 1 cache line copied from PMEM to DRAM <i>Worst case</i> 1 cache line copied from PMEM to DRAM 2 cache lines copied from DRAM to PMEM
Strategy	Software defined	All memory accesses are cached in DRAM

Table 2: Comparison of the cost of migration vs. caching.

pages such that exactly 2 pages map to each cache location. A given hot page has a 5% chance to compete for the cache with another hot page, and a 95% chance to compete with a cold page. In other words, most hot pages are "paired" with a cold page, and are thus unlikely to be evicted frequently from the DRAM cache.

The dynamic policy makes more informed choices at page allocation time, and the daemon fixes conflicts that may have been missed at allocation time. The dynamic policy borrows the notion of heat from software migration systems, but the heat is used to track and *avoid conflicts* between hot pages rather than to migrate hot pages to DRAM. We demonstrate in Section 5.2 that, in the general case, avoiding conflicts is less costly than migrating hot data to DRAM.

## 4 Implementation

In this section, we describe the implementation of the page allocation policies and the migration daemon. The code is available at <https://github.com/BLepers/JohnnyCache>.

### 4.1 Page initialization and associated metadata

Our policies are implemented in the kernel, as hooks in the kernel initialization function, the page initialization function, the page fault handler and the page unmap handler. To ease the development of policies, we implemented a framework that contains the logic common to the policies. In the remainder of the paper, we refer to the framework as Johnny Cache (*JC*).

In this paper, we assume a directly-mapped 1-way cache, in which data is cached at its physical address modulo the size of the cache – as implemented by Intel in the "memory mode" of tiered DRAM+PMEM systems. It would be easy to account for associativity in *JC* by changing the definition of a conflict: currently, a conflict involves 2 or more pages; in an *N*-way cache, a conflict would involve *N*+1 or more pages.

While DRAM caches data at cache line granularity, the kernel can only allocate and migrate data at page granularity. All the metadata maintained by *JC* are thus at the page level. When the kernel boots, we query the processor's memory controller to find out the size of the DRAM cache. In the remainder of this section, we refer to the maximum number of

pages that the cache can hold as the cache *capacity*. Because the cache is directly-mapped, every page in the system maps to a unique index in the cache, which we call a *bin*. The bin of a page is its page frame number (physical address of the first byte of the page / size of a page) modulo the capacity of the cache. Furthermore, each bin of the cache has a *heat*. The definition of heat depends on the policy. For instance, for the static policy it corresponds to the number of allocated pages that map to that bin.

As is the case with the default page allocation policy of Linux, we use a lazy page allocation mechanism: pages are physically allocated only when they are first accessed. We thus hook the page fault handler to implement our page placement policies. The framework maintains a list of bins with available pages, sorted per heat. When a page fault occurs, a page from a bin with the lowest heat is returned, and the current allocation policy is informed of the page fault. Similarly, whenever a page is freed, the kernel unmap handler is called, and the current allocation policy is made aware of the unmapping.

Listing 1 summarizes the metadata and code of the page fault hook used by our framework. The overhead of keeping the metadata in memory is small (less than 50MB for a system with 128GB of DRAM and 1TB of PMEM).

Our policies are implemented at the kernel level and oblivious to the notion of a thread or an application. The policies try to minimize conflicts across the entire machine, and no partitioning of the cache is done (unlike page-coloring approaches). A major benefit of this approach is that conflicts are minimized globally. For instance, the conflict avoidance daemon remaps hot conflicting pages even if they belong to different applications.

### 4.2 Static policy

The static policy allocates a new page in a bin with the fewest allocated pages. The static policy consists of counting the number of allocated pages that map to a given cache bin. The policy is called on every page fault and page unmap by the framework. Listing 2 summarizes the code of the static policy. During a page fault, the policy increments by one the *heat* of the bin of the newly allocated page. Because the page fault handler of the common framework allocates a page from the bins which have the lowest heat, subsequent page faults will

---

**Listing 1** JC framework.

---

```
1 // struct for each cache bin (page granularity)
2 struct bin* bins[CACHE_CAPACITY] = { ... };
3 // avail[heat] = list of bins with free pages
4 struct bin* avail_bins[HEAT_LEVELS];
5 // full[heat] = list of fully allocated bins
6 struct bin* full_bins[HEAT_LEVELS];
7
8 struct page* page_fault_handler(void) {
9     for(i = 0; i < HEAT_LEVELS; i++) {
10        bin = list_first(avail_bins[i]);
11        if(bin) {
12            struct page *p =
13                list_pop(bin->avail_pages);
14            current_policy.page_fault(bin, p);
15            if(list_empty(bin->avail_pages))
16                list_move(bin, full_bins[bin->heat]);
17            else
18                list_move(bin, avail_bins[bin->heat]);
19            return p;
20        }
21    }
22    // OOM
23 }
24
25 void page_unmap(struct page *p) { ... }
```

---

likely avoid that bin. When a page is unmapped, the heat of the bin is decremented by one, increasing the likelihood of that bin being chosen for subsequent allocations.

---

**Listing 2** In the static policy, the heat of a bin corresponds to the number of pages allocated to that bin.

---

```
1 void static_pf(struct bin *b, struct page *p) {
2     b->heat++;
3 }
4
5 static_policy = {
6     .page_fault = static_pf, .unmap = ...
7 };
```

---

### 4.3 Dynamic policy and migration daemon

The dynamic policy allocates a page in a bin with available pages and with the lowest heat. The dynamic policy monitors memory accesses to infer the heat of each page and bin. We monitor read accesses to the DRAM cache, read accesses to PMEM and all stores using the Processor Event-Based Sampling (PEBS) feature of Intel's CPUs. When a memory access is sampled, we increase the heat of the accessed page and accessed bin. We also artificially increase the heat of the bin of newly allocated pages to avoid multiple pages being mapped to the same bin during bursts of allocations. To avoid heat continually increasing over time, we trigger page cooling as soon as a page becomes "super hot", i.e., when its heat becomes double that of the threshold to detect a hot page.

In theory, our dynamic policy could monitor conflicts in the cache instead of monitoring memory accesses, but no such event exists in Intel CPUs. Our heat detection and cooling approaches are identical to those used by HeMem [20], which allows for a fair comparison between software-based migration and conflict-avoidance (both solutions use the same PEBS events, the same definition of heat and the same cooling function).

The migration daemon monitors conflicts between allocated pages. When two hot pages are present in the same bin, one of them is remapped to a physical location in a different bin. The daemon periodically looks for pages in the upper heat buckets and remaps them. The remapping operation calls the page fault handler which allocates a new page in a cold bin and calls the unmap function, which decreases the heat of the original bin. Algorithm 3 summarizes the approach of the dynamic policy and migration daemon.

HeMem triggers migrations as soon as a hot page is detected. To allow for a fair comparison, we trigger the daemon as soon as we detect a bin containing two hot pages (i.e., as soon as we detect a conflict that involves two hot pages).

---

**Listing 3** The dynamic policy and migration daemon that remaps pages from highly accessed bins.

---

```
1 // Migration daemon
2 void migration_daemon() {
3     wait();
4     for(i=HEAT_LEVELS-1; i>MIN_CONTENTION; i--) {
5         foreach(bin, avail_bins[i]) {
6             if(bin->nb_hot_pages >= 2)
7                 remap(get_hot_page(bin));
8         }
9         foreach(bin, full_bins[i]) {
10            if(bin->nb_hot_pages >= 2)
11                remap(get_hot_page(bin));
12        }
13    }
14 }
15
16 // Called on every sampled memory access
17 void add_sample(struct bin *b, struct page *p){
18     b->heat++;
19     ... // increase the page's heat &
20     ... // update the metadata
21     if(b->nb_hot_pages > 2)
22         migration_daemon.wakeup();
23 }
24
25 void dyn_pf(struct bin *b, struct page *p) {
26     b->heat++;
27     ... // increase the page's heat &
28     ... // update the metadata
29 }
30
31 dynamic_policy = {
32     .page_fault = dyn_pf,
33     .unmap = ...
34 };
```

---

## 5 Evaluation

The evaluation aims at answering the following questions:

- What is the performance of JC compared to state-of-the-art tiered memory management systems?
- What is the overhead of JC, in terms of performance and latency spikes, compared to other systems?
- What are the limitations of JC? Which applications benefit from hardware caches, and which benefit from page migration?

We show that the static page allocation policy of JC achieves close-to-optimal performance in many applications, and sometimes outperforms the dynamic policy (and related work) when minimizing CPU overhead is essential for performance. The surprising conclusion of this evaluation is thus that hardware caches often outperform existing software-based migration strategies, provided minimal changes in the kernel page allocation policy are put in place.

### 5.1 Setup

**Hardware configuration.** All the experiments presented in this paper are run on a two-node NUMA machine, with 40 Intel Xeon Gold 6230 cores running at 2.10GHz (20 cores per NUMA node), 128GB of DRAM, and 8\*128GB Intel Optane NV-DIMMs (64GB DRAM and 512GB PMEM per NUMA node). In memory mode, each NUMA node has a DRAM cache of 48GB (16GB is used by the CPU for the cache metadata).

**Workloads.** We borrow the workloads used to evaluate HeMem [20], a state-of-the-art software page migration system. The GUPS microbenchmark allocates a large array, zeroes it, and then threads perform updates to a random subset of 8-byte array elements. BC, from the GAP benchmark suite, computes the betweenness centrality algorithm on a powerlaw graph [4]. Silo [22] is an in-memory database running the standard TPC-C benchmark suite. Finally, Masstree [16] is an in-memory key-value store, running a YCSB workload<sup>1</sup>. We also present results from the NAS benchmark suite [3]. JC equals or more commonly outperforms the related work in all these benchmarks, with the exception of the MG.E application from the NAS benchmark suite, which allows us to demonstrate the limitations of our approach. As in the original HeMem evaluation, NUMA effects of tiered memory are beyond the scope of this paper, and we run the applications on a single NUMA node.

**Software configuration.** We compare JC against unmodified Linux and HeMem. *Linux* uses the machine in memory mode

<sup>1</sup>HeMem benchmarked FlexKVS [17], an in-memory key-value store which we could not evaluate due to the lack of an RDMA network card on our server.

with the default Linux page allocation policy. With the default page allocation policy, pages are allocated on the local NUMA node, but contiguous virtual memory ranges may end up fragmented in physical memory. Any array larger than 2 pages may thus conflict with itself in the DRAM cache (the larger the array, the more likely 2 pages of the array conflict). We refer to *JC-static* as the machine in memory mode with our static page allocation policy and to *JC-dyn* as the machine in memory mode with the dynamic page allocation policy plus the page remapping daemon. We benchmark HeMem using the provided artifact [19].

### 5.2 GUPS

The GUPS microbenchmark, from HeMem [20], allocates a large array, a subset of which is hot. 90% of the updates are done on the hot section of the array, and 10% on the cold section. We configure the array to be 96GB, twice the DRAM cache size and measure performance when 10% of the array is hot (9.6GB).

The performance of HeMem and JC-dyn is dependent on their ability to detect hot and cold pages. Intuitively, the more threads perform memory accesses, the easier it is to detect hot pages. To assess the impact of the workload on the detection of hot and cold pages, we thus vary the number of threads. Furthermore, HeMem and JC-dyn use two separate threads to sample memory accesses and to migrate pages. To assess the overhead of these threads, we either run them on separate cores or on the cores used by GUPS. We refer to these configurations as (M+N) where M is the number of cores used by GUPS, and N is either 0 or 2 and reflects the number of cores dedicated to monitoring and migration in HeMem and JC-dyn. We use three such configurations: (16+2), (8+2) and (8+0). These results are presented in Section 5.2.1.

In the original GUPS implementation the hot and cold data items are located in separate regions of the array. While this microbenchmark reflects the partitioning done by some applications, it implies that all hot items are located in a small number of pages, and all cold items are located in the other pages. To reflect the behavior of applications that do not partition their hot and cold items in this manner, we also run GUPS with hot items scattered randomly in the array. These results are presented in Section 5.2.2. Finally, in Section 5.2.3 we explore the performance of the different systems with a larger data set of 480GB.

We measure the throughput achieved for a given combination of system and workload. When the hot data fits in DRAM, we present the results as the percentage of the throughput achieved when all hot data is manually allocated in DRAM. Otherwise, we present the result in terms of millions of updates per second.

### 5.2.1 Random updates to clustered hot values

We first benchmark GUPS with hot values clustered on a few pages, the scenario favoring page migration.

The allocated array is twice the size of the DRAM cache so, initially, half of the array is in DRAM, and all systems start with low throughput. Figure 2 presents the performance of JC-static, JC-dyn, HeMem, and Linux over time, as a percentage of the performance achieved when all hot pages are manually allocated in DRAM.

**Steady-state performance in configuration (16+2):** Both HeMem and JC-dyn achieve 100% of DRAM performance, JC-static 85% and Linux 60%. There is (conflict-free) space in the cache for all hot pages, so JC-dyn eventually eliminates all conflicts, and HeMem eventually moves all hot pages to DRAM, explaining their performance being equal to DRAM.

The good performance of JC-static is explained by the low number of conflicts on hot data. The array is twice the size of the cache, and JC allocates exactly 2 pages per cache bin. Let  $P$  be a hot page.  $P$  conflicts with a single other page  $Q$ , and  $Q$  only has a 10% probability of being hot. JC thus only suffers from conflicts between 10% of the hot data (0.96GB).

The low performance of Linux is explained by the large number of conflicts when no care is taken to properly spread the pages in the cache. Just as with the "birthday paradox", even though a year has many days (*even though the cache has many bins*), in a small group of people, many are likely born on the same day (*many pages are mapped to the same cache bin, even when allocating only 100GB*). On average, Linux uses only 32GB of the DRAM cache because the allocated pages map to a subset of the available cache bins, while JC takes advantage of the full cache. Figure 2(d) presents the performance of an average run of Linux, but, depending on page placement, performance varies between runs from 20% to 80% of DRAM performance. These extreme values are rare, with most runs achieving around 60%.

**Steady-state performance in configuration (8+2) - The difficult configuration of heat detection systems:** The performance of JC-static and Linux relative to DRAM performance remains the same as in configuration (16+2). HeMem does not reach steady state even after 2 minutes, only reaching 40% of DRAM speed. JC-static is between  $4\times$  faster than HeMem (at the beginning of the execution) and  $2.2\times$  faster (after 2 minutes of execution). JC-dyn also does not reach steady state, but its performance is closer to DRAM performance (85% at the beginning of the execution, 90% at the end).

With 8 threads, fewer samples are generated, and the cooling mechanisms of HeMem and JC-dyn reduce the heat of pages faster than it increases as a result of accesses. HeMem and JC-dyn trigger page cooling as soon as any given page becomes "super hot", i.e., when its heat becomes double the threshold to detect a hot page (see Section 4). We implemented other cooling algorithms, but none ended up working

Figure 2: Hot values clustered in the array. Performance achieved by JC, HeMem, and Linux compared to the performance achieved when all the hot values are manually allocated in DRAM (optimal page placement). (a) JC-static, which does not use any profiling, performs close-to-optimally. (b) The profiling threads of the migration daemon can negatively interfere with the application threads (brown line). (c) The performance of HeMem is highly dependent on its ability to detect hot pages. When GUPS is launched with a low number of threads, hot pages are rarely detected and HeMem performs suboptimally. (d) The default page placement policy of Linux performs suboptimally because of conflicts.

in all configurations of GUPS. For instance, forcing cooling to happen periodically but less frequently results in most of the array being detected as hot in some other configurations (e.g., on smaller arrays). Replacing periodic cooling with other algorithms such as LRU also performs poorly in some configurations (e.g., when the hot set size exceeds the DRAM size). Most of the related work on page migration explores new ways of measuring heat accurately and with low overhead [1, 9, 11, 12, 14, 20, 23–25] but, in our experience, these heuristics require fine-tuning for each application and configuration.

It is possible to tune the sampling rate of memory accesses to gather more samples in a given amount of time, but doing so is also fraught with problems. For instance, doubling the sampling rate actually decreases the performance of GUPS running with 16 threads by 20%, due to profiling overheads. Some literature describes attempts to use dynamic sampling rates, but these algorithms also need to be precisely tuned for each machine or workload (e.g., to detect pages that need to be migrated between NUMA nodes, Carrefour [11] adjusts

its sampling rate based on the workload, but all its parameters are fine-tuned for each machine).

The inability to detect most hot pages negatively impacts the performance of HeMem. In comparison, caches "work well", even without any heat detection or page migration. Once an item is updated, it is cached in DRAM. After a few seconds, most items have been updated, and the cache has reached its warmed-up state. JC-static and JC-dyn perform close-to-optimally without any fine-tuning, regardless of the number of GUPS threads. Just as HeMem, JC-dyn only manages to detect a subset of the (conflicting) hot pages. The partial detection of hot pages explains why JC-dyn is unable to reach optimal performance, but also explains why it performs slightly better than JC-static.

**Performance over time in configuration (16+2) - Caches reach steady-state performance faster:** As expected, the performance of JC-static and Linux remains constant after allocation is completed, since the number of conflicts remains the same throughout the execution. HeMem and JC-dyn require some time to reach maximum performance, in the case of JC-dyn to migrate pages to avoid conflicts, in the case of HeMem to migrate hot pages initially allocated in PMEM to DRAM and vice versa for cold pages. The time to reach this steady state performance is, however, much longer for HeMem than for JC-dyn, 38 seconds versus 2 seconds.

HeMem needs to sample memory accesses in order to perform informed migration decisions, and each migration consists in evicting a cold page to PMEM and promoting a hot page to DRAM. Migrations are thus inherently asynchronous and costly. In JC, once an item is updated, it is cached in DRAM. After a few seconds, most items have been updated, and the cache has reached its warmed-up state.

A surprising observation is that fixing conflicts requires fewer page migrations than migrating hot and cold pages. Indeed, before doing any page migration, only 0.96GB of the data conflicts, and these conflicts can be avoided by migrating 0.48GB of data. In HeMem, 4.8GB of the hot data is misplaced and needs to be brought to DRAM, which also causes 4.8GB of cold data to be migrated to PMEM. HeMem thus migrates 9.6GB (20× more data) to reach steady state performance.

**Performance over time in configuration (8+0) - A background daemon can be counterproductive:** JC-static and Linux do not use any profiling threads, and their performance is obviously the same as in configuration (8+2). The performance of both HeMem and JC-dyn becomes quite variable, and JC-dyn on average drops below JC-static in terms of performance. When the monitoring and migration threads execute on dedicated cores, JC-static and JC-dyn have similar performance, but, when they are scheduled on the same cores as the GUPS application, they have a non-negligible impact on performance. In that situation, JC-static outperforms JC-dyn by 10% on average and maintains a much more stable

throughput over time.

## 5.2.2 Random updates to distributed hot values

In the previous experiment, all the hot items were clustered on the same pages, which is the best case scenario for page migration systems. However, hot items may not be clustered together in memory. To account for this behavior, we execute GUPS with hot items randomly scattered in the allocated array. As before, we allocate a 96GB array, 10% of which is hot. We execute GUPS with 16 threads, and dedicated cores for the profiling (16+2 configuration). Figure 3 presents the performance of HeMem, Linux and JC over time. JC is 4.5× faster than HeMem.

Figure 3: 16+2 threads, hot values distributed in the array and profiling running on dedicated cores. GUPS throughput over time when the hot set size is equal to 20% of the DRAM cache (higher is better).

In this experiment, because hot items are scattered in the array, most pages contain one or a few hot items. HeMem cannot bring all the hot pages in DRAM because the number of pages that contain hot items exceeds the number of pages that fit in DRAM. Interestingly, the hot data set does not need to be large for HeMem to be unable to migrate data to DRAM. Indeed, 1% of the data being hot (1GB) translates to 134 million 8-byte values, so all pages of the array likely contain many hot values (100GB is "only" 51K 2MB pages).

Just as HeMem, JC-dyn cannot perform any useful remappings, and as a result JC-static and JC-dyn perform equally well in this benchmark. Although hot items are scattered on all pages, since data is cached at the cache line granularity, the hot items rarely overlap in the cache. In this configuration of GUPS, JC reads on average 7× less data from PMEM than HeMem.

## 5.2.3 Performance on large datasets

In the previous experiments, GUPS was configured with a 96GB dataset (2× the cache size), 10% of which was hot. In this experiment, we configure GUPS to use 480GB (10× the cache size), the maximum workload size that fits on a single NUMA node, and we vary the percentage of hot data so that the hot data either fits in the cache or not. We run HeMem with dedicated cores for profiling and migration.

Because GUPS allocates all the available memory, JC's static page allocation policy and Linux have the same performance. Indeed, JC allocates pages in an order that minimizes conflicts but, in the end, both JC and Linux end up allocating all the pages of the system.

**When the hot dataset is clustered and fits in the cache.**

We measure performance when 2% of the data is hot (9.6GB, same as in the smaller experiments). Figure 4 presents the performance of JC and HeMem compared to the performance obtained when the hot data is placed in DRAM.

As in the smaller dataset experiment, HeMem and JC's dynamic performance depends on their ability to detect hot pages. When GUPS is configured to run with 8 threads, HeMem does not reach steady state after 2 minutes of execution. In comparison, caches "work well", even without heat detection or page migration.

When GUPS is configured with 16 threads, both HeMem and JC-dyn eventually reach optimal performance. As seen earlier, caches reach optimal performance faster because avoiding conflicts requires fewer page migrations (1.7GB of the data initially conflicts in JC, 4.3GB of the data is initially misplaced in HeMem). The number of conflicting pages is higher in the 480GB experiment than in the 96GB experiments, even though the same number of pages are hot, because more pages map to the same slot. In the 96GB experiment, 2 pages map on a given slot, so a hot page has a 10% probability of conflicting with another hot page. In the 480GB experiment, a hot page conflicts with 9 other pages, each of which has a 2% probability of being hot, so it has a 16% probability of conflicting with another hot page. The higher number of conflicts explains why JC-static performs worse on bigger datasets than on smaller datasets: large datasets hinder the ability of JC-static to minimize conflicts at allocation time.

Figure 4: Hot values clustered in the array. 480GB dataset, 2% of which is hot (9.6GB). (a) With few threads, hot pages are rarely detected, and HeMem performs suboptimally. (b) With a large number of threads, JC reaches optimal performance faster than HeMem.

**When the hot dataset is clustered but does not fit in the cache.**

We measure performance when 50% of the data is hot (240GB, 5x the cache size). Figure 5 presents the performance of JC and HeMem compared to the performance that GUPS would get if all the data were to fit in DRAM. Interestingly, HeMem's performance slightly increases at the beginning of the benchmark as it brings hot pages in the DRAM cache. JC's performance slightly decreases as the cache fills with dirty data. Regardless of the policy, GUPS end up doing most of its memory accesses in PMEM because most of the data does not fit in the cache. In their steady state, all solutions have the same performance.

Figure 5: Hot values clustered in the array. 480GB dataset, 50% of which is hot (250GB). JC and HeMem do most of their accesses in PMEM because the hot dataset vastly exceeds DRAM capacity, which explains the low overall performance.

**When the hot dataset is not clustered.**

Figure 6 presents the performance of GUPS when the hot data is not clustered. As in the smaller experiment, HeMem cannot bring the hot data to DRAM and performs most of its accesses in PMEM. The performance of JC depends on the likelihood of conflicts. When a small percentage of the data is hot (2%, 9.6GB), then conflicts in the cache are unlikely. When most of the data is hot, JC also performs most of its accesses in PMEM and has the same performance as HeMem.

Figure 6: Hot values distributed in the array, 480GB dataset. The performance of JC depends on the percentage of hot values. Because hot values are spread on most pages, HeMem cannot improve performance and performs suboptimally.

## 5.2.4 Summary

In summary:

- + Hardware caches perform well, even without any active monitoring and page remapping. Software migration is highly dependent on its ability to detect hot pages.
- + Hardware caches reach steady-state performance faster than software migration.
- + Hardware caches often vastly outperform software migration when working with scattered small hot items.

## 5.3 BC

In this section, we evaluate the performance of BC, running with as many threads as cores, using the default Linux page allocator, HeMem and JC. Figure 7 presents the average duration of an iteration of the betweenness centrality algorithm.

Figure 7: BC, average duration of an iteration, in seconds (lower is better). Linux-DRAM is the performance of BC when all data is manually allocated in DRAM. Linux-DRAM runs out of memory on BC 27 and BC 28. JC-static outperforms HeMem and JC-dyn.

**When the hot data fits in DRAM** With a scale of 26, BC allocates 35GB of memory and fits in DRAM. With a scale of 27, BC allocates 70GB, but then only actively accesses 45GB, so its "hot" dataset also fits in DRAM.

We confirm the results of the original HeMem paper: HeMem is faster than Linux in these two configurations. However, JC-static outperforms Linux and HeMem by up to  $3.2\times$  and  $2\times$  respectively. On BC 26, JC-static matches the performance of manually allocating all the data in DRAM (Linux-DRAM in Figure 7).

The performance differences are explained by the nature of the processing performed by BC. BC is an OpenMP application, and each of its threads performs a fixed fraction of the computation. The monitoring used by HeMem and JC-dyn uses two CPU-intensive threads, and these two threads compete for CPU with BC's threads. Because BC's threads frequently wait for each other in barriers, interrupting a single thread causes the whole application to be delayed at barriers. When run with HeMem or JC-dyn, BC 26 spends 50% of

its time waiting at barriers. In comparison, JC-static has no overhead during the execution of BC, BC's threads progress at the same pace and spend only 2.5% of their time at barriers.

The BC example again illustrates the difficulty of fine-tuning software-migration systems. In BC, we found that the optimal performance was reached when dividing the default sampling rate by  $10\times$  and performing page cooling once every second. In that configuration, the HeMem and JC-dyn versions of BC 26 match that of JC-static in performance, and for BC 27 they improve from 60% slower to 10% slower. However, with such a low sampling rate, no hot page is detected in the previously tested configurations of GUPS, resulting in JC-static being  $4\times$  faster than HeMem in that benchmark.

The poor performance of Linux is explained by conflicts in the DRAM cache. Conflicts between hot pages are rare (on average 500MB of hot pages conflict in BC 26), but these conflicts are not evenly distributed between threads: some threads end up manipulating pages that mostly conflict, while others manipulate pages that mostly do not conflict. Threads impacted by conflicts slow down the whole application because the fast threads spend most of their time waiting at barriers. We measured that threads spend on average 63% of their time waiting at barriers in BC 26.

**When the hot data does not fit in DRAM** With a scale of 28, BC allocates 140GB of memory and accesses 90GB of it. In this configuration, JC-static is  $5\times$  faster than HeMem, and HeMem is slower than the default Linux page allocation mechanism.

The low performance of HeMem and JC-dyn is again explained by the interference between their monitoring threads and BC, and pressure put by page migrations on PMEM. HeMem copies data from DRAM to PMEM using DMA, which has low CPU overhead, but still increases contention on PMEM. HeMem ends up migrating 40GB of data during the execution of BC 28, continuously putting pressure on PMEM, and exacerbating the imbalance issues observed at scale 26 and 27. At scale 28, on average threads spend 65% of their time waiting at barriers. JC-dyn performs better than HeMem on BC 28 because it creates less contention on PMEM: JC-dyn only infrequently migrates data (on average 4GB per run). Its overhead comes mostly from monitoring memory accesses and cooling pages.

JC-static performs well because it is able to avoid most conflicts at allocation time. Indeed, BC mostly operates on two arrays: a 10GB array is frequently accessed, the other one less so. JC-static allocates the pages of the frequently accessed array so that they do not conflict with each other, effectively minimizing conflicts without the need for any migration. It may seem "lucky" that the hot data was allocated at once, which causes JC-static to place all hot pages in different cache bins, but we found this pattern to be extremely common in HPC applications (e.g., all the NAS applications start by allocating large arrays, only a subset of which are hot).

Figure 8: Masstree throughput (higher is better).

**Summary** Software-based migration requires monitoring memory accesses to perform informed migrations. The overhead of this monitoring can have cascading effects on HPC applications that rely on barriers to synchronize their threads. In contrast, it is possible to minimize conflicts in hardware caches at allocation time, without any profiling. Hardware caches thus vastly outperform software migrations when CPU overheads need to be avoided.

## 5.4 Masstree

We configured Masstree to execute with a 120 GB database, and we use 16 threads to avoid competition for CPU between Masstree’s threads and the profiling and migration threads, which run on dedicated cores. The YCSB workload used by Masstree uses 128B items (1 billion items in total) and follows a Zipfian distribution: 20% of the dataset is accessed 80% of the time. Most of the accesses thus target the index (5GB) and a subset of the values (25GB).

### 5.4.1 Performance

**Throughput** Figure 8 summarizes the performance of Masstree on the YCSB workload. In both applications, JC outperforms Linux and HeMem by up to  $2\times$ .

The memory access behavior of Masstree is similar to that of GUPS when the hot items are randomly scattered in the allocated array. During initialization, items are inserted in the key-value store in random order. It is thus possible for a hot value to be allocated next to a cold value. Similarly, the nodes of the index are populated in random order, and it is possible for a hot node to sit next to a cold one. Because the hot data is scattered on all pages, it is not possible to bring the hot dataset to DRAM.

In the case of GUPS with distributed hot values, HeMem could not improve the performance of the application at all because hot items were uniformly hot. In Masstree, the index is slightly hotter than the values, and values are accessed in a Zipfian way. HeMem thus manages to migrate some of the "hottest" pages to DRAM, but 45% of the memory accesses performed by Masstree still hit PMEM. In comparison, hardware caches operate at the cache line granularity, and the

hottest nodes and values are unlikely to conflict. On average, only 15% of the memory accesses hit PMEM with JC-static.

JC-dyn performs marginally better than JC-static because it detects that the pages used by the index are hotter than the pages used by the values. The difference with JC-static is negligible (14% of the data found in PMEM vs 15%).

It may seem surprising that migrations do not improve performance and that statically minimizing conflicts is enough to achieve close to optimal performance in Zipfian workloads, but conflicts between the hottest items are extremely unlikely (items are only 128B each in a 48GB cache). The benefit of adding active monitoring and conflict avoidance is thus negligible on average.

**Latency** The migrations performed by HeMem and JC-dyn have an impact on the observed latencies. Table 3 summarizes the latency spikes observed while running YCSB. While all systems have excellent 99p tail latency, the migration daemon pre-empts the Masstree threads, sometimes delaying the processing of a request by up to 4ms. Even though we use fewer threads than cores, the threads are not pinned to cores. The scheduler sometimes schedules two threads on the same core, explaining the pre-emption delays. The phenomenon happens when the scheduler tries to schedule threads that frequently block and unblock, such as the migration daemon.

Configuration	99p	Maximum latency
Linux	10us	10us
HeMem	10us	4ms
JC-static	10us	10us
JC-dyn	10us	4ms

Table 3: Maximum latency observed on the YCSB workload.

### 5.4.2 Performance over time, impact of the sampling rate

Both JC and HeMem perform better after a warm-up period: the DRAM cache needs time to cache accessed data, and HeMem needs time to detect and migrate hot pages to DRAM. Figure 9 presents the evolution of the performance of YCSB C. We initialize Masstree by inserting keys in random order, and then launch multiple iterations of YCSB C. Each iteration of YCSB C performs 10 million lookups, and keys

are accessed following a Zipfian distribution. For HeMem, we compare 4 configurations with varying sampling rates. *HeMem-1K* corresponds to the highest sampling rate, with 1 sample analyzed every 1,000 memory accesses, and *HeMem-50K* to the lowest sampling rate. The default rate of HeMem is *HeMem-10K*. We also evaluate the impact of the sampling rate on JC-dyn (*JC-10K* and *JC-50K*).

Figure 9 illustrates the impact of the sampling rate on performance. When the sampling rate is too high, the overhead of sampling negatively impacts performance (*HeMem-1K*). Even when the profiling and migration threads run on dedicated cores, the other cores still handle the interrupts generated by the performance monitoring units of the CPU when a memory access is sampled. These interrupts explain the lower performance of HeMem-1K. When the sampling rate is too low, many accessed pages are never marked as hot and are never migrated to DRAM (*HeMem-50K*). In this benchmark, the optimal performance of HeMem is reached when the sampling rate is close to the default sampling rate (*HeMem-5K*, *HeMem-10K*).

JC is less impacted by such considerations because its performance is good even without any conflict avoidance daemon. JC-dyn (*JC-50K*) also fails to detect any conflicts, but its performance reaches 3% of our optimal configuration after 100s of execution. Even without any conflict avoidance daemon (*JC-static*), JC is only 5% slower than the optimal configuration.

Figure 9: Performance of YCSB C. Every iteration of YCSB C runs 10 million queries.

### 5.4.3 Summary

Hardware caches outperform page-based migrations when working with scattered small items. Again, caches tend to "work well" when conflicts are minimized at allocation time, and their performance is not strongly dependent on monitoring memory accesses to find and fix possible conflicts.

## 5.5 Silo

Silo is configured to execute a TPC-C workload on a 100GB database. The TPC-C workload is heavily skewed: most of

the TPC-C data consists of the description of (sold) items, but most of the memory accesses are done on the customer and warehouse metadata. Figure 10 summarizes the performance of Silo, varying the number of threads.

Due to the order of initialization of the database, most of the hot working set used by Silo is allocated at the beginning of the execution. JC is able to allocate hot pages in a non-conflicting way, and HeMem allocates most of the hot pages in DRAM. Both JC and HeMem perform equally well on this workload, but better than Linux.

Figure 10: SILO (TPC-C) throughput (higher is better)

## 5.6 NAS benchmarks

Figure 11 presents the performance of the NAS benchmark suite running with Linux, HeMem and JC. We only include applications that executed in less than 24 hours on our machine.

Most HPC applications follow the same pattern as BC: large arrays are allocated and initialized at the beginning of the application, and then only a subset of the arrays is used during the execution of the algorithm. When the hot arrays fit in the DRAM cache, JC and Linux outperform HeMem by up to 2.8 $\times$  (class D size of the NAS benchmark, on the left of Figure 11). As BC, the NAS applications use OpenMP to parallelize their computation, and the profiling and migration threads of JC-dyn and HeMem have cascading effects on the performance of threads waiting at barriers.

Figure 11: NAS application runtime (lower is better). JC outperforms Linux and HeMem except when the hot set size vastly exceeds the cache size (CG.E, MG.E).

The NAS benchmarks also allow us to demonstrate the limitations of our approach. On MG.E, HeMem runs 1.8 $\times$  faster than JC, despite its profiling overhead. MG uniformly accesses a large array and does not benefit from DRAM caching:

most of the cached data is evicted before being reused. It is well known that applications with uniform access to large data sets or streaming access patterns do not benefit from caching. For instance, in large streaming workloads, the streamed content keeps replacing itself in the cache, and data is always evicted before being re-read. In the worst case scenario, with DRAM caching, 100% of the memory accesses end up in PMEM. With software-based migration, some of the data is allocated in DRAM, and some of the memory accesses are resolved in DRAM.

Such applications are hard to support efficiently at the kernel level because no data is hot, and no conflict is particularly worthy of fixing. However, caching could be improved at the hardware level. CPUs already implement special cases for streaming workloads in their CPU caches: most recent CPUs implement QLRU, in which data that was cached by a streaming thread is evicted before data cached by threads performing random accesses [7]. Such a strategy could be implemented in a DRAM cache as well, for instance by avoiding caching large streams. The performance of the DRAM cache could also be improved by optimistically flushing dirty data to PMEM, when PMEM is idle, to reduce the latency of future evictions of dirty data.

**Summary** JC-static equals or outperforms Linux and HeMem on most NAS benchmarks. When, however, an application does not have a clear hot dataset, but rather streams or accesses large datasets that do not fit in the DRAM cache, DRAM caches are inferior to software migration.

## 6 Discussion

**Recommendations** From our experience, working with hardware caches and page migration systems, no solution fits all workloads, but the general rule of thumb is:

- Systems that rely on monitoring memory accesses are finicky to configure and can introduce huge performance overheads if not properly fine-tuned. In our experience, it is more likely for a migration daemon to be misconfigured than to perform well. This observation is not unique to this paper nor to the monitoring done by HeMem and JC-dyn. For instance, by default, most Linux distributions deactivate AutoNUMA, the page migration daemon of Linux because it negatively impacts most workloads. So, unless working with a known and predictable workload, we recommend using hardware caches with a static page allocation policy.
- When working with very large datasets that do not have a clear hot subset, caches should be avoided.

A surprising observation of this paper is that, for many workloads, large hardware caches perform close to optimally with a static page allocation policy, and that having a conflict

avoidance daemon is unnecessary. This seemingly counter-intuitive observation is explained as follows: conflicts that would be fixed by a daemon happen between frequently accessed cache lines. The number of such cache lines has to be small compared to the size of the DRAM: at current DRAM speed, it takes a few seconds to read the full DRAM cache, so any dataset that is large compared to the DRAM cache size cannot be "frequently" accessed. Because the number of frequently accessed cache lines is small compared to the DRAM size, the likelihood of problematic conflicts is small and a conflict avoidance daemon is more often a source of overheads than useful.

It is possible to craft adversarial workloads for which the static page allocation policy underperforms, and in which the dynamic policy performs well. In hand-crafted corner-case workloads, we found that running the conflict avoidance daemon infrequently and with a low sampling rate was enough to detect the most problematic conflicts and get close-to-optimal performance.

**Applicability to systems other than DRAM+PMEM** To the best of our knowledge, Intel's Memory Mode is the only currently commercially available hardware DRAM cache, so we focused the performance evaluation on DRAM+PMEM systems. We believe that the findings of this paper apply more broadly. Indeed, we have shown that tracking memory accesses at the software level is costly (profiling overhead) and requires migrating a large amount of data (migration overhead). These observations are fundamental limitations of software migration and independent of the underlying technology. If anything, software migration cost is likely to increase in future hardware with larger and faster memory – higher sampling rates will be required to detect and migrate more pages faster, incurring even more CPU overhead.

In comparison, provided that conflicts are minimized, hardware caches tend to "work well by default". Because hardware caches perform close to optimally even without any active conflict avoidance daemon, they can be operated with limited or no CPU overhead, and are more likely to perform well on future hardware.

## 7 Related Work

**Software-managed migration** Previous work focused on managing tiered memory systems at the software level. HeMem [20] is the state-of-the-art page migration system for DRAM+PMEM systems. HeMem focused on reducing the overhead of page migration, but still suffers from profiling and metadata overheads. Over the years, multiple metrics have been explored to accurately infer the heat of pages. Thermostat [1] and AutoNUMA [9] compute heat by sampling the accessed bit of the page table. Nimble [25] uses the OS active/inactive page list. TMO [23] counts the number of cycles wasted waiting for unavailable resources. HeteroOS [14]

uses hints from guest OSes to help the host OS perform informed page placement decisions. X-Mem [12] uses hints from the application developers to compute the hottest pages. UniMEM [24] uses performance counters and hints from the MPI runtime. Carrefour [11] gathers high-level performance metrics from the CPU (e.g., average latency of memory accesses) to tune the frequency of memory access sampling. All these works show that measuring heat accurately is a hard problem, but crucial to the performance of software migration. In this paper, we have shown that hardware caches are less sensitive to heat measurement and can even operate efficiently without if conflicts are statically minimized at page allocation time.

**CPU cache management systems** In this work, we assume the DRAM cache to be a 1-way directly mapped cache. This assumption holds true on current systems, and is likely to hold true in the future – for large caches DRAM, 1-way caches have been shown to outperform multi-way caches [18].

Multiple strategies have been proposed for maximizing the efficiency of CPU caches. In the early 90s, Kessler et al. [15] simulated the relationship between page placement and conflicts in caches and showed that it is possible to reduce the number of conflicts at allocation time. Bershad et al. [5] simulated the impact of page migration on the efficiency of caches. The generalization of caches with large associativity (many-ways CPU caches) allowed CPUs to keep a few conflicting cache lines in their caches and reduced the impact of system-level page placement on the performance of caches. These techniques have gradually been replaced by much coarser-grain page coloring techniques that partition the cache to avoid cache trashing between users or applications [6, 26] or by scheduling techniques to better share the cache between cache-intensive and cache-friendly applications [2, 21, 27]. It is interesting to note that current DRAM caches resemble the state of large CPU caches simulated in the 90s, and that page allocation policies matter in current tiered memory systems. In this work, we chose to avoid partitioning the cache. Adding page coloring on top of conflict minimization could be implemented to give a larger portion of the DRAM cache to an application.

The impact of page placement on cache performance has also been studied on Intel Xeon Phis. Xeon Phis can be configured to use a large MCDRAM pool as a hardware cache that sits in front of DRAM. Intel’s Zonesort [28] aims at limiting conflicts in the MCDRAM pool at page allocation time. In its first release, ZoneSort [10] periodically sorted the list of available free pages in an order that limits conflicts with already allocated pages. The module incurred significant CPU overhead and only partially limited conflicts. A later version of ZoneSort [28] allocated pages from bins in a round-robin order, an approach which does not always minimize conflicts when pages are not freed in the same order as they are allocated. JC always allocates pages from the bin with the

lowest heat. Zonesort was thought of as a temporary solution for applications that have not been adapted to the Xeon Phi architecture. In our paper, we show that the hardware management of a tiered memory system, combined with low-overhead conflict avoidance techniques, outperforms traditional page migration on a wide range of workloads. We believe that this novel counter-intuitive conclusion is important in the widening context of cacheable disaggregated memory.

## 8 Conclusion

We have demonstrated that hardware caches offer better performance than software management of tiered main memory systems, provided minor modifications of the operating system. We have shown that, surprisingly, statically minimizing conflicts at allocation time is sufficient to avoid most conflicts between hot pages in the cache.

# TAILCHECK: A Lightweight Heap Overflow Detection Mechanism with Page Protection and Tagged Pointers

Amogha Udupa Shankaranarayana Gopal   Raveendra Soori   Michael Ferdman   Dongyoon Lee

*Stony Brook University*

## Abstract

A heap overflow vulnerability occurs when a program written in an unmanaged language such as C or C++ accesses a memory location beyond an object allocation boundary. Malicious users may exploit this vulnerability to corrupt an adjacent object in memory, creating an entry point for a security attack. Despite decades of research, unfortunately, it still remains challenging to detect heap overflow vulnerabilities in real-world programs at a low cost.

We present TAILCHECK, a new lightweight heap overflow detection scheme that leverages page protection and pointer tagging. When an object is created, TAILCHECK allocates an additional page-protected shadow object, called a TailObject, placing the distance from the object to its TailObject as a tag stored in the unused high-order bits of the object pointer. For every access to the original object, TAILCHECK performs an additional memory access to the TailObject, whose address is computed using the tag. Heap overflows are detected as page faults when an access occurs beyond the TailObject. We evaluated TAILCHECK with four server applications (apache, nginx, memcached, redis) and the SPEC CPU2017 and SPEC CPU2006 benchmarks, successfully finding heap overflows in SPEC CPU2017 gcc. TAILCHECK experiences 4% and 3% run-time overhead for the average and tail (99%) latencies for server applications; and only 33% and 29% run-time overhead for SPEC CPU2017 and SPEC CPU2006, respectively, less than the state-of-the-art solution.

## 1 Introduction

A heap overflow [47,48] is an anomaly that occurs when a program attempts to access a memory location beyond the bounds of its allocated memory. This type of vulnerability is commonly found in programs written in unmanaged languages such as C and C++, as these languages allow programmers to directly manipulate pointers without providing compile-time (*e.g.*, as in Rust) or run-time protection (*e.g.*, as in Java or Go). A malicious user may exploit a heap overflow vulnerability in a C or C++ program to perform a variety of security

attacks [57,58], including corrupting code pointers to divert control flow or leaking sensitive information.

Today, many critical software systems—such as server applications and operating systems—are developed in unsafe languages. Programming errors in these systems can therefore lead to heap overflow exploitation. For example, a vulnerability in the `nginx` web server (CVE-2014-0133) allowed attackers to send a specially-crafted request that caused a heap overflow, allowing them to execute arbitrary code on the server. The `mysql` database code had a vulnerability (CVE-2021-2429) which allowed attackers to send a specially-crafted request that caused a heap overflow, potentially gaining access to the data or taking control of the database. A heap overflow in the PHP programming language related to encryption (CVE-2022-37454) could be used to remotely execute arbitrary code on a web server. The prevalence of heap overflow vulnerabilities in deployed software systems highlights the need for effective run-time techniques to protect production systems against exploitation, even when running vulnerable software.

Several systems have made significant strides toward run-time mitigation of heap overflows. AddressSanitizer [54], the state-of-the-practice solution, incurs high run-time overhead: 80% (geometric mean) slowdown for SPEC CPU2006 applications [45]. Modern operating systems offer heap overflow protection by allocating an object at the boundary of a virtual memory page and adding a protected page (with no access permission) after it; this feature is available in Linux as Electric Fence [49] and in Windows as PageHeap [61]. However, allocating just one object per protected page suffers from extremely large memory overhead, along with high run-time cost due to frequent TLB misses. Delta Pointers [28], the state-of-the-art technique, achieves the lowest run-time overhead (35% for SPEC CPU2006), but requires restricting the address space of the protected application. Delta Pointers reserves the  $N$  most significant bits (32, by default) for pointer tagging and supports only a  $48 - N$  bit address space for 64-bit architectures. This limits Delta Pointers' applicability for modern software: it cannot be used for server software

with many-gigabyte footprints and even fails for the reference inputs of `xz` and `mcf` in the SPEC CPU2017 suite.

In this work, we present TAILCHECK, a new lightweight heap overflow detection scheme that leverages a custom memory allocator, OS-based page protection, and compiler-directed pointer tagging. When an object is created, TAILCHECK allocates an additional shadow object, called a TailObject, at the boundary of a page whose subsequent page is protected by the OS. The TAILCHECK memory allocator returns a tagged pointer in which the otherwise unused most significant bits (e.g., 16 bits for a 64-bit architecture with 48-bit address space) encode the distance from the original object to its TailObject, keeping the address of the original object unmodified in the low-order bits as usual. A TAILCHECK compiler pass instruments each dereference of a tagged pointer, using the embedded tag to compute the shadow address within the corresponding TailObject and inserting an additional memory access to the shadow address alongside each access to the original object. In the event of a heap overflow, the shadow memory accesses reach beyond the bounds of the TailObject, causing a page fault and triggering the OS to terminate the program. This prevents the exploitation of heap overflow vulnerabilities (both over-writes and over-reads) and ensures the integrity and confidentiality of the system.

The TAILCHECK tags allow many objects to share space used by the TailObjects and the OS-protected pages, limiting the memory overhead of the technique and eliminating the performance overheads of frequent system calls to protect pages during memory allocation. To further reduce run-time overhead, TAILCHECK performs three compile-time optimizations to prune the shadow accesses for heap accesses that are statically proven to be safe.

TAILCHECK makes use of well-known page protection and pointer tagging techniques, yet it does not share the limitations of prior solutions. TAILCHECK achieves low run-time overhead by using page protection for heap overflow detection, but unlike Electric Fence and PageHeap, it allows multiple small objects to be co-located on a virtual memory page. TAILCHECK uses pointer tagging, but unlike Delta Pointers, it allows a program to utilize the full address space by only re-purposing the otherwise unused most significant bits.

We implemented TAILCHECK by extending the *mimalloc* allocator [33] and developing LLVM [31] compiler passes for code instrumentation. We evaluated TAILCHECK with four server applications (`apache`, `nginx`, `memcached`, `redis`) and the SPEC CPU2017 and SPEC CPU2006 benchmark suites. Interestingly, TAILCHECK identified an out-of-bounds read in SPEC CPU2017 `gcc` (v4.5.0), a known bug with an available patch [1], yet the patch is not present in SPEC CPU2017 v1.0.5. For performance, TAILCHECK experiences 4% and 3% run-time overhead for the average and 99% tail latencies for server applications. TAILCHECK exhibits 33% (geometric mean) run-time overhead and 3% memory overhead for SPEC CPU2017. TAILCHECK exhibits 29% (geometric mean) run-

time overhead for SPEC CPU2006, lower than Delta Pointers, the state-of-the-art compiler-based solution with the lowest previously-reported run-time overhead (35%).

This paper makes the following contributions:

- To the best of our knowledge, TAILCHECK is the first lightweight heap overflow detection scheme based on page protection that does not place one object per page.
- TAILCHECK introduces a new pointer tagging scheme for heap overflow detection, which encodes distance metadata only in the otherwise unused pointer bits and thus does not restrict the application address space.
- An evaluation of TAILCHECK demonstrates that it incurs low run-time and memory overheads and supports applications with large many-gigabyte memory requirements.

## 2 Background & Motivation

This section briefly describes the background on heap overflows, discusses the threat model we assume in this work, and highlights the need for a new solution.

### 2.1 A Heap Overflow Vulnerability

The lack of run-time and compile-time heap overflow protection in C and C++ exposes many critical software systems to security threats. Stack-based buffer overflows have received significant early attention from both academia and industry. Mature mitigations using stack canaries [11] and shadow stacks [60] are readily available: for example, GCC and Clang have built-in support with the `-fstack-protector` and `-fsanitize=safe-stack` compiler flags. On the contrary, standard solutions for heap overflows have not yet been settled, with solutions offering trade-offs in run-time and memory overheads, soundness, and completeness (§2.3).

Heap overflows are responsible for many critical real-world security problems. A heap overflow *over-write* is particularly critical as it may allow malicious users to divert the control flow of a victim program or gain privilege escalation. For instance, a heap overflow over-write vulnerability is found in `sudo` (CVE-2021-3156), a widely-used utility on Unix-like operating systems, which enables a user to run programs with the security privileges of another user. This heap overflow was particularly critical in that an attacker could control not only the size of the buffer that can be overflowed but also the size and contents of the overflow. As a result, when exploited, the vulnerability could allow an unprivileged malicious user to gain root privileges on a vulnerable host.

A heap overflow *over-read* can lead to information leakage. The Heartbleed [19] vulnerability in the popular OpenSSL cryptographic software library (CVE-2014-0160) is a representative example. A missing bounds check in the SSL/TLS heartbeat extension could be exploited to reveal up to 64KB of memory, which may include private keys and other secrets.

## 2.2 Threat Model

In this work, we address the threat of overflows on heap-allocated objects. We assume an attacker can feed a crafted malicious input to a victim program to exploit a heap overflow vulnerability. We mitigate heap overflows (both over-write and over-read) that occur in application and library code that can be instrumented with our tool, providing integrity and confidentiality when the underlying software contains vulnerable code. We provide no protection for uninstrumented code such as third-party libraries. We do not consider other memory safety violations such as use-after-free or uninitialized read vulnerabilities.

## 2.3 Motivation: Haven't we solved it yet?

Given the critical implication for security, many solutions have been proposed for mitigating heap overflows. We present several representative works, discussing their limitations and the lessons that we draw upon when designing TAILCHECK. A more comprehensive related work discussion follows in §8.

The idea of leveraging a virtual memory *protected page* to detect a heap overflow dates back to 1987. Electric Fence [49], proposed by Perens and now included in Linux, was the first to place allocated objects immediately before protected pages, which are configured by the OS to trigger a hardware page fault when accessed. Reads or writes beyond the allocated object would land on the protected page, triggering a fault and allowing the OS to mitigate the heap overflow. Successors to Electric Fence, including DUMA [5], DYBOC [56], OSX's libmalloc [35], and Windows' PageHeap [61] follow a similar design. However, despite its simplicity, the approach of allocating one heap object per virtual memory page has unacceptable memory overhead. Moreover, this approach incurs large run-time overheads from multiple sources: performing system calls to protect a page on every heap allocation is expensive, spreading heap allocations across many pages results in excessive TLB misses, and placing objects at common offsets from the end of memory pages increases data cache contention. For example, Liu *et al.* [36] reports Electric Fence incurs a 7x slowdown for the PARSEC benchmarks [7]. As a result, the idea of using protected pages for run-time heap overflow mitigation has lost its attraction and is rarely found outside of debugging environments. Using protected pages can offer heap overflow protection without explicit metadata lookups and bounds checks, yet require a new solution that supports placing multiple objects per virtual memory page and avoids frequent page protection system calls.

AddressSanitizer (ASan) [54] is an alternative approach with lower run-time overhead. ASan manages a fine-grained inaccessible region called a *redzone* after each allocated object by maintaining a disjoint shadow (metadata) memory space. On each memory access, ASan looks up the metadata space and checks if the target location falls in a redzone. Other

prior solutions, notably SoftBound [40], keep *base and bound* metadata in a shadow memory space. On each memory access, SoftBound performs a metadata lookup and explicitly checks that the instrumented access falls within the object bounds. Although the implementation details differ across these systems, they all share two downsides. First, the metadata lookup (comprising additional shift, add, and load instructions) and bounds check (including comparison and branching instructions) have significant run-time overhead. Second, the redzones and metadata store incur significant space overheads. For example, for the SPEC CPU2006 benchmarks, Oleksenko *et al.* [45] report 1.8x run-time and 4x memory overheads for ASan, and 2x run-time and 3x memory overheads for SoftBound. Such performance overheads and memory capacity requirements are unacceptably high for modern large-memory performance critical applications which would most benefit from run-time heap overflow protection.

To reduce the metadata overheads and/or to facilitate metadata lookup, researchers proposed *pointer tagging* techniques that keep metadata in the high-order bits of a pointer itself (*e.g.*, unused 16 bits in 64-bit architecture). For instance, Baggy Bounds [2] tags a pointer with the encoded size of an object. However, Baggy Bounds still requires expensive array table look-ups and bounds checking on pointer arithmetic. Taking one step further, Delta Pointers [28] remove the bounds check (comparison and branching instructions) by transforming the heap overflow detection problem into an integer overflow detection problem, managing pointer tags in a way that would cause out-of-bound pointer arithmetic to set an overflow bit in the tags, thereby making such pointers “uncanonical” and causing the MMU to generate a fault on dereference. Delta Pointers are considered the state-of-the-art software-only solution based on its low run-time overhead, exhibiting only 35% slowdown for SPEC CPU2006 benchmarks. However, Delta Pointer tags must include the distance from the current pointer to the end of an object, requiring significantly more than 16 bits for large objects. To work around this limitation, Delta Pointers shrink the process address space. By default, Delta Pointers use a 32-32 bit split, supporting applications with up to 4GB of address space. Delta Pointers offer a glimpse of a low-overhead solution without metadata lookups or bounds checks, but are still limited in terms of practicality due to its address space restrictions.

## 3 TAILCHECK Design

TAILCHECK extends the memory allocator and compiler to produce executables that are protected against heap overflow exploitation at run-time. Whenever a programming error leads to an access that overruns the end of a heap-allocated object, TAILCHECK ensures that a hardware page fault is triggered, causing the operating system to mitigate a potential attack by trapping the fault. Although this effect can be achieved by placing each heap object at the end of its own virtual memory

Figure 1: TAILCHECK allocates a (shadow) TailObject at the boundary of a protected page and tags object pointers with the distance between the original and shadow objects.

page (followed by a protected page) [49], such an approach is prohibitively expensive; allocating a virtual memory page for each heap object results in massive heap capacity bloat, while performance is severely impacted at the time of allocation (due to configuring a protected page on each allocation) and also at the time of use of the allocated object (due to a significant increase in TLB and cache pressure).

Rather than coupling each heap object with its own protected page, TAILCHECK reserves one TailObject and a protected page per memory region managed by the heap allocator. Figure 1 depicts this arrangement. When the TAILCHECK memory allocator requests a region of memory from the OS, it reserves space for the TailObject and configures a protected page at the end of the region. After this, the allocator places dynamically allocated heap objects, such as A and B, as usual.

To trigger a page fault on a heap overflow, the TAILCHECK compiler instruments the application code to perform a shadow memory access to the TailObject alongside each load and store operation to the original heap object. Figure 1 shows that the base address of object A is a known distance  $p$  away from the base address of its TailObject. The base address of object B is similarly a known distance  $q$  from its TailObject. To compute the address for the shadow memory access, the compiler simply adds the offset ( $p$  or  $q$  in this example) to the address of the original access, as shown in Figure 2. Although an access beyond object A (e.g., to the address  $p210$ ) would erroneously read or write data belonging to object B, the corresponding shadow access (e.g., to the address  $0210+p$ ) that TAILCHECK performs before the original object access will exceed the bounds of the TailObject, attempting to access the protected page and triggering a page fault.

To store the distances (such as  $p$  and  $q$ ) from the moment when heap objects are allocated to the time when they are accessed, TAILCHECK uses tagged pointers. We leverage the otherwise unused high-order bits of pointers to store the distances, using the compiler to emit code that masks these high-

Figure 2: TAILCHECK adds shadow memory access for the TailObject. A heap overflow beyond object A is detected as a page fault on the shadow access beyond its TailObject.

order bits before performing an access to the original object and adds the distance encoded in these bits to compute the address of the shadow access. Modern x86 and ARM systems use a 48-bit address space, leaving 16 unused bits in 64-bit pointers, thereby allowing TAILCHECK to store distances for allocator regions of up to 64KB. A key advantage of this approach is that the distances encoded in the tagged pointers are propagated implicitly, requiring code instrumentation only at the time of pointer dereference or comparison. Notably, TAILCHECK still protects large heap objects allocated within their own allocator regions by using protected pages and setting the distance for shadow accesses to 0, therefore treating all accesses uniformly, but incurring a small overhead due to the duplication of memory accesses to the large objects.

We note that reserving space for the TailObjects is necessary because shadow memory accesses for stores write data into the TailObject space. Although these data are never used, if the space were not reserved, the application could allocate an unrelated object in the same space (at the end of the managed region), causing the shadow stores to clobber that object. An alternative implementation, which uses shadow loads for the corresponding original object stores, is possible. At first glance, this arrangement would eliminate the memory overheads of TAILCHECK. However, this approach can have significant performance drawbacks because loads are on the critical path of the processor pipeline and have a higher execution cost compared to stores.

### 3.1 TAILCHECK Code Instrumentation

We use the compiler to add TAILCHECK to executables. The compiler performs three tasks: it replaces memory allocation calls with the TAILCHECK allocator, adds shadow memory accesses at pointer dereference sites, and masks pointer tags when interacting with uninstrumented code (e.g., shared libraries). We detail these tasks below.

**Allocator Injection.** TAILCHECK uses a custom memory allocator. Unlike regular allocator functions that return a pointer carrying the address of the allocation in virtual memory, the TAILCHECK allocator functions return a tagged pointer. The tag is inserted into the otherwise unused high-order bits of the returned value, and corresponds to the distance between the address of the allocated heap object and the address of its corresponding TailObject.

Replacing the memory allocator provided by the standard library is traditionally done with the dynamic linker. However, TAILCHECK needs its custom allocator only for the heap objects that it protects. To inject its custom allocator during code instrumentation, the TAILCHECK compiler identifies allocator calls (*e.g.*, `malloc`, `new`, `strdup`, etc.) and replaces them with their TAILCHECK allocator equivalents. Any code linked into the executable, but not instrumented with TAILCHECK, continues to use the unmodified system allocator.

For each allocator-managed memory region requested from the OS by the TAILCHECK allocator, we reserve space for the TailObjects at the end of the region and `mprotect` the virtual memory page immediately following the region. TAILCHECK requires for the TailObject reservation at the end of the managed memory region to be as large as the largest object allocated within that region. In practice, it is common for modern allocators to separate memory regions by *size class*, dividing each region into slots of this size and allocating one object per slot. With this strategy, the TAILCHECK allocator can simply reserve the last slot within each managed memory region. Notably, the distance encoded in the pointer tags is computed for the TailObject address equal to *address\_of\_protected\_page minus size\_of\_allocated\_object*, which lands in the middle of the reserved slot whenever the allocated object size is smaller than the size class, or lands at the start of the reserved slot when the allocated object size equals the size class.

When the requested allocation size is larger than the largest allocator size class (*e.g.*, one that requires multiple virtual memory pages), modern allocators switch to a large-object allocation mode where a separate memory region is requested from the OS. When handling large-object requests, the TAILCHECK allocator will `mprotect` a page immediately following each allocated large object and compute the returned pointer as *address\_of\_protected\_page minus size\_of\_allocated\_object*, effectively falling back to the behavior of Electric Fence. For such large-object allocations, the tag of the returned pointer is set to 0.

We note that, when computing TailObject addresses, we round up the *size\_of\_allocated\_object* to honor the original object's memory alignment requirements. This is useful for both correctness and performance, as we want the shadow access instructions to have the same alignment properties as their corresponding original object access instructions. As a result of this rounding, objects whose requested size is not a multiple of their alignment size will have a small (several bytes) region where heap overflows may go undetected

with our TAILCHECK implementation. We discuss the generally benign nature of such overflows and the ramifications of adding support for precise overflow detection independent of alignment constraints in §7.2.

**Memory Access Instrumentation.** The TAILCHECK compiler operates at *module* granularity, treating all pointers local to a module as tagged pointers. On every pointer dereference in the instrumented code, a tagged pointer must be deconstructed into two parts, the object address (by masking the tag) and the shadow access address (by adding the tag to the object address). A compiler pass iterates over the pointer dereferences, inserting compiler IR for tag handling and injecting the TailObject shadow accesses. Each shadow access (load or store) is performed first, immediately followed by the original object access. For both loads and stores, the same store value and load target registers can be used by the two accesses, avoiding tying up additional register resources for the shadow accesses. Compiler optimization passes are performed both before and after the TAILCHECK instrumentation pass, ensuring that all dereferences eliminated by the optimizer are not instrumented and that the address calculation code for handling the tagged pointers is optimized. The shadow accesses are marked as volatile to ensure that they are not moved or eliminated as dead code.

Pointer arithmetic with integers does not require special handling for tagged pointers. However, whenever a tagged pointer is compared (either to another tagged pointer or to NULL), the TAILCHECK compiler must mask the tag bits prior to the comparison. Similar to the case of pointer dereference instrumentation, comparison tag manipulation logic is inserted as compiler IR, allowing an optimization pass to minimize the overhead of these operations.

We note that memory access instrumentation does not differentiate between objects allocated with the regular and large-object modes. All pointers within the instrumented code are treated as tagged pointers. For large-object allocations, the tags are set to 0 by the memory allocator, resulting in minor overhead for tag manipulation and harmless shadow accesses that load or store exactly the same address as the original access. Uniform handling of tagged pointers simplifies the implementation, while the overhead of back-to-back instructions that access the same cache line is minimal in modern superscalar out-of-order processors.

**Linking with Uninstrumented Code.** Although it is theoretically possible to compile all modules of a program with TAILCHECK instrumentation, in practice, we must provide the ability to link against uninstrumented modules, such as shared libraries. In these situations, pointers passed by instrumented code into uninstrumented code (*e.g.*, library function calls that have pointers in their arguments) must have the pointer tags removed. Even if all libraries, including the standard library, are instrumented with TAILCHECK, there are still

situations where pointers are passed as arguments to system calls, also requiring the stripping of tags.

The TAILCHECK compiler performs a pass over the instrumented module to identify all function call sites. Calls to functions within the same module receive unmodified tagged pointers as arguments. However, for calls to external functions, compiler IR is inserted to mask the tags of all pointer arguments. Notably, it is safe to pass function pointers of instrumented functions to uninstrumented code (e.g., as callbacks), as any pointer arguments passed by uninstrumented code into these functions will have tags set to 0 and will execute correctly, albeit with harmless duplicated memory accesses as in the case of the large-object allocations.

TAILCHECK keeps pointers without tags in globals because they may be accessed by uninstrumented libraries. To this end, TAILCHECK identifies all pointer stores to global variables in the instrumented code and ensures that the values written into these variables are masked prior to being stored. The TAILCHECK compiler uses the LLVM instruction operand type `GlobalVariable` to identify globals (after calling `stripPointerCasts` on the operand). There is a possibility that TAILCHECK may store a tagged pointer into a global if a program uses a local alias to write to that global, potentially leading uninstrumented code to later dereference a tagged pointer stored in the global. However, we observe that accessing a global variable via a local pointer alias is uncommon in practice: during our evaluation (§6), none of the tested server, SPEC CPU 2017, or SPEC CPU 2006 applications shows any unexpected behavior (e.g., segmentation fault), which would happen if uninstrumented libraries accessed tagged pointers in globals. Thus TAILCHECK does not perform additional pointer alias (provenance) analysis. Furthermore, we treat the `environ` variable as a special case where not only the variable itself, but also the nested pointers within its structure, are written with their tags masked.

Finally, if the standard library is not instrumented with TAILCHECK, there are two classes of commonly used functions (`mem*` and `str*`) that can benefit from special handling, following the practices of previous works [28, 29, 45]. These functions are often responsible for heap overflows, making it practical to insert bounds checks at their call sites when their function bodies (part of the standard library) are not instrumented. For the *MemIntrinsics* functions (`memcpy`, `memmove`, and `memset`), we inject a TAILCHECK-like bounds check by performing a shadow access to the last byte of the arrays passed as arguments. Notably, we must first check that the `size` argument is non-zero, as the function semantics dictate that no pointer dereferences occur if the size is zero. The common string manipulation functions (e.g., `strstr`, `strchr`, etc.) return pointers. Although instrumented code handles these functions correctly (treating them like other 0-tag pointers), calling these functions effectively removes TAILCHECK protection from the pointers passed to them. To avoid losing heap overflow protection after these function calls, TAILCHECK

instruments the call sites of these functions to save the tags of the pointer arguments before the call and re-applies the tags on the returned pointers. Similarly, TAILCHECK masks tags in the return values of those functions that convert a string to a number (e.g., `strtol`) when used in arithmetic operations.

**Mixing Memory Allocators** Having the same allocator in the application and shared libraries is not a requirement for TAILCHECK. In our setup, we use `LD_LIBRARY_PATH` to ensure that all linked libraries use the TAILCHECK memory allocator, primarily to maintain performance consistency across all experiments. However, it is worth noting that libraries cannot and should not call `free()` on objects they did not allocate themselves [53]. If application code includes such a construct, it would cause failures in many scenarios (e.g., where custom allocators are used), including with the TAILCHECK allocator.

**Custom Memory Allocators** By default, TAILCHECK protects heap objects that are allocated and deallocated via standard interfaces (e.g., `malloc`, `realloc`, and `free`), replaced by `LD_LIBRARY_PATH`. Thus, there could be a heap protection granularity mismatch if an application uses a custom allocator. For example, for an application-level pool (slab) allocator, TAILCHECK may protect a `malloc`-allocated pool at a coarse granularity, not at the fine-grained custom allocation granularity. Our `nginx` server evaluation (§6) compares two cases with and without application-level pool allocations (by disabling a pool allocator using a debugging flag).

## 3.2 TAILCHECK Optimizations

To reduce the performance overheads of TAILCHECK, we apply several compiler IR optimizations that reduce the cost of instrumentation. We detail these optimizations below.

**Merging Tag Handling.** The tags of TAILCHECK tagged pointers remain constant throughout the lifetime of the pointer. When the same pointer is dereferenced multiple times within a function, potentially with different offsets (for accessing different members of the heap object), the operations to compute the `TailObject` pointers are redundant. To reduce the overhead of this common case, the TAILCHECK compiler instrumentation pass keeps track of the computed `TailObject` pointers and reuses their already computed values.

**Hoisting Tag Handling.** Heap pointers are frequently dereferenced inside loops, accessing different locations within the same heap object (i.e., if the object is an array). To reduce the overhead of tag handling, we hoist the computation of the `TailObject` pointer outside of the loop, leaving only the dereference operations inside the loop body. As a result of this optimization, the `TailObject` accesses within the loop

body exactly mimic the original object accesses, including using the same x86 scale-index-base-displacement for the shadow memory access and pushing all other TAILCHECK instrumentation overheads outside of the loop body.

**Statically Safe Dereferences.** TAILCHECK is effective at preventing heap overflow exploitation with relatively low overheads at run-time. However, while many pointer dereferences must be verified (*e.g.*, using shadow accesses to the TailObjects), some of the checks are unnecessary because static analysis of the code can guarantee that all accesses remain within the bounds of a heap object. As such, to further reduce the overhead of TAILCHECK, we adopt the *SafeAllocs* [28] static analysis implementation from the Delta Pointers work.

SafeAllocs identifies all heap allocations with statically known sizes and uses the compiler metadata to track object bounds along with the pointer corresponding pointer. Whenever such pointers are dereferenced in the code, the compiler checks if the offset of the dereference can be statistically determined and, if it can be determined and falls within the object bounds, a run-time check is unnecessary.

When SafeAlloc indicates that all accesses to a heap object are known to be safe at compile time, TAILCHECK uses the standard memory allocator for these objects and does not introduce shadow accesses for them. Some heap objects have both dereference sites that are known to be safe and also dereference sites that must be checked at run-time. We statically identify the safe regions at function granularity, avoiding shadow accesses for objects whose accesses are known to be safe. This also requires masking the tag bits of these pointers in the function preambles, as these objects are still allocated using the TAILCHECK custom allocator and the function call sites continue to pass arguments as tagged pointers.

## 4 TAILCHECK Implementation Details

We develop the TAILCHECK prototype by extending the *mi-malloc* allocator [33] and developing LLVM [31] compiler passes for code instrumentation. Tagged pointers are returned by the TAILCHECK allocator for allocations up to 16KB, with all larger requests treated as large-object allocations.

The TAILCHECK instrumentation is performed using three compiler passes. First, a SafeAllocs pass is done to identify optimization opportunities. Then a Call-Site Instrumentation pass replaces memory allocation function calls (`malloc`, `calloc`, `realloc`, `strdup`, `strndup`, and `free`) with the TAILCHECK custom allocator versions of these functions and masks pointer arguments at call sites of external functions. The Dereference Instrumentation pass inserts shadow loads and stores to the TailObjects for all heap objects requiring run-time checks. These passes are performed as part of the link-time optimization, ensuring that all statically linked sub-modules are combined together into one module for

TAILCHECK instrumentation before the passes are performed. Standard LLVM compiler optimization passes are performed both before and after the TAILCHECK passes.

We take special care to handle function arguments with the `byval` attribute. In LLVM, the `byval` attribute at a call site means that the pointer must be dereferenced and the resulting value copied before being passed as an argument. Because the LLVM `byval` mechanisms cannot handle tagged pointers, we mask the tags of all pointers with the `byval` attribute.

All tagged pointer-based solutions present challenges when linking to uninstrumented libraries, as tagged pointers must be masked before being passed to functions in uninstrumented code. Although pointers to data structures have their tags masked at the function call sites by the Call-Site Instrumentation pass, the nested pointers within these data structures are written as tagged pointers by the TAILCHECK instrumented code and cannot be directly dereferenced by the uninstrumented functions. As in prior work [2, 8, 28], we assume that we can soundly enumerate all call sites of external uninstrumented functions that will operate on nested pointers, and inject the necessary instrumentation code to mask nested tagged pointers. Notably, most C++ Standard Template Library (STL) containers do not require masking of nested pointers because they are implemented in header files and thus come within our instrumentation scope. For the select cases we encountered in our benchmark applications that require masking, we manually add the appropriate instrumentation as discussed in §5. In §7.3 we discuss how TAILCHECK may take advantage of the ARM top-byte-ignore Memory Tagging Extension (MTE) [3] and similar features in other ISAs to avoid the need for explicitly masking pointer tags.

## 5 Evaluation Methodology

We conduct all experiments on a system with an Intel Xeon Gold 5218 CPU. To benchmark TAILCHECK, we use four popular server applications (*apache* v2.4.54, *nginx* v1.22.1, *memcached* v1.6.17, *redis* v7.0.6), as well as the C and C++ applications from the SPEC CPU2017 and SPEC CPU2006 benchmark suites. For SPEC CPU2017, we use the *speed* set and limit applications to one thread.

Server applications often have a custom pool-based allocator. To evaluate potential performance differences between coarse-grained and fine-grained memory allocations, in addition to the *nginx* server results, we also present “*nginx (w/o poolalloc)*,” which is compiled with the `-DNGX_DEBUG_PALLOC=1` flag to disable its custom pool allocator and to use `malloc` and `free` directly. *apache* (v2.4.54) and *memcached* (v1.6.17) do not provide similar pool allocation on/off options, while *redis* does not use pool allocation.

To quantify the performance of the web servers *apache*, *nginx*, and *nginx (w/o poolalloc)*, we measure request latency using the `hey` HTTP load generator [16]. We create two workers to repeatedly request a file 256 times per second. We test

four different file sizes: 32KB, 128KB, 512KB, and 2MB. We configure `apache` with two worker threads and `nginx` with one worker process. For the key value stores, `memcached` and `redis`, we measure the request latency with four workers, each requesting 128,000 keys with a 50% get/set ratio. We use a key size of 16 bytes and four different object sizes: 32B, 128B, 512B, and 2KB. For the SPEC CPU2017 and SPEC CPU2006 benchmarks, we measure performance with reference input as wall-clock time of program execution.

For a fair comparison across all systems, we use unmodified `mimalloc` [33] for all evaluated configurations except `TAILCHECK`. For `TAILCHECK`, we use unmodified `mimalloc` for the uninstrumented code and only extend the `mimalloc` functionality with wrappers for the allocation functions, retaining all of the core functionality of the `mimalloc` allocator even when called from the instrumented code. The memory overheads we report are measured as peak resident set size.

As part of our evaluation, we include a comparison to Delta Pointers [28] and AddressSanitizer [54]. To ensure fairness, we reproduce the Delta Pointers results in our test environment after enabling only the comparable heap overflow protection features and ensuring that all available optimizations are applied. To make the results directly comparable, we perform this study with the same SPEC CPU2006 benchmark suite that was used in the original Delta Pointers publication. AddressSanitizer is compared for the server applications.

`TAILCHECK` works for all SPEC CPU 2017 benchmarks using LLVM -O3 with Link Time Optimization (LTO). However, we use -O2 and LTO in our evaluation to make the results directly comparable to the prior work [28]. We introduced specialized handling for the following benchmark applications to address compatibility issues with uninstrumented libraries:

- In the case of `403.gcc`, pointers stored in “long long” variables are passed to functions invoked through function pointers. Consequently, an uninstrumented `libc` function is called with a long long argument containing a tagged pointer. This causes a segmentation fault in the uninstrumented code, with the faulting address being a tagged pointer. Debugging this situation is straightforward, as the stack trace directly points to the problem. To address this, we utilized source instrumentation and manual pointer tag masking in the benchmark sources, similar to techniques applied in previous works [28, 29, 45].
- `520.omnetpp` employs a C++ data structure, `evbuf`, inherited from `basic_stringbuf`. This object contains a nested tagged pointer, whose information is lost due to C++ inheritance, leading to a tagged pointer being passed to a `libstdc++` function. This triggers a segmentation fault, easily identified by the faulting tagged pointer. To overcome this, we explicitly marked the `evbuf` type to ensure its members are always written as untagged pointers, thereby maintaining the integrity of the passed pointer irrespective of inheritance nuances.

Except for the above two cases, `TAILCHECK` is compatible with many complex real-world applications, including four servers and all other SPEC CPU 2017 and SPEC CPU 2006 applications. We note that although the two exception cases were easily identifiable and debuggable because they triggered a segmentation fault, it is theoretically possible that a tagged pointer may lead to silent data corruption and exhibit an observable event far later in time. `TAILCHECK` provides limited support for such cases, and fixing them may require manual code reviews. Indeed, addressing compatibility issues with uninstrumented libraries is a common limitation of pointer tagging-based solutions [2, 8, 28] with a notable exception `LowFat` [30] (see related work discussion in §8.2).

## 6 Evaluation Results

Below, we first describe the heap overflow vulnerabilities that were successfully caught by `TAILCHECK`. We then present the performance and memory overheads of our technique, and explain the impact of the optimizations described in §3.2 which mitigate some of the performance impacts. Finally, we present a comparison with the prior art, demonstrating comparable and lower overheads compared to Delta Pointers, without being subject to its address space limitations.

### 6.1 Heap Overflow Detection

We developed a set of test cases that exhibit various types of heap overflows to ensure that a segmentation fault is experienced when running such cases when the code is instrumented with `TAILCHECK`. The cases were drawn from prior empirical studies [36, 65] that analyzed the types and frequencies of heap overflows in 85 CVEs. For example, our test suite includes the following cases:

- Loop accessing heap-allocated arrays, representing 35/85 studied CVE cases (41%).
- `memcpy()`, `memset()`, or `memmove()` into an insufficiently large buffer; 18/85 cases (21%).
- `strncpy()`, `strncmp()`, or `sprintf()` into an insufficiently large buffer; 6/85 cases (7%).
- Incorrect pointer arithmetic; 8/85 cases (9%).
- Accessing a derived class member on a base class object
- Attempting to iterate through `char*` cast to `long*`

Beyond the artificial test cases that we created, `TAILCHECK` also uncovered a heap overflow read in the SPEC CPU2017 `gcc` application (v4.5.0. function `vn_nary_may_trap` in `tree-ssa-sccvn.c:3365`). When instrumented with `TAILCHECK`, the application triggered a segmentation fault and produced a core file pointing to the error. This heap overflow was present in the code for 16 months before being detected with Valgrind (PR

	average latency	99th% latency	memory
apache	4% (3~6%)	3% (1~5%)	26% (15~32%)
nginx	2% (1~3%)	3% (1~5%)	41% (32~45%)
nginx (w/o poolalloc)	4% (3~6%)	3% (0~6%)	49% (44~52%)
memcached	3% (2~3%)	4% (3~5%)	2% (1~3%)
redis	6% (5~7%)	4% (0~18%)	3% (1~5%)
(Mean)	4%	3%	17%

Table 1: TAILCHECK runtime overhead (average latency and 99th% latency) and memory overhead on server applications, normalized to an uninstrumented base system. The latencies and memory overhead slightly vary for different file and object sizes tested. The first percentage is a geometric mean and the two numbers in parenthesis represent the range. The overall geometric (Mean) is computed for four servers, excluding nginx (w/o poolalloc), across all input sizes.

Figure 3: TAILCHECK run-time overhead on SPEC CPU2017, normalized to an uninstrumented base system.

tree-optimization/44124 [1]). The bug made it into the SPEC CPU2017 suite v1.0.5<sup>1</sup> and, to the best of our knowledge, TAILCHECK is the first to report it in the literature.

## 6.2 TAILCHECK Performance

We present the performance overhead of TAILCHECK on server applications in Table 1, which shows the average and 99th-percentile latencies. Both latencies vary only slightly for different test input sizes: 32KB, 128KB, 512KB, and 2MB files for web servers and 32B, 128B, 512B, and 2KB objects for key-value stores. There were no noticeable differences for nginx with and without application-level pool allocations. Redis with 2KB objects shows the highest 99th% latency overhead of 18%, yet with high variance. All the rest, in-

<sup>1</sup>The bug patch has been merged to gcc v4.5.1. The ChangeLog of SPEC CPU2017 does not indicate version update or bug fix.

cluding redis with smaller objects, show minor performance degradation ( $\leq 7\%$ ). An individual 99th-percentile latency result for different file/object sizes can be also found in Figure 5 (for the comparison with AddressSanitizer [54]). The geometric mean across the four servers was 4% and 3% for the average and 99th-percentile latencies, respectively.

The TAILCHECK performance results for SPEC CPU2017 are shown in Figure 3. The geometric mean of the TAILCHECK performance overhead for SPEC CPU2017 is 33%, among which perlbench shows the highest 1.8x slowdown. We present a performance comparison study with prior art in §6.5. Overall, we find that the combination of these servers and SPEC CPU performance results indicate overheads that are likely low enough to warrant production use of TAILCHECK for run-time heap overflow detection in security-conscious environments.

## 6.3 TAILCHECK Memory Usage

In addition to the performance overheads, TAILCHECK increases application memory requirements because it reserves space for the TailObjects at the end of each allocator managed region. Table 1 (last column) shows the memory overhead for the server applications. The relative increase in memory usage was small for the key-value store applications, while nginx shows the highest overheads. In TAILCHECK, a protected page for small objects is a virtual page with no access permission and thus does not require a physical page. However, for large objects, TAILCHECK still requires one TailObject and one protected page. Upon further investigation, we found that at start-up, nginx allocates a large number of large objects, incurring a relatively high memory overhead. However, we also observed that once initialized, its peak RSS does not change while serving client requests. Nginx (w/o poolalloc) allocates more (non-pool) large objects, showing a slightly higher memory overhead than nginx with pool allocations.

Next, we present the memory overheads in Table 2 for SPEC CPU2007 applications. Because TAILCHECK shares the space of the TailObjects for small objects within a region, the capacity overheads is minimal. The most affected benchmarks (perlbench, gcc, and nab) experience only a 9% increase in the peak RSS. The geometric means were 17% for the servers and 3% for the SPEC CPU2017 applications.

## 6.4 Analysis of Optimizations.

To better understand the TAILCHECK performance overheads, we analyze the benefits of the optimizations described in §3.2. For this experiment, we used the SPEC CPU2006 benchmark instead of CPU2017 because when we compare ours with Delta Pointers in §6.5, we want to compare the impact of the same static optimization (SafeAlloc) on ours and Delta Pointers. However, few benchmark applications in SPEC CPU2017 have memory requirements and cannot be supported by Delta

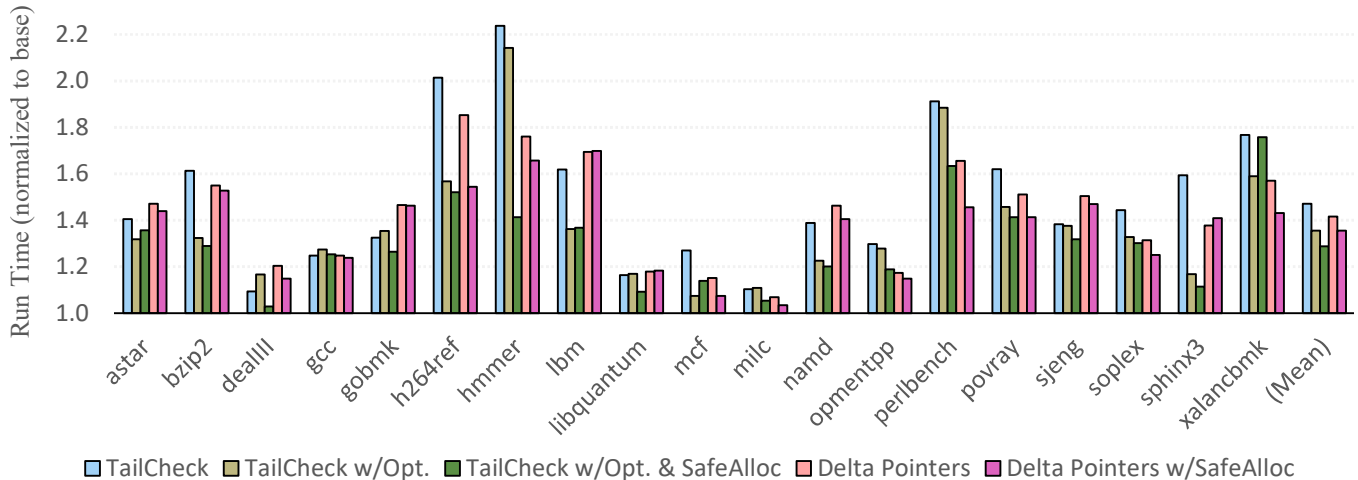

Figure 4: Comparison of run-time overheads on SPEC CPU2006, normalized to an uninstrumented base system: (a) TAILCHECK; (b) TAILCHECK with Opt.; (c) TAILCHECK with Opt. and SafeAlloc; (d) Delta Pointers; and (e) Delta Pointers with SafeAlloc.

application	overhead	application	overhead
deepsjeng	0%	nab	9%
gcc	9%	omentpp	3%
imagick	0%	perlbench	9%
lbm	0%	x264	6%
leela	-1%	xalancbmk	5%
mcf	0%	xz	0%
		geo-mean	3%

Table 2: TAILCHECK memory overhead (peak RSS) on SPEC CPU2017, normalized to an uninstrumented base system.

Pointers: *e.g.*, `xz` and `mcf` with the reference input. Thus, we based our analysis on SPEC CPU2006.

The first three bars in Figure 4 present the impact of optimizations. We first disable the merging of tag handling code when multiple offsets of an object are dereferenced within the same function. Although not drastic, the geometric mean of performance across the SPEC CPU2006 suite improves by 11%, with the biggest gains coming from several applications such as `bzip2`, `h264ref`, and `sphinx3`.

We also examine the benefits of applying SafeAlloc to avoid TAILCHECK instrumentation for heap objects whose accesses are known to be within bounds through static code analysis. Although the gains across all benchmarks are modest, 7% on average, applications such as `hmmer` and `perlbench` exhibit drastic benefits, reducing the run-time overheads by 73% and 24%, respectively. These applications have hot loops iterating over multiple large arrays, allowing SafeAlloc to find a significant number of optimization opportunities.

We note that “Hoisting Tag Handling,” as described in 3.2,

reduces address calculation overheads, but may also increase register pressure. For loops with a small number of pointer dereferences in the loop body, hoisting the computation of the tail pointer may add register pressure to the program, leading to performance degradation. The TAILCHECK compiler performs a simple count of the number of pointer dereferences, applying hoisting if a loop has two or more dereferences. In some cases (*e.g.*, `xalancbmk`), SafeAlloc eliminates some pointer dereferences, leaving just one dereference in the loop body, bypassing optimization in those loops.

## 6.5 Comparison with Delta Pointers

This experiment compares TAILCHECK with Delta Pointers, the state-of-the-art compiler-based solution that shares many similarities with TAILCHECK in that both use pointer tagging and do not perform explicit bound checking. We use `mimalloc`’s unmodified allocator for baseline and Delta Pointers performance measurements.

Figure 4 shows the performance comparison. First, when comparing the last two bars, we can find that the SafeAllocs optimization gives roughly the same relative benefit for Delta Pointers (6%) as for TAILCHECK (7%). One thing to note is that the other two tag merging and hoisting optimizations (excluding SafeAllocs) in §3.2 are only applicable to TAILCHECK, but not to Delta Pointers. The reason is that the two optimizations require the tag of a pointer remain unchanged once defined (until an object becomes freed), which is the case for TAILCHECK, but not for Delta Pointers.

Second, when comparing the two fully optimized versions, the 3rd and 5th bars in Figure 4, TAILCHECK exhibits lower runtime overhead than Delta Pointers: 29% vs. 35%. TAILCHECK has lower than or similar runtime overheads than Delta Pointers for most applications. Two exceptions were

`perlbench` and `xalancbmk`. There are two significant differences in Delta Pointers’ and TAILCHECK code instrumentation. Delta Pointers instruments pointer arithmetic to update a pointer tag, while TAILCHECK does not. TAILCHECK adds additional memory operation on a pointer dereference, while Delta Pointers does not. When considering the number of instrumentation as a factor of runtime overhead, TAILCHECK is likely to perform better than Delta Pointers for those applications with more pointer arithmetic and less dereferences.

For reference, we note that Oleksenko *et al.* [45] reported 1.8x, 1.8x, 2x, and >3x runtime overheads for AddressSanitizer [54], Intel’s MPX (ICC), SoftBound [40] and SAFE-Code [15], respectively, for the SPEC CPU2006 applications (in their experimental settings).

Delta Pointers does not incur additional memory overhead, as it does not use a custom allocator with guard pages like TAILCHECK (Table 2). Rather, the major drawback of Delta Pointers is the need to shrink the process address space (e.g., 32-bit tag and 32-bit address space).

## 6.6 Comparison with AddressSanitizer

Our last experiment compares TAILCHECK with AddressSanitizer [54] for server applications. AddressSanitizer is the state-of-the-practice solution that maintains a disjoint metadata space to distinguish safe regions and (unsafe) redzones. Figure 5 shows the 99th-percentile latency across different file sizes (32KB-2MB) for web servers and object sizes (32B-2KB) for key-value stores. As discussed in §6.2, TAILCHECK shows minor (on average 3%) tail latency degradation. The worst 18% overhead appears only for `redis` with 2KB objects. On the other hand, AddressSanitizer incurs higher overheads for all cases (on average 16%, up to 51%), reflecting its expensive metadata lookup and checking costs. Likewise, AddressSanitizer shows higher average latencies (not shown) than TAILCHECK: 4% vs. 12% on average; and 7% vs. 56% in the worst case.

## 7 Discussion

### 7.1 False Positives and False Negatives

TAILCHECK does not have false positives, assuming there are no use-after-free violations. A shadow memory access computed from a dangling pointer could be wrong if freed and reallocated objects have a different size. Otherwise, the tag in a pointer and the actual distance between a (current) object and its corresponding TailObject always match, and the size of a TailObject is always larger than or equal to that of an original object. Thus, any page fault from a protected page is evidence of a true heap overflow.

We exclude a discussion of potential segmentation faults from passing tagged pointers to uninstrumented code without

proper masking. The mechanisms for using tagged pointers in the presence of uninstrumented code are described in §4.

TAILCHECK may have false negatives (miss some heap overflows). First, TAILCHECK is a dynamic tool. It can detect a heap overflow only along the program paths that are explored at run-time, given a test input and environment. Second, TAILCHECK is an instrumentation-based tool and may miss a heap overflow in an object that crosses the instrumented vs. uninstrumented code boundary, such as calls into third-party libraries and assembly code.

Consider two cases, one in which a heap object is created in the instrumented code, but escapes unmasked into uninstrumented code where it is accessed, and vice versa. TAILCHECK cannot detect an overflow in uninstrumented code as there is no shadow TailObject access. Similarly, if an object allocated in the uninstrumented code is passed to instrumented code, TAILCHECK cannot detect an overflow as there is no tag and no corresponding protected page available for the object.

Finally, TAILCHECK relies on a guard page; thus it may fail to detect an overflow beyond the 4KB protected page (similar to AddressSanitizer’s 128B redzone [54]). However, it is difficult for a malicious user to exploit this, particularly for small objects, because both the original (manipulated) access and the TailCheck (shadow) access must land on legal memory regions to succeed. The TAILCHECK memory allocator scatters 64KB allocation regions for small objects in the process address space, making the distance between a protected page of a memory region and other valid memory regions non-deterministic. Large objects may be easier to exploit as their original and TailCheck accesses are to the same location. We note that this is different from AddressSanitizer’s traditional redzone approach in which a constant length (e.g., 128B) redzone is inserted between adjacent valid memory objects/regions. Prior solutions that use explicit bounds checking (e.g., MPX [45]) or precisely keep track of pointer arithmetic (e.g., Delta Pointers [28]) do not have this limitation.

### 7.2 Benign False Negatives due to Alignment

x86-64 Linux assumes that heap allocators return 16-byte aligned pointers, allowing the compiler to emit memory instructions based on this assumption. As discussed in §3.1, TAILCHECK enforces the same alignment for TailObjects as for the original objects, allowing the compiler to use the same memory instruction for both original and shadow memory accesses. For objects that are not 16-byte aligned (e.g., 11 byte), the bound of the corresponding 16-byte aligned TailObject (of the same 11 byte size) will not be adjacent to the boundary of a protected page and there will be a gap due to the alignment requirement (5 bytes in this example). This gap may lead to a false negative as the shadow access would not lead to a page fault. Nonetheless, we see this as a “benign” overflow, as the original object would also have the same gap before its adjacent object, due to the same alignment requirement.

Figure 5: Comparison of 99th-percentile latency on server applications across different file/object sizes, normalized to an uninstrumented base system: (a) TAILCHECK and (b) AddressSanitizer.

If required, TAILCHECK can be extended to put the bound of a TailObject immediately before the protected page without a gap. TAILCHECK would create an unaligned TailObject, and there will not be a false negative due to alignment. However, in this case, the shadow memory access instrumentation pass may need to use different instruction opcodes for the shadow accesses, because the instructions used to access the original object may not support unaligned addresses. Although such a change is possible to eliminate these benign false positives, it is likely to come at a performance cost.

### 7.3 Potential Hardware Support

TAILCHECK performance could benefit from the following hardware support. First, TAILCHECK (on x86-64) must currently mask the tags of pointers before accessing an original object and before passing pointers to uninstrumented code. TAILCHECK could take advantage of the top-byte-ignore feature of ARM’s MTE [3] to avoid masking overhead, similar to HWAsan [55], a hardware-assisted ASan.

Second, TAILCHECK (on x86-64) relies on load and store instructions to perform shadow memory accesses for overflow detection. It would be sufficient for TAILCHECK shadow operations to only check for access permission. TAILCHECK could make use of new pseudo load/store-like instructions which perform virtual to physical address translation and check permissions, without performing an actual memory access or perturbing the data cache, eliminating cache pollution, cache coherence traffic, etc. Such shadow accesses would not modify memory, reducing the TAILCHECK run-time overhead and reducing the memory overhead because TailObject space would no longer need to be reserved.

Lastly, one can design a hardware TAILCHECK without compile-time dereference instrumentation. Given a tagged pointer, the memory management unit of a processor can transparently perform a page permission check or a shadow memory access to the TailObject.

### 7.4 Extensions to Other Memory Safety

**Heap Intra-Object Overflow.** TAILCHECK defines a heap object protection granularity at the time of heap allocation. Thus, TAILCHECK does not protect a more fine-grained sub-object from an overflow (e.g., an overflow of an array field of a struct to another field of the same struct) as in per-object bound checking solutions [2, 13, 17, 18, 25, 30, 51, 67]. If desired, TAILCHECK’s compiler instrumentation pass could be extended to “heapify” a subobject, similar to CCured [43]. This is analogous to the additional “bound narrowing” feature in some per-pointer bound checking solutions [40, 45].

**Heap Underflow.** Though buffer underflow is less critical than overflow in terms of security, if desired, the design of TAILCHECK could be flipped to “HeadCheck.”

**Heap Use-After-Free.** TAILCHECK does not support any temporal memory safety, yet it could be combined with existing use-after-free detection schemes that do not use pointer tagging: e.g., Oscar [12] or DangZero [20] that rely on page protection could be a good candidate for integration.

**Stack Overflow.** TAILCHECK assumes that stack is protected by other schemes such as stack canaries [11] and shadow stacks [60]. In the current form, TAILCHECK’s instrumentation pass does not need to distinguish stack and heap objects as any address-taken stack object would hold a tag of 0, leading to harmless redundant memory accesses.

If desired, TAILCHECK can be extended to support stack overflow protection. The simplest solution is to replace stack allocation with heap allocation, similar to CCured’s “heapified” stack [43], at some performance cost. Alternatively, TAILCHECK could be extended to add a protected page to stack and protect the stack objects similar to heap objects (using a distance tag, a TailObject, and a shadow memory access),

with the following instrumentation pass changes. The size of a TailObject (a max of projected objects) can be determined as the sizes of the stack objects are known. The location of TailObject (before a protected page) should be kept in a reserved register or a global variable by instrumenting the entry function: *e.g.*, `main`. For each function, any address-taken stack object (*e.g.*, defined by LLVM's `alloca`) should be instrumented to tag the distance from the stack object (whose address is computed from a stack pointer) to the TailObject (whose address is kept separately). Then, TAILCHECK can use the same mechanism for stack objects as heap objects. The default size of TAILCHECK's tag is 16 bits, implying that it can support a stack up to 64KB. If a larger stack is needed, the address space should be reduced for a wider tag. Selectively using heapification for a large stack object could be helpful.

## 8 Related Work

There are hundreds of prior memory safety solutions, with a little bit of exaggeration. This section does not attempt to cover them exhaustively. Instead, we focus on discussing where TAILCHECK sits among these related works.

### 8.1 Buffer Overflow Detection

The first group maintains “redzone” metadata and checks if a program accesses the red zone on each memory access. Purify [22] is the first to use redzone. LBC [21] introduces a fast path optimization skipping metadata lookup with a random canary. ASan [54] and Valgrind [44] are popular redzone-based tools using static instrumentation and dynamic binary translation, respectively.

The second group performs explicit “bounds checking.” Some maintain per-object bound metadata and perform bounds checking on pointer arithmetic: *e.g.*, J&K [25], CRED [51], D&A [13], Baggy Bounds [2], PAriCheck [67], LowFat [17, 30], and EffectiveSan [18]. Others keep track of per-pointer bound metadata and check bounds on pointer dereferences: *e.g.*, SoftBound [40], SGXBounds [29], Mid-Fat [27], MPX [45], CUP [8], and FRAMER [42]. Static analysis can be used to avoid some bound checks on memory accesses proven to be safe: *e.g.*, PICO [26]. The pointer-based approach has another advantage that makes it easy to support intra-object overflow protection: *e.g.*, an array in a struct.

The third group leverages “page protection”: *e.g.*, Electric Fence [49], DUMA [5], DYBOC [56], libgmalloc [35], and PageHeap [61]. They do not maintain redzone/bound metadata nor perform explicit checking as in the above two groups. However, as discussed in §2.3, allocating one object per page incurs huge memory and run-time overheads. Prober [37] shows low overhead but it only protects heap arrays. TAILCHECK proposes a new low-overhead page protection-based solution for all heap objects.

On the other hand, Delta Pointers [28] check the integer overflow of a tagged pointer. It does not make use of a redzone, a bound, or a protected page; and thus does not fall into any of the above groups.

### 8.2 Pointer Tagging

Many of the above solutions need to maintain some metadata. Some use “fat pointers” that stores the metadata (*e.g.*, base and bound) in separate words alongside the actual pointer value. Examples include Safe-C [4], Cyclone [24], and CCured [43]. CHERI [62, 63] provide hardware support for fat pointers.

Many recent works leverage “pointer tagging” that embeds metadata into some bits of a pointer itself, to avoid a code layout change. For example, Baggy Bounds [2] uses the spare top bits to store the distance between an out of bound pointer and its intended referent. Delta Pointers [28] uses a 32-bit tag to encode the distance from the current pointer to the end of an object. As discussed in §2.3, one common downside of pointer tagging is that it may restrict the address space: *e.g.*, Delta Pointers only support a 4GB of 32-bit address space. This may not be a problem for SGXBounds [29], which is designed for an Intel SGX enclave with already-limited 32-bit address space, and thus it can use a 32-bit tag to store the upper bound of the pointer's referent without any sacrifice. However, other pointer tagging solutions (including Delta Pointers) that require more than 16 unused bits in the current 64 bit architecture cannot be used for general (non-SGX) programs with big memory requirements. TAILCHECK does not share this limitation. Alternatively, CUP [8] takes an extreme design that uses the entire pointer width to store tags. Low-fat pointers [17, 30] store the tag implicitly in the pointer value, and thus can be safely dereferenced without masking.

Several works proposed hardware support for pointer tagging. In-Fat [64] is a hardware extension of EffectiveSan [18], which tags the upper bits of a pointer with an index into a bounds table, performing bounds checking on pointer arithmetic. HeapCheck [52] stores an index into a per-pointer bounds table, and checks bounds on pointer dereferences. PACMem [34] leverages ARMv8 AArch64 Pointer Authentication (PA) [50], computing cryptographic hashes based on the value of pointers (and other contexts) for pointer integrity. PACMem seals object metadata into the high-order bits of pointers via PA and uses the seal as the index to retrieve it. The tagged PA codes are propagated by hardware along with the pointers. No-Fat [23] supports low-fat pointers [17, 30].

### 8.3 Use-After-Free Detection

Existing use-after-free solutions can be categorized into three groups based on their detection techniques. Some solutions such as CETS [41], ViK [10] and xTag [6] tag the allocated memory and the pointer with a unique identifier (referred to as lock and key), and check if the tags of pointer and memory

match on dereference. Any mismatch indicates that a pointer used for dereference is a dangling pointer. ARM's Memory Tagging Extension (MTE) [3] and SPARCS's Silicon Secured Memory (SSM) [46] provide hardware support to assign random 4-bit tags to object-pointer pairs to probabilistically find use-after-free bugs on tag mismatch. HWAsan [55] an extension of ASan with ARM's MTE makes use of its top-bit-ignore feature and avoids masking on memory dereference.

Other solutions such as Undangle [9], FreeSentry [66], DangleNull [32], DangSan [59], BOGO [68] maintain metadata to find and invalidate dangling pointers on free. Then a use-after-free is detected as an invalid pointer use: *e.g.*, null pointer dereference.

Yet others such as D&A [14], Oscar [12], and DangZero [20] leverage page protection: a page becomes inaccessible after a free. Oscar [12] reduces physical memory and run-time overhead by mapping multiple virtual pages into a single physical page. DangZero [20] further lowers run-time overhead by directly accessing the page tables with support from virtualization extensions and a privileged backend (*e.g.*, Kernel Mode Linux). TAILCHECK does not provide use-after-free detection, but its page-based approach makes it possible to integrate the above page-based use-after-free solutions to achieve both spatial and temporal memory safety. We leave this to future work.

## 8.4 Uninitialized Memory Read

Uninitialized memory reads can lead to information leakage, similar to buffer overflow reads. Purify [22] and Valgrind [44] detect an uninitialized memory read by maintaining and checking (initialized vs. uninitialized) state metadata at a byte or bit granularity, respectively. UniSan [38] uses data-flow analysis to zero-out variables that might be disclosed to an attacker. SafeInit [39] modifies the compiler and heap allocator to ensure that all stack/heap regions be initialized.

## 9 Conclusions

Heap overflow vulnerabilities leave many software systems exposed to security attacks and exploitation. This work presented TAILCHECK, a novel heap overflow mitigation scheme that leverages a custom memory allocator, OS-based page protection, and compiler-directed pointer tagging. TAILCHECK achieves low run-time overhead by detecting heap overflows using page protection, without maintaining bound metadata and without performing explicit bounds checks. TAILCHECK uses pointer tagging and shadow memory accesses to detect overflows, allowing multiple original objects to share a single TailObject, which reduces both performance and memory overheads compared to the previously explored techniques. The results of our experimental evaluation demonstrate the effectiveness and efficiency of TAILCHECK in detecting heap overflows in C and C++ programs.

## Abstract

Disaggregated memory (DM) is an increasingly prevalent architecture in academia and industry with high resource utilization. It separates computing and memory resources into two pools and interconnects them with fast networks. Existing range indexes on DM are based on B+ trees, which suffer from large inherent read and write amplifications. The read and write amplifications rapidly saturate the network bandwidth, resulting in low request throughput and high access latency of B+ trees on DM.

In this paper, we propose to use the radix tree, which is more suitable for DM than the B+ tree due to smaller read and write amplifications. However, constructing a radix tree on DM is challenging due to the costly lock-based concurrency control, the bounded memory-side IOPS, and the complicated computing-side cache validation. To address these challenges, we design **SMART**, the first radix tree for disaggregated memory with high performance. Specifically, we leverage 1) a *hybrid concurrency control* scheme including lock-free internal nodes and fine-grained lock-based leaf nodes to reduce lock overhead, 2) a computing-side *read-delegation and write-combining* technique to break through the IOPS upper bound by reducing redundant I/Os, and 3) a simple yet effective *reverse check* mechanism for computing-side cache validation. Experimental results show that SMART achieves  $6.1\times$  higher throughput under typical write-intensive workloads and  $2.8\times$  higher throughput under read-only workloads, compared with state-of-the-art B+ trees on DM.

## 1 Introduction

Distributed range indexes are fundamental building blocks of many applications, *e.g.*, databases and key-value stores, to conduct range queries [2, 21, 53, 57, 59]. To improve resource utilization, many new proposals adopt the disaggregated memory (DM) architecture [53, 59]. DM can decouple computing and memory resources into two elastic resource pools (*i.e.*,

computing pool and memory pool) interconnected with high-speed networks, *e.g.*, remote direct memory access (RDMA) connections [3, 9, 16, 19, 20, 27, 47]. In this way, a DM range indexing system can utilize resources more efficiently.

Current DM index systems [53, 59] use B+ tree to build range indexes, following the idea generally adopted in the monolithic server solutions. However, B+ trees can bring severe read and write amplification issues on DM. Specifically, when reading or writing a key-value item in a B+ tree, one should search the tree by traversing many nodes which contain many useless keys and pointers since only one key is the target. This inevitably amplifies the network bandwidth consumption. As such network bandwidth is generally the bottleneck of the DM architecture [23], the amplified bandwidth consumption incurred by B+ trees exacerbates the bottleneck. This issue will lead to low overall throughput and high access latency. Our experimental study shows that it can dramatically degrade the throughput of Sherman [53], the state-of-the-art B+ tree index on DM. The throughput is  $10.8\times$  lower than the theoretical bound of RNICs under the YCSB workloads [10].

In this paper, we propose that radix tree is a more suitable tree index structure for DM. Compared with B+ trees, radix trees have smaller read and write amplifications since they do not store the entire keys in internal nodes. Moreover, the state-of-the-art radix tree design, *i.e.*, ART [32], further reduces read and write amplifications with an adaptive internal node design. However, several challenges should be addressed before radix trees become a high-performance, practical indexing solution for DM.

**(1) Lock-based concurrency control is expensive.** Remote lock operations are expensive on DM. However, the existing ART design adopts a lock-based algorithm for concurrency control [33], which contains many remote lock operations, worsening the write performance. In addition, computing-side caches are required on DM to reduce operation latency. The traditional read-copy-update (RCU) scheme for radix trees causes frequent changes in the addresses of cached nodes, leading to cache thrashing.

**(2) Redundant I/Os deteriorate the throughput.** RNICs

\*The work was mainly conducted when Xuchuan and Jiacheng were interns at Huawei Cloud.

in the memory pool of DM have bounded IOPS (I/O per second) [51]. However, radix trees have multiple small-sized read and write operations when traversing and modifying the tree index. Many of these read and write operations are redundant when multiple clients on the same compute node concurrently traverse the tree. These redundant I/Os on DM waste the limited IOPS of RNICs and thus decrease the peak throughput of radix trees.

(3) *The complicated computing-side cache validation.* Tree indexes on DM typically adopt computing-side caches to reduce access latency [56]. However, the structural features of radix trees (e.g., path compression) incur many address changes and metadata changes in radix tree nodes. These changes add more cache invalidation situations and thus complicate the cache design.

To address the above challenges, we propose **SMART**, a **dis**aggregated-me**M**emory-friendly **A**daptive **R**adix **T**ree. First, for better concurrency control, we present a *hybrid ART concurrency control* scheme with a lock-free internal node design and a lock-based leaf node design to achieve high performance without cache thrashing. Second, for an IOPS breakthrough, we propose a *read-delegation and write-combining (RDWC)* technique to reduce computing-side redundant I/Os. Third, for cache validation, we co-design SMART with an *ART cache*, including a reverse check mechanism to handle new cache invalidation situations of ART.

We implement SMART from scratch and evaluate it using the YCSB benchmark [10]. Compared with Sherman [53], the state-of-the-art B+-tree-based range index on DM, SMART achieves up to  $6.1\times$  higher throughput and  $1.4\times$  lower latency for typical write-intensive workloads and  $2.8\times$  higher throughput with similar latency for read-only workloads. The code of SMART is available at <https://github.com/dme/msys/SMART>.

In summary, this paper makes the following contributions:

- We propose that ART is a better tree index on DM, based on theoretical analysis and experimental results.
- We present the first memory-disaggregated radix tree, SMART, with three key designs for high performance, including a hybrid ART concurrency control scheme, a read-delegation and write-combining technique, and a reverse check mechanism for cache validation.
- We implement SMART and evaluate it using YCSB workloads [10]. The evaluation results demonstrate the efficacy and efficiency of SMART.

## 2 Background

### 2.1 Disaggregated Memory Architecture

As shown in Figure 1, the DM architecture physically separates computing (e.g., CPUs) and memory (e.g., DRAM) resources into two independent resource pools to address the resource utilization issue in traditional data centers with monolithic servers [18, 31, 42, 43, 46, 54]. In the DM architecture, compute nodes (CNs) own powerful computing resources but

Figure 1: The architecture of disaggregated memory.

only have a small piece of memory serving as local caches. In contrast, memory nodes (MNs) are equipped with masses of memory but only own a few wimpy computing cores for simple tasks such as establishing network connections and allocating memory spaces.

A high-speed network with high bandwidth and low latency, e.g., RDMA network, is a crucial component in the DM architecture that interconnects CNs and MNs [12, 17]. RDMA network interface cards (RNICs) allow CNs and MNs to communicate with each other using *one-side verbs* (e.g., RDMA\_READ, RDMA\_WRITE, RDMA\_CAS) or *two-side verbs* (e.g., RDMA\_SEND, RDMA\_RECV). One-side verbs are preferred on the DM architecture to enable computing-side clients to operate directly on the disaggregated memory without involving the weak CPUs on MNs.

### 2.2 B+ Trees on Disaggregated Memory

Tree indexes are critical for many applications requiring range queries. All previously proposed tree indexes on DM are variants of the B+ tree, including FG [59] and Sherman [53]. FG is the first RDMA-based index supporting DM. It uses a B-link tree structure and completely leverages one-sided verbs to perform index operations, with RDMA-based spin locks for concurrency control. Since FG directly ports the spin-lock-based concurrency control and B-link tree node designs on monolithic servers to DM, its performance suffers from severe network contention on lock retries and write amplification on B-link tree nodes. Sherman [53] is the state-of-the-art B+ tree on DM that addresses the network contention and write amplification issues of FG. First, it addresses the network contention on lock-fail retries with a *hierarchical on-chip lock (HOCL)* scheme. The network requests on lock-fail retries are reduced with a local lock table shared among clients on the same CN. The on-chip memory of RNICs is leveraged to reduce PCIe transmissions further. Second, it mitigates the write amplification by allowing fine-grained modification to B+ tree nodes with a *two-level version mechanism*. Therefore, Sherman achieves much better performance than FG. However, Sherman still suffers from the natural performance bottleneck of B+ trees, i.e., coarse-grained lock-based concurrency control and inherent read amplification, which are analyzed in Section 3.

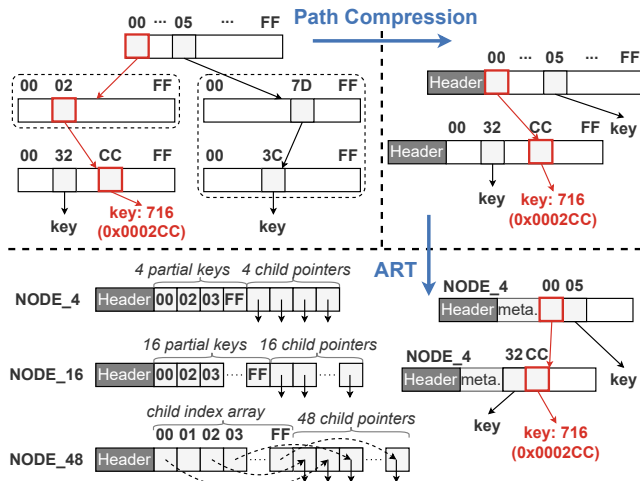

Figure 2: The optimization process from the basic radix tree to ART. For clarity, hexadecimal partial keys are shown. NODE\_256 is simply an array of 256 pointers, which is not shown due to space limitation.

## 2.3 Radix Tree

The radix tree is another popular tree index structure. It stores the segmented key in the top-down search path over the tree rather than storing the whole key in the internal node. Specifically, each internal node in the radix tree consists of an array of child pointers. Each pointer is associated with a segment of bits of the whole key, called *partial key*, as shown in Figure 2.

**Path compression.** Path compression is an optimization method for the radix tree to reduce tree height by removing one-child internal nodes, and can be implemented in three ways [32]: 1) *The optimistic method* simply abandons the partial keys in the removed nodes and instead stores a depth value to ensure the subsequent traversal process. 2) *The pessimistic method* stores all the partial keys of the removed nodes in the header of the subsequent node. 3) *The hybrid method* integrates the two methods above by storing partial keys into the fixed-sized header of the subsequent node, together with a depth value to ensure the subsequent traversal if some partial keys overflow from the header.

**Adaptive radix tree (ART).** ART [32] is the state-of-the-art variant of the 8-bit-span radix tree, designed to optimize the memory utilization of traditional radix trees. Traditionally, an internal node of a radix tree has all 256 pointers representing all possible partial keys. Many pointers are empty due to the sparse key distribution [32], wasting memory space in these internal nodes. ART addresses the issue by proposing four well-designed internal node structures with different numbers of pointers, *i.e.*, 4, 16, 48, and 256. It dynamically chooses the best-fit internal node structure to save memory space. As for concurrency control, ART is synchronized using a lock-based algorithm, *i.e.*, the *read-optimized write exclusion (ROWEX)* protocol [33]. There are some proposed ART-based indexes designed on monolithic servers [26, 29, 30, 37], while none of them is designed for DM.

Table 1: Read and write amplification factors of different trees.

	ART	B+ Tree	Sherman
Read	$\frac{M_1+E}{E} = 1.10$	$\frac{M_2+S \cdot E}{E} = 32.7$	$\frac{M_2+S \cdot (M_3+E)}{E} = 33.0$
Write	$\frac{M_1+E}{E} = 1.10$	$\frac{M_2+S \cdot E}{E} = 32.7$	$\frac{M_3+E}{E} = 1.01$

## 3 Analysis of Tree Indexes Built on DM

In this section, we first theoretically and experimentally compare B+ trees with a vanilla ART (§ 3.1). We then present the challenges of designing ART on DM (§ 3.2).

All the experiments in this section are conducted with 8 CNs and 1 MN, each equipped with a 100Gbps Mellanox ConnectX-6 RNIC. Each CN launches 32 clients with one shared 600MB cache. We use YCSB workloads [10] (including 60 million entries) with 32-byte string keys and 64-byte values, which is typical in real-world workloads [4, 58].

### 3.1 Motivations: B+ Tree vs. ART on DM

The main problem of B+ trees on DM is their severe read and write amplifications. In internal nodes, the B+ tree stores the whole keys. In leaf nodes, the B+ tree stores multiple keys together. Without optimizations, the B+ tree needs to read and write the entire nodes during each index operation, causing serious read and write amplifications. In the following, we first theoretically compare the read and write amplifications of ART with the B+ tree and the write-optimized B+ tree (*i.e.*, Sherman [53]). We then experimentally show the performance impacts due to the read amplification.

#### 3.1.1 Theoretical Analysis

The read and write amplification factors of different tree structures are shown in Table 1, respectively. We assume the internal nodes are cached and no node split occurs for brevity.  $M_1$  and  $M_2$  denote the metadata size of the leaf node of the radix tree and B+ tree, respectively.  $M_3$  denotes the size of the additional metadata (*i.e.*, entry-level versions) that Sherman applied to each key-value item.  $S$  denotes the span size of the B+ tree node.  $E$  denotes the key-value item size.

The amplification factor is defined as the ratio of bandwidth consumption from the server and bandwidth returned to the application. Without optimizations, when a client reads or writes a single key-value item in a tree index, the whole leaf node should be read or written. We use the same size of the key-value item, *i.e.*, 96 bytes, for all trees as an example.

The leaf node of the ART contains one item with its metadata. In our implementation, 10 bytes of metadata is enough for each item in ART. The read and write amplification factors are  $\frac{M_1+E}{E} = \frac{10B+96B}{96B} = 1.10$ .

The leaf node of the B+ tree contains  $S$  items together with the metadata. The metadata at least includes two fence keys ( $2 \cdot 32B$ ), a valid bit, a lock bit, a 1-byte level field, and two 7-bit versions [53], *i.e.*, 67 bytes in total. We use the

Figure 3: The read performances of Sherman and ART under the YCSB C workload (100% read). (a) The throughput bottleneck with no cache. (b) The impact of key size and span size with no cache. (c) The peak throughput with various sizes of caches. (d) The latency deterioration with excess requests.

default span size in Sherman, which is 32. The read and write amplification factors are  $\frac{M_2+S+E}{E} = \frac{67B+32\cdot 96B}{96B} = 32.7$ .

For Sherman, each key-value item in the leaf node is surrounded by a pair of 4-bit entry-level versions. Thus the read amplification factor is  $\frac{M_2+S\cdot(M_3+E)}{E} = \frac{67B+32\cdot(1B+96B)}{96B} = 33.0$ . When writing an item without node splitting, the client only requires to write back the modified item with its associated entry-level versions. Thus the write amplification factor is  $\frac{M_3+E}{E} = \frac{1B+96B}{96B} = 1.01$ .

### 3.1.2 Experimental Results

To show the impact of read amplification on the performance, we compare the performances of Sherman and ART under *read-only workloads*. The impact of write amplification is similar. We observe that the amplification leads to low throughput and high latency of B+ trees on DM.

**Observation 1: The throughput of the B+ tree is bounded by network bandwidth.** The memory-side network bandwidth is generally the performance bottleneck in the DM architecture [23]. The read and write amplifications of B+ trees cause more bandwidth consumption for each request, exacerbating the network bottleneck and resulting in low throughput.

As shown in Figure 3a, with an increasing number of clients, the limited bandwidth prevents the throughput of Sherman and ART from continually rising. With the same RNIC bandwidth, Sherman has a lower peak throughput than ART due to the severe read amplification. As shown in Figure 3b, the larger the key size or the span size (*i.e.*, the number of keys stored in a leaf node) is, the larger the read amplification is, which decreases the peak throughput of Sherman.

A computing-side cache is usually used for caching the internal nodes of the B+ tree on DM. As shown in Figure 3c, with the increasing size of the cache, the throughput of Sherman keeps bounded by the bandwidth bottleneck and finally saturates at 4.17 Mops/s. The bandwidth consumption from the server equals the maximum network bandwidth of 100 Gbps (12.5 GBps), and the bandwidth returned to the application is  $4.17 \text{ Mops/s} \cdot 96B = 0.39 \text{ GBps}$ . Thus the measured read amplification factor of Sherman is  $12.5 \text{ GBps} / 0.39 \text{ GBps} = 32.1$ , which is close to our theo-

retical analysis in § 3.1.1.

In contrast, without the read amplification from leaf nodes, the throughput of ART reaches about 45 Mops/s, which is the IOPS upper bound of the RNIC we use. This indicates that ART can make full use of the RNIC capacity and achieve the best resource efficiency as DM desires.

**Observation 2: The latency of the B+ tree is worsened by early network congestion.** Network congestion occurs when computing-side requests saturate the bandwidth or IOPS upper bound of RNICs. As the number of clients keeps growing, excess client requests need to queue up across the network, which results in latency deterioration. The read and write amplifications make B+ trees consume the bandwidth rapidly, expediting the process of network congestion.

As shown in Figure 3d, with the increase of throughput, the latency of Sherman and ART is stable in the beginning and then experiences a sudden surge due to the network congestion. Moreover, with the same memory-side RNIC bandwidth, Sherman has a much smaller inflection point (*i.e.*, the throughput threshold that triggers network congestion) than ART. As a result, Sherman shows an extremely high latency with relatively few clients. By contrast, ART has a high tolerance to this latency deterioration thanks to its small amplifications.

## 3.2 Challenges: ART on DM

Even though ART has superiority under *read-only workloads*, it suffers from significant challenges on DM under *hybrid read-write workloads*.

**Challenge 1: Lock-based concurrency control of ART causes poor write performance.** Existing ART adopts lock-based algorithms to perform synchronization [33]. However, lock operations are expensive on DM and lead to poor write performance, as shown in Figure 4a. Specifically, unlike local memory, each lock operation on DM requires additional network transmission (*e.g.*, RDMA\_CAS). Furthermore, the lock conflict mechanism (*i.e.*, busy waiting) causes frequent RDMA retries when failing to acquire a lock, which wastes the limited IOPS of RNICs and reduces the throughput.

One feasible solution is to design lock-free algorithms. However, lock-free design is not the best choice for ART as

Figure 4: (a) The write performance of ART under the YCSB insert workload (100% insert) with no cache. (b) The performance degradation caused by cache thrashing under the YCSB A workload (50% read + 50% update) with sufficient caches. (c-d) The inter-client redundant I/Os on DM in terms of reads and writes.

well. Specifically, an out-of-place update scheme is required for lock-free algorithms to update items larger than 8 bytes. It atomically compares and swaps the corresponding 8-byte addresses instead of modifying the items in place, as the latter cannot be realized atomically. However, in high-concurrency scenarios, a mass of out-of-place updates lead to frequent changes in the addresses of items. This brings about the severe cache coherence issue since the old addresses of the items have been cached in other CNs. Even worse, in skewed workloads, the addresses of hot items are changed continuously and repeatedly, resulting in cache thrashing.

To verify this, we evaluate the two update schemes in ART with the YCSB A workload,<sup>1</sup> as shown in Figure 4b. The out-of-place scheme brings about an average of 19.1% invalid cached addresses of leaf nodes and thus results in a 44.5% throughput decline compared with the in-place scheme.

**Challenge 2: Inter-client redundant I/Os on DM waste the limited IOPS of RNICs.** As mentioned in **Observation 1**, B+ trees suffer from bandwidth bottleneck, while ART can break through the bottleneck and achieve the IOPS upper bound of RNICs, with small read and write amplifications.

However, we find that there are redundant I/Os that waste the limited IOPS of RNICs in the DM architecture, hindering ART from continually breaking through the IOPS upper bound. Specifically, taking read operations as an example, when several clients on the same CN read the same key-value item concurrently, they send identical RDMA\_READs across the network. This is superfluous duplication of effort since all these requests do the same transmission work.

To measure the extent of underlying inter-client redundant reads, we launch various numbers of clients on the same CN. Each client continuously issues 1KB RDMA\_READs, with their destination addresses following a Zipfian distribution of skewness 0.99 (*i.e.*, the same as YCSB’s). As shown in Figure 4c, during each read time window, the average number of redundant RDMA\_READs increases with the number of clients and achieves up to 0.48 with 64 clients, implying 48% read performance improvement potential.

<sup>1</sup>To eliminate the impact of concurrency conflicts, we scatter the update part of workloads among clients without intersection.

As for inter-client redundant writes, we issue constant RDMA\_WRITES with lock-based concurrency control via RDMA\_CASes from each client. As shown in Figure 4d, during each write time window (including lock acquisition and release), the average number of redundant RDMA\_WRITES grows and reaches up to 3.3, indicating around 330% write performance improvement space with 64 clients. Interestingly, the number of redundant writes is more than the read one since redundant writes inevitably exacerbate the concurrency conflicts, leading to a longer write time window and thus more redundant writes in return. The nearly exponential growth of the redundant number of RDMA\_CASes saturates the IOPS upper bound rapidly and causes poor write performance.

**Challenge 3: Structural features of ART deteriorate the problem of computing-side cache invalidation.** As presented in § 2.3, *path compression* and *adaptive nodes* are two important structural features that reduce memory consumption by reducing the tree height and the node size, respectively. However, these two features introduce new cache validation problems. For instance, adjustments on the parent-child relationship of nodes may happen during insertion into compressed nodes. The caches on other CNs still store the old content of the parent node. If a client on those CNs does not conduct a cache verification, it incorrectly reads the old child node according to the outdated cache and thus fails to access the newly inserted node. Similarly, node type changes are invisible by the computing-side cache either, which may lead to incomplete node fetching.

## 4 SMART Design

We propose SMART, a high-performance ART for DM. Figure 5 shows the overview of SMART. To improve the efficiency of concurrency control (**Challenge 1**), we present a *hybrid ART concurrency control* scheme. The scheme contains a lock-free internal node design and a lock-based leaf node design to achieve high write performance without cache thrashing (§ 4.1). To save the limited IOPS of RNICs (**Challenge 2**), we propose a *read-delegation and write-combining (RDWC)* technique to eliminate inter-client redundant I/Os (§ 4.2). To handle the cache validation (**Challenge 3**), we co-design SMART with an *ART cache* (§ 4.3), including a reverse check

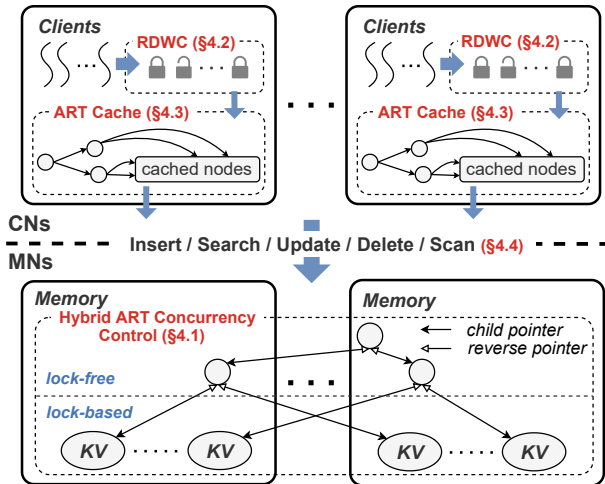

Figure 5: The overview of SMART.

mechanism. Lastly, we summarize the operations (*i.e.*, insert, search, update, delete, scan) that SMART supports (§ 4.4).

## 4.1 Hybrid ART Concurrency Control

In this section, we first describe the data structures and concurrent operations of the hybrid concurrency control scheme in SMART. We then introduce RDMA-related optimizations.

### 4.1.1 Data Structures

**Lock-free internal node.** As the addresses of internal nodes change more infrequently, internal nodes do not cause cache thrashing like leaf nodes. Hence, it is feasible for lock-free internal nodes to achieve high performance. We modify the internal nodes of ART as follows.

(1) **Homogeneous adaptive internal node.** As illustrated in Figure 2, a naive ART stores partial keys and child pointers separately. Such a heterogeneous design makes it hard to design a lock-free algorithm since the separated partial key and child pointer should be modified atomically. Besides, it incurs additional read amplification due to the inflexible fixed-sized internal nodes.

We come up with a homogeneous internal node design that embeds the partial keys into slots. First, this enables a child pointer to be modified together with its corresponding partial key atomically, laying the foundation for lock-free algorithms. Second, the read amplification can be reduced since internal nodes can have an arbitrary number of slots.

As shown in Figure 6a, an internal node of SMART consists of an 8-byte reverse pointer, several 8-byte slots, and an 8-byte header. The reverse pointer is used for cache validation, which will be presented in § 4.3. As for each slot, apart from the embedded 8-bit partial key and the 48-bit child pointer, we add a 1-bit *Leaf* field to indicate whether the pointer is pointing to a leaf node. When *Leaf* is set, a  $Len_{leaf}$  field is provided, which is used to support variable-sized keys (§ 4.5). When *Leaf* is unset, there is a 5-bit  $Type_{node}$  field to indicate

(a) The homogeneous adaptive internal node with the pessimistic 8-byte header.

(b) The update-in-place leaf node with the rear embedded optimistic lock.

Figure 6: The structure of the internal node and the leaf node in SMART. The reverse pointer and the in-header  $Type_{node}$  field are used for cache validation.

the type of the following internal node. Note that SMART mainly uses the  $Type_{node}$  to reduce the network bandwidth consumption rather than memory consumption. When fetching an internal node, SMART can RDMA\_READ only the required number of slots according to the  $Type_{node}$  field, reducing the read amplification and thus saving the network bandwidth.

(2) **Pessimistic 8-byte header of the internal node.** We choose the pessimistic method for path compression since both the optimistic and hybrid methods need two tree traversals to insert a nonexistent key. One entire tree traversal is required to search for the nonexistent key since not all compressed partial keys are stored in the header. The other traversal executes the actual insertion. In contrast, the pessimistic method can insert the nonexistent key through one traversal.

Besides, following previous designs [29, 33, 37], we fix the header size to 8 bytes, which can be changed atomically. If some partial keys overflow from the header, we store them in an empty following node. Although this may increase the tree height, we mitigate this with the help of cache (§ 4.3).

As shown in Figure 6a, a header consists of an 8-bit *Depth* field, a 5-bit  $Type_{node}$  field, a 3-bit  $Size_{array}$  field, and a 6-byte array of partial keys. The *Depth* field indicates the start position for matching the target key. The  $Type_{node}$  field is used for cache validation, which will be illustrated in § 4.3. The  $Size_{array}$  field records the length of the partial key array, where at most six partial keys can be stored.

**Lock-based leaf node.** In-place update schemes are preferred as it does not cause cache thrashing. To adopt the in-place update, lock-based concurrency control for the leaf node is required. This is acceptable since locks are fine-grained, as each leaf node in the radix tree only contains one key-value item. We design the leaf node structure as follows for concurrency control.

(1) **Checksum-based update-in-place leaf node.** The in-

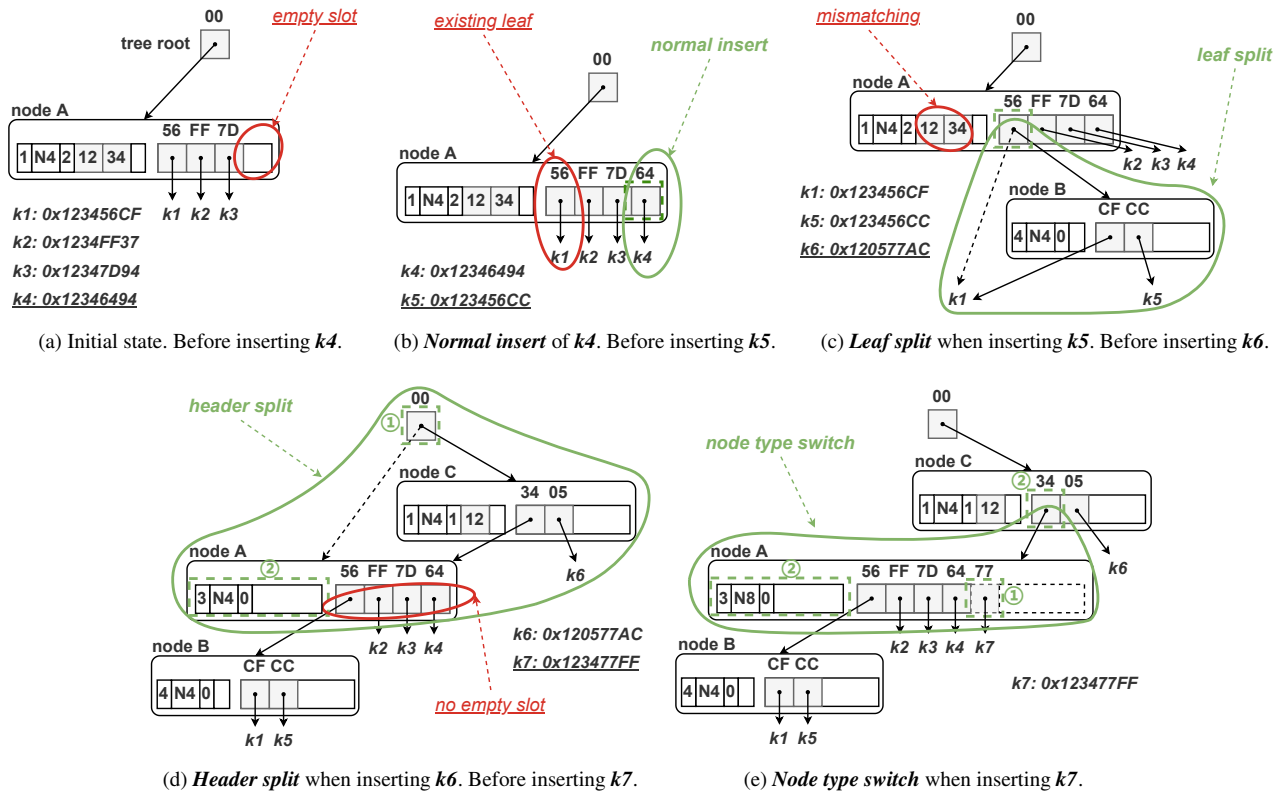

Figure 7: A step-by-step example of inserting several new keys into SMART with 8-bit partial keys. For clarity, hexadecimal partial keys are shown and reverse pointers are omitted. Each thick dotted box indicates an atomic CAS.

place update scheme overwrites the leaf node at the same address, causing conflicts among readers and writers. To avoid conflicts, we adopt an optimistic lock in each leaf node with a checksum-based consistency check mechanism [40, 53], where the fixed-sized key-value item in the leaf node is protected by a checksum. For write-write conflicts, an exclusive lock is used to synchronize the writers. As for read-write conflicts, when a writer modifies the leaf node, the checksum is re-calculated based on the new content of the leaf node and written with the new content. The readers verify the checksum after reading the leaf node. If the checksum verification fails, the reader conducts a re-read.

(2) *Rear embedded lock*. To further reduce the overhead of locks, we combine the lock release with the writing back of the updated leaf node by embedding the lock into each leaf node. Therefore, the two operations can be done via one single RDMA\_WRITE. Particularly, to avoid premature lock release, we ensure that the lock release is always triggered after the completion of writing back. We achieve this by placing the lock at the rear of a leaf node, which leverages the in-order delivery property of RNICs [12].

As shown in Figure 6b, a leaf node of SMART consists of an 8-byte reverse pointer, a *Valid* bit, an 8-byte checksum, a 1-byte rear lock and a fixed-sized key-value item. The reverse

pointer is used for cache validation, which will be illustrated in § 4.3. The *Valid* bit is used to indicate the deleted state.

#### 4.1.2 Concurrent Operations

Based on the above structural modifications, we demonstrate essential write-related sub-operations with a step-by-step example, as shown in Figure 7. Except for the in-place leaf update, all the sub-operations are lock-free. The complete operation process will be described in § 4.4.

*Normal insert*. During an insert, the target partial key may not be in the internal node yet. As shown in Figure 7b, after the WRITE of the new leaf node ( $k_4$ ), the client CASes the first empty slot in the node, together with the new partial key. If the CAS fails, the client checks whether the return value (*i.e.*, a new value of the slot written by a concurrent client) contains the target partial key. If yes, the client continues to traverse the tree following the return pointer. Otherwise, the client tries the insert again with the next empty slot.

*Leaf split*. If an existing leaf node is found during an insert, a leaf split is needed as shown in Figure 7c. Specifically, the client first calculates the rest of the longest common key prefix of the two leaf nodes ( $k_5$  and  $k_1$ ). Then it allocates sufficient sequentially-connected internal nodes to store the common key prefix in their headers. The last internal node will contain two child pointers pointing to the old and new leaf nodes. All

internal nodes and the new leaf node can be written in parallel, after which the client CASes the parent slot to point to the first new internal node. If the CAS fails, the client continues to traverse following the return pointer.

**Header split.** If a mismatching for in-header partial keys is found, a header split is required as shown in Figure 7d. Specifically, the client allocates a new NODE\_4 pointing to the split internal node and new leaf node ( $k_6$ ), with its header storing the matched part of partial keys. The new internal and leaf node can be written in parallel. Then the client CASes the parent slot to make it point to the new internal node (①). If CAS succeeds, the redundant in-header old partial keys are removed via an additional CAS (②). Otherwise, the client continues to traverse following the return pointer.

Note that the correctness of concurrent searches can be guaranteed by the in-header *Depth* value, which indicates the start position for matching the current key. A concurrent search READs the parent node and then the child node. Therefore, there are two situations of read-write conflicts. First, the READ of the parent node occurs after the CAS of the parent slot (①), while the READ of the child node occurs before the CAS of the split header (②). In this situation, redundant in-header partial keys are read, which does not affect the correctness. Second, the former READ occurs before the former CAS (①), while the latter READ occurs after the latter CAS (②). In this case, the reader re-reads the parent slot if finding partial keys missing according to the *Depth* value.

**Node type switch.** To avoid copy-on-write (COW) overhead and additional cache coherence introduced by out-of-place updates (**Challenge 1**), we conduct an in-place node type switch. This is feasible thanks to the homogeneous adaptive internal node design (§ 4.1.1). To be specific, we pre-allocate the contiguous space of NODE\_256 on MNs for each internal node. This consumes a little additional memory but enables lock-free operations during the node type switch. When neither a matching partial key nor an empty slot is found in the current internal node, the client can try to CAS the following empty slots one by one, whose addresses are behind the node (①) as shown in Figure 7e. After a successful CAS, the current best-fit node type can be determined by the index of the newly inserted slot. The client then tries to update the two old  $Type_{node}$  values (on the header and the parent slot) with the new one via two concurrent CASes (②), making the newly inserted leaf visible by subsequent search. If both CASes succeed or fail with return values containing  $Type_{node}$  values larger than/equal to the expected one, the node type switch is finished. Otherwise, the client retries the CASes.

**In-place leaf update.** To update a leaf node, the client first acquires the rear embedded lock in the leaf node. It then WRITES back the updated leaf node with the re-calculated checksum and the unset lock, after which the in-place leaf update is finished with the lock properly released.

### 4.1.3 RDMA-related Optimizations

To further optimize performance on DM, SMART adopts the following RDMA-related optimizations [23].

**Inline write.** For small-sized WRITE (e.g., writing internal nodes smaller than NODE\_16 or leaf nodes), the INLINE flag is set, enabling the RNIC to encapsulate payload into the work queue entry (WQE) and thus reducing PCIe overhead.

**Unsignaled verbs.** As for writing commands allowing asynchronous execution (e.g., CAS of the header during *header split*), SMART unsets the SIGNED flag to reduce the overhead of polling RDMA completion queues.

**Doorbell batching.** If a client issues multiple WQEs to the same queue pair (e.g., to the same MN), a doorbell batching is conducted to reduce PCIe overhead.

## 4.2 Read Delegation and Write Combining

SMART proposes the read-delegation and write-combining (RDWC) technique on DM to eliminate inter-client redundant I/Os in terms of reads and writes, respectively, to break through the IOPS upper bound.

**Hash-based local locks.** The inter-client redundant I/Os on each CN occur among the concurrent read and write operations on the same key or address. Therefore, computing-side local locks are needed to collect the concurrent operations.

We maintain the local locks in each CN as a table, similar to the local lock table of HOCL in Sherman [53]. However, unlike Sherman, which maintains each local lock for a coarse-grained global lock, SMART maintains each local lock for a key (i.e., fine-grained leaf node). It is challenging to store all such locks in each limited computing-side memory. To address this, we use hash-based local locks, where a lock corresponds to a set of keys with the same hash value.

We dynamically maintain a *unique key* in each local lock to solve the hash-conflict problem of our hash-based scheme. Specifically, the first client who acquires a local lock successfully will record its target key as the unique key of this local lock. The subsequent clients who fail to acquire this local lock will conduct a hash-conflict check by comparing their target key with the unique key. If the target key is exactly the same as the unique key, the client can be involved in the read delegation or write combining. Otherwise, a hash conflict is found, and the client should execute a normal remote read or write on its own for correctness. The unique key is freed when the first client releases the local lock.

**Read delegation.** To reduce inter-client redundant I/Os for reads, a *delegation client* can be elected on each CN to execute the same read, and then share its RDMA\_READ result with other waiting clients. The first client who acquires the local lock successfully is the delegation client and the subsequent clients who fail to acquire the lock are the waiting clients. The relationship between the delegation client and the waiting clients is similar to that between the first cache miss and the subsequent delayed cache hits in the cache system [5].

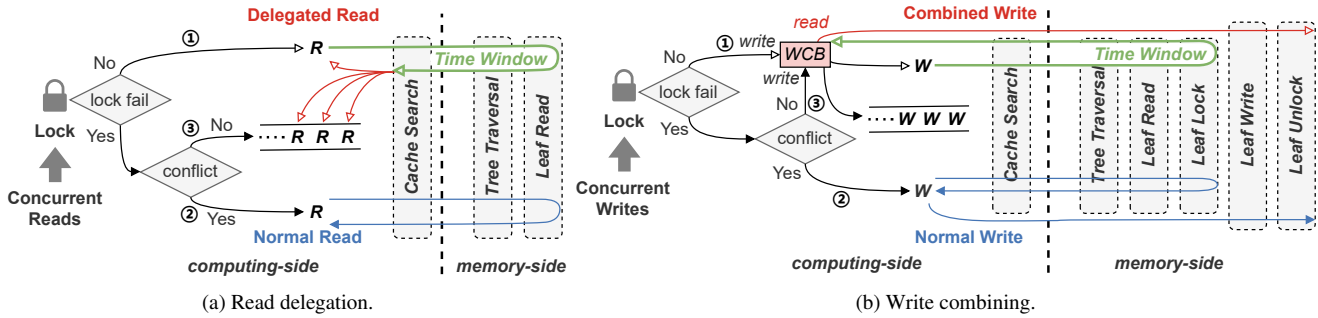

Figure 8: The processes of the read delegation and the write combining on SMART respectively.

We implement this as shown in Figure 8a. After acquiring the corresponding local lock successfully, the delegation client records its target key as the unique key and then conducts the remote tree search (*i.e.*, including cache search, tree traversal, and leaf node read), which is the time window of read delegation (①). During the time window, the subsequent clients failing to acquire the local lock first execute the hash-conflict check by comparing their target key with the unique key. If a hash conflict is found, the client executes a normal tree search by itself (②). Otherwise, it pushes itself into a read-waiting queue and waits for the search result from the first client (③). Finally, the delegation client shares its search result with the waiting clients and releases the local lock.

**Write combining.** Write combining (WC) is a normal technology in modern processors [11]. When a processor intends to issue multiple writes to the same memory region in a small time window, it combines the writes into a single burst write so as to save the system bus bandwidth. This idea, also known as write coalescing, is applied to many storage systems [22, 28, 50]. Inspired by this, we find it feasible to conduct a WC on each CN. When clients intend to make several concurrent key-value writes to the same memory-side key or address, they can combine the writes into a single consensus write so as to save the network bandwidth and the limited IOPS of RNICs.

We implement WC on DM as shown in Figure 8b. A client that succeeds in acquiring the corresponding local lock first records its target key as the unique key and writes its new value into the write combining buffer (WCB), and then conducts the remote tree insert or update (①). Differently, the time window of write combining is the former partial period of tree insert or update (*i.e.*, cache search, tree traversal, and lock acquirement on leaf node). After that, the client reads the combined consensus result from WCB and then makes a RDMA\_WRITE to write back the result and release the remote lock. Finally, the client releases the local lock. During the write-combining time window, the subsequent clients first perform the same hash-conflict check. If a hash conflict is found, the client performs a normal tree insert or update on its own (②). Otherwise, it first writes its expected value into the

WCB (with local lock-based concurrency control), making the value visible to the first client. Then the client pushes itself into a write-waiting queue to wait for the completion of the remote write (③).

**Put both together.** Naively putting read-delegation and write-combining together may introduce incorrect read results when a client reads a key-value item after writing it. Specifically, the latter read may be delegated by a client whose read happens before the write operation. In this case, the old value (*i.e.*, the value of the item before the client’s write) is returned to the read operation that happens after the write, breaking the causality of the read and write. We use the same time window for read-delegation and write-combining to address this issue. In this way, the write and read operations with causal relations are included in two non-overlapped time windows, and thus, the above issue can be avoided. To achieve this, we let readers and writers operating on the same key fairly acquire the same local lock, where the winner decides the time window. Each local lock is associated with two waiting queues, *i.e.*, a read queue and a write queue, so as to conduct read delegation and write combining exclusively and concurrently. In our implementation, 4M 32-bit local locks are sufficient on each CN, consuming only nearly 3% of cache size.<sup>2</sup>

### 4.3 ART Cache

**ART-indexed cache.** To reduce remote access during tree traversal, a memory-efficient ART-indexed cache is designed on each CN to store partial internal nodes of SMART. To be specific, utilizing the feature that each radix tree node (excluding header) can be uniquely identified by a key prefix, we adopt a local ART on each CN to index the cached internal nodes. As shown in Figure 9, each leaf node (*i.e.*, cache entry) of the local ART contains the snapshot of a traversal context (*i.e.*, the content of an internal node being read from MNs, the *Depth* value, and the address of the node).

**Cache invalidation situations.** Since we cache the slots of the internal nodes in clients, changing the slots in the disaggregated memory leads to cache invalidation. We analyze all

<sup>2</sup>Note that with  $N$  clients in each CN, there are at most  $N$  dynamically-allocated WCBs and unique keys at the same time, whose memory consumption (*i.e.*, size of  $N$  key-value items) is negligible.

Figure 9: The structure of the ART cache.

operations that change the slots (*i.e.*, slot insert, update, and delete) and find there are only three types of cache invalidation in the current SMART design, *i.e.*, Type 1: *adjustments on the parent-child relationship*, Type 2: *node type changes*, and Type 3: *deleted nodes*. Specifically:

**For slot insert**, inserting a new slot does not affect the client cache since the new slot is not in the client cache.

**For slot update**, it contains four situations according to the structure of slots in Figure 6a (note that the *Partial Key* field keeps unchanged until deleted):

- Updating the *Child Pointer* field. This type of cache invalidation corresponds to Type 1.
- Updating the  $Type_{node}$  field. This type of cache invalidation corresponds to Type 2.
- Updating the *Leaf* field. Since leaf nodes have different addresses from internal nodes, the *Leaf* field update should be combined with a *Child Pointer* update. Thus this type of cache invalidation corresponds to Type 1.
- Updating the  $Len_{leaf}$  field. This field keeps unchanged since SMART is currently designed for fixed-sized leaf nodes. The support for variable-sized leaf nodes will be discussed in § 4.5.

**For slot delete**, this type of cache invalidation corresponds to Type 3.

**Reverse check mechanism.** To handle the above three types of cache invalidation situations, we design a reverse check mechanism specifically for SMART, as existing solutions on B+ trees are infeasible for ART. We store the check information in remote internal and leaf nodes. A mismatch between check information and cache content indicates an outdated cache entry, which will be invalidated.

**(1) Adjustments on the parent-child relationship.** We store a reverse pointer in the front of each node to point to its parent, as shown in Figure 6. If the client reads a remote node according to a cached pointer, it checks whether the reverse address is equal to the node address in the cache entry. If not, a mismatch is found, which indicates that a newly inserted node (*e.g.*, caused by *leaf split* or *header split*) is invisible to the client due to the outdated cache entry.

**(2) Node type changes.** We design a  $Type_{node}$  field in the header of each node to indicate the current type of the node, as shown in Figure 6a. If the client reads a remote node according to a cached pointer, it checks whether the in-header

$Type_{node}$  value being read is the same as that in the cached slot. If not, and the in-header  $Type_{node}$  value is larger than the cached one, read the rest of the remote node.

**(3) Deleted nodes.** We set the in-header  $Type_{node}$  value to zero to indicate the deleted state of an internal node. As for a deleted leaf node, the *Valid* bit is unset.

## 4.4 Operations

All operations first search in the cache for the deepest slot that is matched by the prefix of the target key. If none of the cached slots hits, start the traversal from the tree root slot.

**Search.** The client first reads the node according to the slot, after which a *reverse check* is conducted to check if the cache entry expires. If yes, invalidate the cache entry and retry this search. As for a leaf node being read, the target item is found if its key is the same as the target key. Otherwise, it does not exist. As for an internal node, if all the in-header partial keys are matched, and the next target partial key can be found in a slot, read the next node along the child pointer in the slot and repeat the process. Otherwise, the target item does not exist.

**Insert/Update.** The client first reads the node and conducts a *reverse check* like the search. After that, as for a leaf node, if its key is the same as the target key, execute an *in-place leaf update*. Otherwise, a *leaf split* is needed. As for an internal node, if a mismatching for the in-header partial keys is found, conduct a *header split*. Otherwise, turn to search among the slots. If the current target partial key can be found in a slot, read the next node along the corresponding child pointer in the slot and start the process again. Otherwise, conduct a *normal insert* with the next empty pointer slot. If no empty slot can be found, a *node type switch* is needed.

**Delete.** Delete operations have a similar process as insert operations. A normal delete clears the slot pointing to the target leaf node via RDMA\_CAS and unsets the *Valid* bit of the deleted leaf node. Opposite operations of *leaf split* and *header split* are conducted for path compression.

**Scan.** At each level of traversal, the client conducts parallel RDMA\_READs to fetch all nodes inside the target key range. For each RDMA\_READ, the client processes the node being read in the same way as the search operation, with an additional comparison between partial keys and target key range to exclude unwanted concurrent search paths. Like many other existing tree indexes [53, 59] on DM, SMART does not guarantee the scan is atomic with concurrent insert or update operations.

## 4.5 Discussion

**Support for variable-sized keys and values.** SMART currently supports fixed-sized keys and values. For variable-sized keys and values, the optimizations of *update-in-place leaf node* and *rear embedded lock* in SMART are no longer applicable. Instead, SMART can use the RCU scheme to out-of-place update the leaf node to support variable-sized keys and values. The search, insert and delete operations on

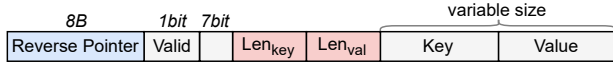

Figure 10: The structure of the variable-sized leaf node.

variable-sized key-value items are the same as that on fixed-sized ones.

As for the leaf node structure, SMART can follow the design in RACE [60]. As shown in Figure 10, the leaf node structure includes a  $Len_{key}$  field and a  $Len_{val}$  field, which indicate the sizes of the following *Key* and *Value* fields, respectively. SMART can use the 7-bit  $Len_{leaf}$  field in the parent slot and a pre-configured  $length\_unit$  value to indicate the length of the leaf node. The maximum length of a leaf node is  $2^7 \cdot length\_unit$ . When a key-value item exceeds the maximum length, SMART can store the remaining content in a second key-value block linked to the leaf node.

Moreover, the cache validation mechanism (§ 4.3) can be extended to support variable-sized leaf nodes with a new cache invalidation situation, *i.e.*, Type 4: *leaf node length changes*. When a client reads a remote leaf node according to a cached slot, it checks whether the sum of the  $Len_{key}$  and  $Len_{val}$  values equals the  $Len_{leaf} \cdot length\_unit$  value. If not, the cached slot is invalid.

**Generality of techniques in SMART.** Some techniques in SMART can also be applied to other kinds of indexes. Particularly: 1) The *RDWC* technique can benefit any tree indexes since it is transparent to the lower-level index structures. When applied to other index structures, it brings about the same performance improvement as applied to ART. 2) The *reverse check mechanism* can benefit any radix-tree-based indexes. It is designed to handle the cache validation problems caused by ART’s features. 3) The *rear embedded lock* can be adopted in any lock-based structures on DM to save one RTT.

**The first lock-free ART design.** A pure lock-free ART can be formed with the lock-free node design in Figure 6a and a lock-free leaf node design with a traditional RCU scheme. To our knowledge, this is the first lock-free ART design. In our implementation, SMART can degenerate into the pure lock-free ART by disabling the optimizations of *update-in-place leaf node* and *rear embedded lock*.

## 5 Evaluation

### 5.1 Experimental Setup

**Testbed.** We run all experiments on 16 physical machines (16 CNs and 2 MNs)<sup>3</sup> on the Clemson cluster of Cloud-Lab [13]. Each machine has two 36-core Intel Xeon CPUs, 256GB of DRAM, and one 100Gbps Mellanox ConnectX-6 IB RNIC. Each RNIC is connected to a 100Gbps Ethernet switch. Each MN owns 64GB DRAM and 1 CPU core for network connection and memory allocation. Each CN owns

<sup>3</sup>Like Sherman [53], we make two physical machines act as both CN and MN to save machine resources.

4GB DRAM and 64 CPU cores, where each core can serve as a client. The MNs register memory with huge pages to reduce page translation cache misses of RNICs [12].

**Workloads.** Without explicit mention, we use the index microbench [55] to generate YCSB [10] workloads like previous work [6, 26, 39]. We evaluate SMART with 6 YCSB core workloads: A (50% read, 50% update), B (95% read, 5% update), C (100% read), D (latest-read, 95% read, 5% insert), E (95% scan accessing up to 100 items, 5% insert) and an additional LOAD (100% insert) workloads, using the default Zipfian distribution for all workloads except for YCSB LOAD and D. For most workloads, we test 2 key types, *i.e.*, integer (8-byte) and string (32-byte). For string workloads, we use 125 million publicly available email addresses [15] and conduct a common pre-processing (*i.e.*, swap username and domain fields of email addresses) like previous work [32, 38, 39, 55]. We use 8-byte values consistent with prior work [6, 24, 38, 41, 53, 56]. For each workload, we populate 60 million keys before conducting 60 million operations, except for the LOAD test.

**Comparisons.** We compare SMART with two state-of-the-art tree indexes, *i.e.*, Sherman [53] and ART [32]. We use the default configuration of Sherman (*e.g.*, a span size of 32 for long key) with all optimizations enabled (*e.g.*, on-chip memory). Since ART is not designed for DM, we port it to DM by re-implementing it from scratch (as mentioned in § 3), including its synchronization design (*i.e.*, ROWEX [33]). For better baseline performance, we apply the HOCL of Sherman to ART and any other baselines of SMART. Coroutines are used in each client to hide RDMA polling overhead.

### 5.2 Performance Comparison

Figures 11 and 12 present the throughput-latency curves of the three indexes with integer and string keys respectively, using various numbers of clients (16 at least and 896 at most, evenly distributed across 16 CNs). Without loss of generality, we discuss the performance of integer keys in the following.

**Search-only workload (YCSB C).** For the YCSB C workload, SMART outperforms Sherman by  $2.8\times$  due to no leaf read amplification, as mentioned in § 3. Moreover, it outperforms ART by  $1.2\times$  due to the read delegation mechanism for reducing redundant I/Os. It is worth noting that SMART achieves up to 96M requests per second, which breaks through the total IOPS upper bound of memory-side RNICs (about 90 Mops in total with the two MNs). This is because the read delegation can perform concurrent duplicated reads with only one delegated read. Besides, the similar P99 latency of SMART and ART shows that the read delegation causes near-zero overhead.

**Insert workload (YCSB LOAD, D).** For the YCSB LOAD workload, SMART outperforms Sherman and ART by  $1.6\times$ ,  $1.5\times$  in throughput and achieves  $1.4\times$ ,  $1.5\times$  lower P99 latency respectively. This can be attributed to the design of the lock-free internal nodes. Specifically, both Sherman and ART have low throughput and high latency due to the node-

Figure 11: The performance comparison of tree indexes on DM under YCSB workloads of integer keys.

Figure 12: The performance comparison of tree indexes on DM under YCSB workloads of string keys.

Figure 13: The scalability of Figure 14: The performance of scan untree indexes under the YCSB E workload of integer keys with different value sizes.

grained locks, which introduce additional RTTs with frequent lock-fail retries, thus wasting the limited IOPS of RNICs in write-intensive scenarios (*i.e.*, 50% insert). Interestingly, with string workloads, the latency of ART becomes much worse since the smaller set of string partial keys (*e.g.*, alphanumeric characters) aggravates concurrency conflicts.

For the YCSB D workload, SMART achieves  $2.4\times$  and  $1.4\times$  higher throughput and  $1.1\times$  and  $1.8\times$  lower P99 latency, compared with Sherman and ART respectively. With fewer write conflicts (*i.e.*, only 5% insert), read and write amplifications become the main reason for the poor performance of Sherman. ART still has a high tail latency since concurrent writes cause cache misses, leading to remote tree traversals and thus continuous lock operations on the remote tree.

**Update workload (YCSB A, B).** Compared with Sherman and ART, SMART gains  $6.1\times$  and  $3.4\times$  improvement

in throughput and  $1.4\times$  and  $1.3\times$  reduction in latency for YCSB A, and achieves  $2.4\times$  and  $1.8\times$  higher throughput and  $1.1\times$  and  $1.7\times$  lower P99 latency for YCSB B, respectively.

Unlike the insert workload, YCSB A and B follow a Zipfian distribution of skewness 0.99, indicating a high amount of update concurrency conflicts. Consequently, Sherman performs poorly with YCSB A due to its coarse-grained, lock-based concurrency control. ART performs better than Sherman since update operations do not modify the partial key fields and thus do not need to acquire locks. However, the out-of-place update scheme used by ART causes cache thrashing, resulting in huge cache-miss overhead and thus much higher latency than SMART. Note that the cache thrashing also impacts search performance, leaving a poor performance of ART on YCSB B (with only 5% update). As shown in Figure 13, ART experiences performance collapse with increasing clients due to severe cache thrashing. In contrast, SMART shows excellent scalability due to the cache-friendly in-place leaf node design and fine-grained concurrency control.

**Scan workload (YCSB E).** We evaluate the performance of scan operations with 128 clients using varying value sizes as shown in Figure 14. For a small value size (*e.g.*, 8 bytes), SMART shows poorer performance than Sherman since the small-sized leaf nodes saturate the memory-side IOPS upper bound, which is an inherent shortcoming of radix trees. However, for a value size larger than 64 bytes, which is common in real-world workload [4, 58], the scan performance of Sherman becomes worse than SMART since the large-sized leaf nodes rapidly saturate the bandwidth bottleneck.

Figure 15: The factor analysis of overall performance on SMART.

### 5.3 Factor Analysis for SMART Design

Figure 15 presents the factor analysis on SMART. We start with the naive ART and apply each proposed technique one by one. We use 16 CNs (each launches 24 clients) and integer keys for experiments in this section.

**+ Lock-free internal node.** The lock-free internal nodes mainly contribute to the insert workload. With YCSB LOAD, it brings  $1.5\times$  improvement in throughput and  $1.8\times/1.4\times$  reduction in P50/P99 latency. Unlike ROWEX, lock-free internal nodes eliminate expensive lock overhead during insertion and thus improve performance.

**+ Update-in-place leaf node.** In-place update scheme mainly contributes to the update workload. It achieves  $1.5\times$  improvement in throughput and  $1.4\times/1.7\times$  reduction in P50/P99 latency with YCSB B. The in-place update scheme alleviates the cache coherence problem, as the addresses of the cached leaf nodes never expire until being deleted.

**+ Rear embedded lock.** The rear embedded locks further optimize the in-place update scheme. It eliminates the lock-releasing overhead, saving one RTT during each update. With YCSB A, it improves throughput by  $3.0\times$  and reduces tail latency by  $11.3\times$ .

**+ Read delegation.** The read delegation mechanism contributes to the search workload. It brings  $1.1\times$  throughput improvement and  $1.3\times$  tail latency reduction with YCSB C. It eliminates superfluous reads and thus saves network I/O consumption, so as to support more client requests.

**+ Write combining.** The write combining mechanism mainly contributes to the write-intensive workload. It improves the throughput by  $1.1\times$  and reduces tail latency by  $1.3\times$  with YCSB A.

As the RDWC technique can reduce concurrency conflicts similar to HOCL, we compare their efficiency by applying them on SMART respectively. As shown in Figure 16, when applying the primitive HOCL design, SMART shows poor performance with an average of 0.76 lock-fail retry count, due to the limited on-chip memory space (128MB per RNIC in our evaluation) with only 2 MNs, which is insufficient for a large number of fine-grained locks. With E-HOCL (*i.e.*, integrating the rear embedded lock technique into HOCL), SMART achieves much better performance with an average

Figure 16: The efficiency comparison of HOCL, E-HOCL and RDWC under the YCSB A workload. Figure 17: The factor analysis of cache efficiency on SMART under the YCSB A workload.

of 0.29 lock-fail retry count. However, despite the optimization, HOCL still shows lower improvement efficiency than RDWC, which can introduce a 26.2% higher throughput. This is because RDWC saves not only the lock overhead but also the superfluous bandwidth consumption of reads and writes.

As the design of RDWC is transparent to the lower-level index structures, it will lead to the same amount of performance improvements on Sherman, *i.e.*,  $1.3\times$  and  $1.1\times$  under write-intensive and read-only workloads (Figure 15). Therefore, after applying RDWC to Sherman, SMART can still achieve  $4.7\times$  ( $= 6.1/1.3$ ) higher throughput under write-intensive workloads and  $2.5\times$  ( $= 2.8/1.1$ ) higher throughput under read-only workloads.

**Cache-related techniques.** Some cache-related techniques contribute to cache efficiency: **1) Homogeneous adaptive internal node.** Due to the homogeneous adaptive internal node design, more fine-grained and flexible adaptive nodes are available, saving cache space with smaller sizes of cached nodes. **2) ART-indexed cache.** Compared with a normal hash-based cache index, ART-indexed cache can efficiently save memory consumption of index keys without redundant key prefixes stored. As shown in Figure 17, after applying the above two techniques one by one, SMART achieves an increasing cache hit ratio and overall throughput under each specific limited cache size.

### 5.4 Sensitivity

In this section, we investigate how the workload skewness, key size, and value size affect the performance of SMART. We use 16 CNs with 16 clients each and integer keys for the sensitivity evaluation.

**Skew test.** Figure 18a shows the performances of different tree indexes on a generated Zipfian workload [35] (50% search + 50% update) with various skewness. SMART performs best under both slightly and highly skewed workloads. Sherman shows a good performance in slightly skewed workloads, while having the poorest performance in highly skewed workloads because of its coarse-grained lock-based concurrency control design. ART performs better than Sherman in

Figure 18: The sensitivity analysis.

highly skewed workloads due to the lock-free RCU scheme but performs worst in slightly skewed workloads due to cache thrashing. Note that the RDWC in SMART does not benefit the overall throughput since the network bandwidth is unsaturated. As the Zipfian skewness grows from 0.5 to 0.99, the performance of ART and SMART decrease by the same multiple ( $2.6\times$ ), and thus their performance gap is reduced. The performance of Sherman decreases by  $7.4\times$ , indicating the poor efficiency of coarse-grained lock-based design.

**Impact of key/value size.** Figures 18b and 18c show the impact of key size and value size on the performances of the three tree indexes under YCSB C with sufficient caches. As the key size grows from 8 to 256 bytes, SMART and ART show a slight performance decline ( $1.3\times$ ), while Sherman experiences a rapid drop in performance ( $14\times$ ). As the value size grows from 8 to 1024 bytes, the performance declines of SMART, ART and Sherman are  $3.1\times$ ,  $3.4\times$  and  $64\times$ , respectively. This is because, during each search, Sherman needs to fetch the whole leaf node, whose size grows with key and value size, causing the rapidly increasing consumption of network bandwidth. On the contrary, SMART and ART only need to fetch the fine-grained small-sized leaf node. Thus, they are not bounded by the network bandwidth bottleneck, showing a stable performance with varying key sizes and value sizes. The performances of ART and SMART are close since the read delegation in SMART does not benefit the throughput under the unsaturated network. This is consistent with the results shown in Figure 11d.

## 6 Related Work

**Disaggregated Memory.** The DM architecture is widely discussed in the literature [3, 9, 16, 19, 20, 27, 47], which is proposed to address the problem of a growing imbalance between computing and memory resources. Many recent academic works have been conducted on DM. LegoOS [46] designs a distributed operating system for disaggregated resource management. PolarDB Serverless [8] co-designs the database and DM to achieve better dynamic resource provisioning and faster failure recovery speed. Clover [52] explores an efficient manner to build a key-value store on disaggregated persistent memory (PM), with careful designs between the data plane and the metadata/control plane. FUSEE [48]

designs a fully memory-disaggregated key-value store that brings disaggregation to metadata management. ROLEX [34] proposes a scalable RDMA-oriented learned key-value store that dissociates the model retraining from data modification operations. RACE [60] is an extendible RDMA-based hashing index with lock-free remote concurrency control and efficient remote resizing. Sherman [53] is a B+ tree index on DM with RDMA-friendly software techniques to boost index write performance. SMART focuses on building a fast, scalable radix tree index on DM with small read and write amplifications.

**RDMA-based Tree Indexes.** Attracted by the high performance of RDMA, there are increasing studies focusing on RDMA-based tree indexes [1, 41, 45, 53, 59]. Many studies conduct operations via remote procedure calls (RPCs), which is unsuitable for DM due to weak memory-side computation power. FG [59], designed as a B-link tree, is the first index that completely leverages *one-side verbs* for write operations and thus supports DM. Sherman [53] is the state-of-the-art B+ tree index with several RDMA-friendly software techniques. However, constrained by the structure of the B+ tree, it suffers from low peak throughput and early latency deterioration due to read and write amplifications. Besides, extending RDMA interfaces is another approach to design tree indexes on DM, which offloads index write operations into memory-side NICs via SmartNICs or other customized hardware [1, 7, 14, 25, 36, 44, 49]. To our knowledge, SMART is the first radix tree index on DM that achieves high performance with commodity RNICs.

## 7 Conclusion

Based on a thorough theoretical and experimental analysis of tree indexes built on DM, this paper points out the performance bottleneck of B+ trees on DM due to severe read and write amplifications and then presents SMART, the first radix-tree-based index on DM. SMART addresses the challenges of applying ART on DM, including a hybrid concurrency control scheme to reduce lock overhead and avoid cache thrashing, a read-delegation and write-combining technique to reduce redundant I/Os, and a tailed cache validation mechanism. Our evaluation results show that SMART outperforms the state-of-the-art B+ tree on DM by up to  $6.1\times$  under write-intensive workloads and  $2.8\times$  under read-only workloads.

## A Artifact Appendix

### Abstract

The artifact provides the source code of SMART and automated scripts to reproduce all the experiment results in the paper. The experiment results can show the superiority of ART on DM compared with the B+ tree and demonstrate the efficacy and efficiency of SMART we design.

### Scope

**Superiority of ART on DM.** By reproducing the experiments of Figure 3, the artifact can validate that the radix tree is more suitable for DM than the B+ tree due to smaller read amplification under *read-only workloads*.

**Challenges of ART on DM.** By reproducing the experiments of Figure 4, the artifact can validate that ART suffers from significant challenges on DM under *hybrid read-write workloads*.

**Efficacy and Efficiency of SMART.** By reproducing the experiments of Figure 11-18, the artifact can validate that SMART can show better performance under YCSB workloads, compared with the state-of-the-art B+ tree on DM and a naive ART design.

### Contents

**Source codes.** The artifact contains source codes of SMART and the compared baselines (*e.g.*, ART). Specifically, the source code of SMART contains the implementation of our three key designs, *i.e.*, the hybrid ART concurrency control scheme, the read-delegation and write-combining technique, and the reverse check mechanism for cache validation.

**Automated scripts.** The artifact also contains automated scripts to reproduce all the experiment results in the paper, *i.e.*, Figure 3-4, 11-18. Each figure has a Python script to automatically reproduce and visualize the experimental results.

### Hosting

The artifact is available at <https://github.com/dmemsys/SMART>. Please use the *latest* commit version on the *main* branch.

### Requirements

The artifact is developed and tested using the r650 machines on CloudLab. 16 r650 machines are needed to reproduce all the results. Each r650 machine has two 36-core Intel Xeon CPUs, 256GB of DRAM, and one 100Gbps Mellanox ConnectX-6 IB RNIC. Each RNIC is connected to a 100Gbps Ethernet switch.

### Tutorial

**Environment setup.** To set up the environment, please clone the source codes to the r650 machines. The necessary dependencies can be installed using our provided shell scripts in the artifact. Listing 1 shows the commands to set up the experiment environment.

Listing 1: Commands to set up the environment.

```
1 # Get the source codes
2 git clone https://github.com/dmemsys/SMART
3 git clone https://github.com/River861/Sherman
4 # Set bash as the default shell
5 sudo su && chsh -s /bin/bash
6 # Install Mellanox OFED
7 cd SMART
8 sh ./script/installMLNX.sh
9 # Resize disk partition
10 sh ./script/resizePartition.sh
11 reboot
12 sudo su && resize2fs /dev/sda1
13 # Install libraries and tools
14 cd SMART
15 sh ./script/installLibs.sh
16 # Setup hugepages
17 echo 36864 > /proc/sys/vm/nr_hugepages
```

**Workloads generation.** The index microbench is used to generate YCSB workloads, including two key types, *i.e.*, integer and string. Listing 2 shows the commands to generate all the workloads to reproduce the results.

Listing 2: Commands to generate all workloads.

```
1 # Download YCSB source code
2 cd SMART/ycsb
3 sudo su && curl -O --location https://github.
4   com/brianfrankcooper/YCSB/releases/
5   download/0.11.0/ycsb-0.11.0.tar.gz
6 tar xfvz ycsb-0.11.0.tar.gz
7 mv ycsb-0.11.0 YCSB
8 # Download the email dataset
9 gdown --id 1ZJcQOuFI7IpAG6ZBgXwhjEeK01T7Alzp
# Start to generate all the workloads
sh generate_full_workloads.sh
```

**Results Reproduced.** The artifact provides a single batch script to reproduce all the experiments. This script should be run on a *master node*, which can directly establish SSH connections to other nodes of the r650 cluster.

To reproduce the experiments, please set up the *home\_dir* and *master\_ip* values in *./exp/params/common.json*. Then the script can be run. Listing 3 shows the commands. The reproduced results will be saved automatically.

Listing 3: Commands to start all experiments.

```
1 sudo su && cd SMART/exp
2 # Run all the experiments
3 sh run_all.sh
```

# ORC: Increasing Cloud Memory Density via Object Reuse with Capabilities

## Abstract

Cloud environments host many tenants, and typically there is substantial overlap between the application binaries and libraries executed by tenants. Thus, memory de-duplication can increase memory density by allocating memory for shared binaries only once. Existing de-duplication approaches, however, either rely on a shared OS to de-deduplicate binary objects, which provides unacceptably weak isolation; or exploit hypervisor-based de-duplication at the level of memory pages, which is blind to the semantics of the objects to be shared.

We describe *Object Reuse with Capabilities (ORC)*, which supports the fine-grained sharing of binary objects between tenants, while isolating tenants strongly through a small trusted computing base (TCB). ORC uses hardware support for memory capabilities to isolate tenants, which permits shared objects to be accessible to multiple tenants safely. Since ORC shares binary objects within a single address space through capabilities, it uses a new relocation type to create per-tenant state when loading shared objects. ORC supports the loading of objects by an untrusted guest, outside of its TCB, only verifying the safety of the loaded data. Our experiments show that ORC achieves a higher memory density with a lower overhead than hypervisor-based de-deduplication.

## 1 Introduction

In data centers, memory density determines how many applications can be deployed on machines with given memory amounts. Therefore, density is a critical cost factor, as memory contributes significantly to capital and operational expenses [3]. The challenge of achieving high memory density is expected to worsen as applications move to larger working set sizes [20, 36], and machines have more memory [10].

High memory density can be achieved by *de-duplicating* memory pages that have the same contents across a constellation of virtual machines (VMs), containers, and processes running on machines. This exploits that, in practice, the same OS is used across VMs, the same applications across containers, and the same libraries across processes [7, 31, 41, 61].

We observe that there is a trade-off between the efficiency of de-duplication and the level of isolation between tenants. Containers and processes achieve near-perfect memory density when they use a shared OS with binary loaders that explicitly identify de-duplication opportunities, e.g., through dynamic shared libraries [24, 25]. The high efficiency of de-duplication is due to the shared OS, which has visibility of memory at a *binary object level*. For security reasons, cloud environments, however, require stronger isolation between tenants, i.e., by using VMs without a shared OS.

In contrast, hypervisors implement strong isolation at the instruction set architecture (ISA) level, moving OS-level semantics to the guest OS. While this removes complexity from hypervisors, allowing them to provide strong isolation, it loses semantic information about how memory pages are used by VMs for object allocation. Memory de-duplication must thus occur at a *page level*: the hypervisor compares page contents blindly across VMs and performs expensive page table manipulations when de-duplicating, both of which result in performance and tail latency overheads [8, 39]. While hypervisors can accept de-duplication hints from VMs to reduce page scanning [1, 31, 40, 51], this does not eliminate overheads.

Our goal is to design a new cloud software stack that combines high memory density with low overhead, while providing strong isolation guarantees between tenants, relying only on a small trusted computing base (TCB).

We describe **Object Reuse with Capabilities (ORC)**, a new cloud software stack that allows de-duplication across tenants with strong isolation, a small TCB, and low overheads. ORC extends a binary program format (ELF [9]) to enable isolation domains to share binary objects, i.e., programs and libraries, by design. Object sharing is always explicit, thus avoiding the performance overheads of hypervisors with page de-duplication. For strong isolation, ORC only shares immutable and integrity-protected objects. To keep the TCB small, object loading is performed by the untrusted guest OS.

In more detail, the design and implementation of ORC combines the following novel features:

**(1) Object sharing with capabilities.** Current cloud stacks use page tables to control isolation and sharing, but page table manipulation is expensive: inter-VM sharing requires exits into the hypervisor to modify nested page tables [60]; de-duplication must temporarily downgrade page table entries, which can severely affect tail latencies [54].

Instead, ORC shares binary objects by design between isolation domains: it uses hardware support for *memory capabilities* [14, 16, 34, 64, 66] to place objects into *compartments*. Memory capabilities grant access to memory regions, can be copied between memory and registers, and are protected by hardware. They can be a building block for isolating cloud tenants with a small TCB by supporting an OS instance per compartment, as in today’s VMs [49].

With the help of capabilities, ORC isolates multiple compartments within a single address space, while sharing binary objects between compartments with virtually no overhead. ORC uses memory capabilities to isolate compartments within a single page table, safely and efficiently sharing objects in a controlled way.

**(2) Safe sharing of immutable objects.** Current binary formats, memory layouts, and loaders are designed for sharing across address spaces. After an object is loaded into memory, formats such as ELF [9] assume that global variables are mapped at fixed addresses relative to the code. While this is not an issue with per-process page tables, because an object’s global variables are mapped to different physical addresses in each process, ORC’s shared page table means that global per-process-and-object variables must be handled differently when sharing pages across compartments.

As a solution, ORC introduces a new type of variable relocation for *compartment-local storage* (CLS). ORC maintains absolute and code-relative references for code and read-only data, and the area for per-thread variables, i.e., thread-local storage (TLS). It also adds a new mechanism for per-process variables that replaces the traditional global variable references. This allows compartments to share immutable contents directly, i.e., code and read-only data, while still having per-process-and-thread state that is isolated across compartments. Under the hood, ORC allocates writable global variables in each compartment’s CLS, and loads objects to refer always to the executing compartment’s CLS (similar to TLS).

**(3) Untrusted loading of shared objects.** When objects are shared across isolation domains, loading is typically controlled by the TCB. The complexity of object loading bloats the TCB: it requires access to I/O devices, must load binary data into memory, and adjust memory contents to reflect load-time addresses, e.g., through relocations. Such functionality spans user-level, kernel-level and device driver code, and moving it into the TCB exposes a wide attack surface.

ORC avoids this issue by allowing untrusted compartments to handle most of the object loading (i.e., storage and file system I/O, data processing and copying, and adjustments

of memory contents). When an object is requested for the first time, the untrusted compartment manages its loading, and requests ORC to register an immutable and integrity-protected version of the newly-loaded object.

ORC verifies that the loaded object cannot be used to attack future compartments that reuse the same object, and makes it available to future load requests. The verification process is simple: it requires (i) scanning the memory contents of the registered object to calculate a hash, which ensures the object’s integrity in future load requests; and (ii) checking that any contained capabilities used by the object stay within the object’s memory and maintain immutability.

We evaluate ORC using a prototype implementation on the CHERI/Morello platform [42, 66] that includes a new compiler pass and loader support for CLS, a small privileged component that manages compartments and enforces the properties for secure sharing of binary objects, and a port of a library OS and C standard library that execute in each compartment.

We consider three workloads: (1) a cloud-based video transcoding micro-service, showing that ORC’s memory de-duplication is more resource-efficient compared to page-level de-duplication; (2) a latency-sensitive key/value store, demonstrating the lower impact of object-level de-duplication on tail latencies; and (3) an embedded database system, evaluating ORC’s decomposition cost into sharable compartments.

ORC has several limitations: unlike hypervisor-based de-duplication, ORC only de-duplicates read-only contents; it needs applications recompiled to use capability instructions and the new CLS; and it executes all compartments in one virtual address space, because capabilities use virtual addresses.

## 2 Increasing Memory Density in the Cloud

Memory density in cloud computing defines how efficiently the cloud provider is utilizing memory. Improving memory density is crucial for providers, because memory is often the main resource that determines how many tenants can be accommodated [33]. While providers want to exploit as many memory-sharing opportunities as possible, they must ensure that tenants and their workloads remain isolated.

We first discuss different approaches and their associated challenges for page-based isolation and memory sharing (§2.1). After that, we provide background on memory capabilities, which can act as an isolation mechanism without some of the drawbacks of page table-based isolation (§2.2).

### 2.1 Page-based memory sharing and isolation

Cloud tenants expect strong isolation for their applications from those of other tenants, while providers seek ways to minimize the total physical memory footprint by finding shareable memory. The two goals are at odds with each other: the

mechanisms that we have for efficient memory sharing are, in essence, reducing the level of isolation between tenants.

With today's isolation approaches, we must choose between containers [35, 38] and VMs [2, 30, 61], which in turn dictate how memory sharing can be done:

**(1) OS-managed memory sharing.** Container-based deployments rely on a shared OS for isolation. The OS provides user-space abstractions for sharing memory, and a loader can map the same binary object (e.g., dynamic library) across multiple processes. The OS has thus enough user-level information to de-duplicate object contents at load time, sharing memory across containers without extra runtime overhead.

Higher memory density in containers comes at the expense of isolation. Containers are not as strongly isolated as VMs, because they are managed by a shared OS kernel. Such a large, shared TCB is too complex to eliminate all vulnerabilities [11], which can be exploited by malicious containers to access information from other containers and tenants [12, 13].

**(2) Hypervisor-managed memory sharing.** VMs offer stronger isolation compared to containers: they expose a narrow virtualization interface at the level of the ISA, with a potentially small TCB (the hypervisor) that makes security vulnerabilities less likely [29, 57]. To share memory between VMs, typical hypervisors, such as ESX [61] and KVM [30], identify and eliminate redundant memory pages at runtime. Since the hypervisor lacks visibility into the semantics of user-space applications within each VM, it must periodically scan the memory of each VM to find pages with identical content, and remap these guest physical pages across VMs into the same host physical page to de-duplicate their contents.

A popular implementation of this approach is Linux *kernel same-page merging* (KSM) [1], which the KVM hypervisor leverages to eliminate duplicate memory pages across VMs. KSM periodically scans physical memory to find identical pages, and deduplicates them by mapping a single physical copy to multiple virtual locations. It also marks those pages as copy-on-write (COW), which triggers the re-duplication before a modification on shared page contents. Therefore, each VM instance can safely operate on its own copy, without affecting the memory contents of other VMs.

KSM uses red-black trees to search for memory pages with identical content. For efficiency, it utilizes two trees: (1) a *stable tree* that contains already-shared pages; and (2) an *unstable tree* that represents pages not shared but scanned previously. During the scanning process of a memory page, KSM first searches for a match in the stable tree. If the page is found, the redundant copy is eliminated through merging. If there is no match in the stable tree, KSM checks whether the page has been modified since the last scanning round by comparing hashes. If the page has not been modified, it is considered a suitable candidate for searching in the unstable tree. If the page is found in the unstable tree, merging occurs, and the shared page is inserted into the stable tree. Otherwise,

it is inserted into the unstable tree as a scanned page. The unstable tree is also reinitialized after each scanning round.

Despite the advantages of hypervisor-based isolation, its memory de-duplication mechanism has several drawbacks: (1) blindly scanning page contents and manipulating their permissions comes with an overhead on average performance and tail latencies [8, 39, 54]; (2) hypervisors lack the visibility of an OS to application-level load-time semantics, and therefore must rely on page scans; (3) while the use of larger pages in the cloud improves memory performance [27, 47], it can reduce memory density by making memory de-duplication less frequent; and (4) the use of COW semantics on de-duplicated pages has been shown to be vulnerable to timing side-channel attacks across VMs [26, 45, 58, 59, 67, 69].

## 2.2 Isolation with memory capabilities

As described above, using paging for both translation and protection introduces performance challenges in traditional virtualized environments due to its management granularity. In contrast, *memory capabilities* offer an alternative memory protection mechanism that is more flexible, robust, and efficient to manage. At the same time, memory capabilities can co-exist with the use of paging for translation [4, 6, 18, 19, 64].

Memory capabilities replace integer-type pointers with protected capabilities. Unlike regular pointers, capabilities provide information to enforce accesses within a given address range and access type. They can thus be used to partition a single address space into multiple, isolated regions, allowing the use of a single page table across isolation domains.

**Memory capabilities.** The Capability Hardware Enhanced RISC Instructions (CHERI) architecture [62] provides a modern implementation of memory capabilities. It introduces new instructions, registers, and other hardware primitives to support capabilities. CHERI enforces three properties: (1) *provenance validity* ensures that a capability cannot be created from an arbitrary sequence of bytes, but can only be derived from another capability; (2) *capability integrity* guarantees that capabilities in memory cannot be modified. One-bit *validity tags* are used to distinguish them from other data for protection; and (3) *monotonicity* ensures that a capability's permissions, including its bounds, cannot be expanded but only reduced.

CHERI can thus replace all pointers in an application with capabilities to enforce precise bounds and permissions on each memory access. This is known as the *pure-capability* (*pure-cap*) mode. Pure-cap enables spatial memory safety and fine-grained memory sharing, but requires ABI changes and other source code changes, e.g., to pointer-integer casts. CHERI also supports a *hybrid* mode, in which code is permitted to use legacy, capability-unaware instructions. In this mode, all control flow and memory operations are checked against a pair of special registers that contain *program-counter* and *default data capabilities*, thus restricting the code and data accesses performed by capability-unaware instructions.

Fig. 1: Using capabilities to create compartments

Code can use the capability-aware `CInvoke` instruction to perform function calls between isolated memory domains, carrying the necessary capability arguments across domains.

**Capability-based compartmentalization.** Capabilities offer a good mechanism to isolate software components, and their flexibility and efficiency can eliminate the overheads of page-based sharing. CAP-VM [49] describes a new capability-based compartmentalization mechanism: each capability compartment (cVM) has its own separate address sub-range within a shared address space, and executes programs in CHERI’s hybrid mode. cVMs are managed by a shared TCB component called the *Intravisor*, similar to a VM hypervisor. The *Intravisor* is a host process that starts cVMs as one or more host threads within its address space, using the default capabilities in hybrid mode to isolate cVMs. Each cVM has its own library OS instance to support private namespaces and program execution environments.

Fig. 1 shows how multiple components can be placed in capability compartments, potentially sharing access to objects across compartments. An *Intravisor*, or some other cross-compartment TCB, can give each compartment the capabilities needed to jump into/call code in other compartments, allowing the compartments to share capabilities to the same object. The figure also shows how capabilities can be used to request *Intravisor* operations (*hostcalls* at the bottom).

After compiling software components using CHERI’s pure-cap mode, however, it is not possible to use capability-based compartments to share objects efficiently, because: (1) the *Intravisor* has no explicit information about the extent and sharing properties of objects; and (2) existing storage formats and memory layouts of pure-cap binary objects assume that each compartment has its own page table.

In particular, ELF [9] assumes that global variables are reachable through constant addresses relative to code locations. If we use a per-process (or compartment) page table,

we can physically share non-writable pages across processes, while having separate contents for writable pages. This is no longer the case if we use a single page table, which is the only way to avoid page table management overheads.

## 2.3 Efficiency and security considerations

The goal of this paper is to provide high memory density in cloud environments. To achieve this goal, our solution must fulfill the following requirements:

(1) *Strong isolation with a minimal TCB:* Memory sharing is needed for density, but it should not undermine isolation between tenants. We must thus reduce the attack surface by providing a small TCB with a narrow interface to manage isolation and sharing for density.

(2) *Low performance overhead:* The sharing mechanism should not incur high overheads in terms of CPU cycles, and it should not prevent the system from performing other optimizations, such as using large pages to reduce TLB misses.

(3) *High sharing precision:* The sharing mechanism should support arbitrary object sizes and have visibility into the intended object sharing semantics. An ideal solution should not miss opportunities to share, nor unintentionally share memory that soon diverges into different contents. This can be a problem with KSM, because it blindly de-duplicates pages solely based on content and access frequencies.

Note that sharing memory can be used as an unintended *side channel* across compartments. This is an intrinsic trade-off between memory density and isolation that all cloud providers face, regardless of the employed mechanism. Given the importance of side channels, there are proposals to avoid or mitigate them at both hardware and software levels [23, 44].

The sharing of binary objects in this work is limited to side channels on accesses to (i) code and (ii) read-only data only. Since the user controls which binary objects to share and when, they can decide on a suitable policy for trading off between memory efficiency and side-channel resistance. We leave the exploration of such policies to future work.

## 3 Design of ORC

We exploit the capabilities provided by the CHERI architecture [62] to implement both software compartmentalization and binary object sharing. ORC shares binary objects *explicitly*, making the use of physical memory denser without the performance overheads of de-duplication.

Fig. 2 shows an example with two applications (app1 and app2), which use multiple object binaries that are identical across VMs, including the OS kernel (database, libC and kernel). Fig. 2a shows a baseline system in which each application is deployed in a VM for maximum isolation. In this case, the hypervisor incurs overheads of memory de-duplication.

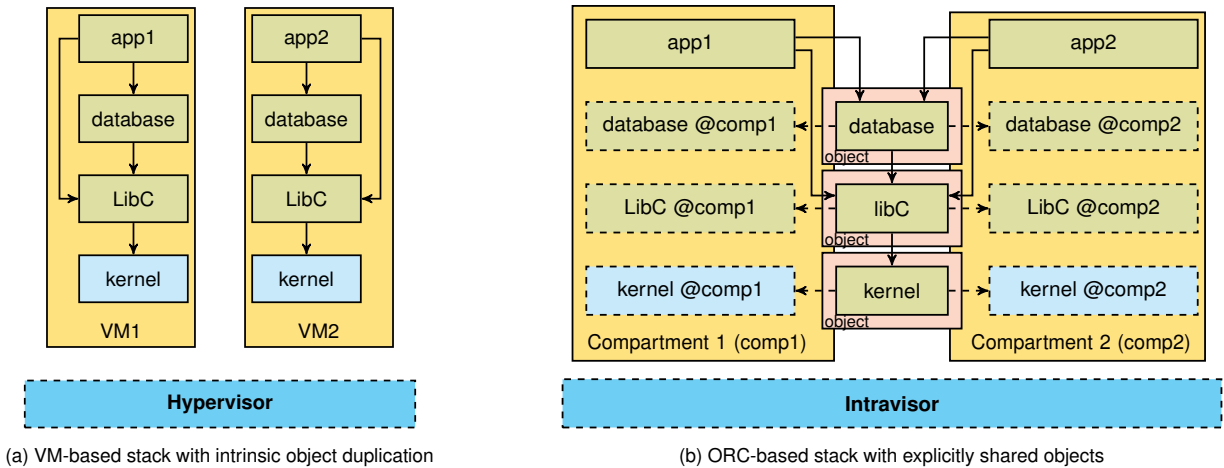

Fig. 2: Comparison between VMs and ORC compartments with explicit object sharing (Dotted lines show compartment-local variables.)

In contrast, Fig. 2b shows the approach taken by ORC. Programs are isolated into *compartments* (shown as light yellow boxes), which contain all needed objects (app1, app2, database and libC) as well as their own OS kernel instance (kernel). ORC compartments are deployed using a shared page table, and obtain access to non-overlapping addresses using *memory capabilities*. Both the page table and capabilities are controlled by the TCB, shown as *Intravisor*.

Compartments are strongly isolated: each has its own OS instance, and they are restricted to access non-overlapping memory address ranges. Sharing objects across compartments is supported through capabilities, which provide access to the object’s contents (light red boxes with objects database, libC and kernel). If possible, the ORC program loader requests capabilities from the Intravisor for an object that has already been loaded by another compartment. Otherwise, the compartment loads the object itself and registers it with the Intravisor, allowing future compartments to reuse it.

To make object sharing across compartments safe, the Intravisor must ensure that a shared object cannot be modified after registration. This, of course, implies that the registering compartment cannot change the object after registering it, but also that shared objects cannot contain writable state. We indicate this with the dotted lines in Fig. 2b: each shared object is recompiled to have per-compartment instances of any writable state. We refer to this as *compartment-local storage (CLS)*.

As a result, objects can be efficiently shared across domains, while retaining strong isolation down to the level of separate OS instances. In addition, sharing is part of the cloud software stack, ensuring that the memory density benefits do not come at the cost of reduced performance.

### 3.1 Architecture overview

Fig. 3 shows the high-level architecture of ORC. Programs execute within a compartment (shown as yellow boxes) and

have statically and dynamically-linked objects, as usual.

- 1 All potentially shareable objects, including the main program binary, must be compiled with our ORC-specific extensions. These extensions move all the writable state of an object into the CLS, i.e., all global writable variables, by extending the binary storage format and the loader (see below). The figure shows an example with three global variables, a constant, a thread-local, and a writable variable (var0, var1, and var2, respectively). Of the three variables, only var2 is moved to the CLS, because thread-local variables are already stored in a per-thread data structure, the TLS [17].

Note that none of these elements are part of the TCB – compartments can still use private copies of objects without the ORC extensions, and only references to global writable variables are changed to the CLS. Heap allocations are supported as usual, resulting in private compartment allocations.

Each compartment has its own, untrusted loader (ld.so in Linux). The compartment itself therefore loads the required objects by reading them from storage and parses their contents according to the binary format (e.g., ELF). 2 When the loader finds an ORC shareable object, it allocates the necessary memory to load the object and prepares it for execution.

- 3 After loading, the compartment calls the Intravisor’s `orc_register()` operation to register the loaded object for future use. The compartment passes the capabilities to where the object’s contents are loaded, and a list of variable references in the object’s code. The Intravisor then copies the object to a new location controlled by itself, computes a hash of its contents, resolves the variable references to the new load address, and registers the object’s hash and allocation capabilities for future use. At this point, all compartments, including the registering one, proceed in the knowledge that the shareable object is available in the Intravisor.

- 4 When a shareable object is registered in the Intravisor, the compartment requests it via `orc_request()`, passing it the expected object content hash. If the hash matches that of

Fig. 3: Architecture of the ORC stack (Circled numbers identify operations referenced in the text.)

a registered object by `orc_register()` above, the Intravisor releases the capabilities for that object. The loader then proceeds by allocating the memory for the CLS variables, and subsequently loaded objects can reference this one.

Note that the main program itself can be an ORC shareable object. In that case, after loading it with `orc_request()`, the whole application is ready for execution.

### 3.2 Compiler support and binary format

To support shared ORC objects, the compiler extends the binary format with CLS variables. With ORC enabled, the compiler adds a flag to identify the object as ORC-enabled, and moves writable global variables to the CLS.

For CLS, the compiler replaces each reference to a writable global variable with a new relocation type. Such relocations are resolved at load time to point to the per-container instance of that variable (see below), similar to how thread-local variables are moved to the TLS at load time.

Fig. 3 shows this process on the left-hand side. Code, constant variables, such as `var0`, and thread-local variables, such as `var1`, are handled as usual by the compiler: they are placed in the `.code`, `.rodata` and `.tdata` sections of the ELF object, respectively, generated with standard relocations. Writable global variables (`var2`) are placed in a new `.cdata` section, and references identified with the new `@cls` relocation.

### 3.3 Secure object loading and reuse

The compartment loader brings the object's file contents into memory, and handles all relocations that are independent of the load address. It then calls the Intravisor's `orc_register()` operation by passing the capabilities that delimit the memory regions in which the object was loaded and a description of the yet-unprocessed relocations.

To ensure that the object contents cannot be changed once shared, the Intravisor allocates new memory in capabilities  $C$ , copies the object contents into them, and checks that the object contains no capabilities pointing outside the  $C$  allocations to avoid malicious use of `orc_register()`. At this point, the Intravisor computes a hash  $H$  of the object contents, resolves the remaining relocations that depend on the information of the secure load location, and registers the object's hash and a non-writable version of the allocation capabilities,  $H$  and  $C$ , respectively. The CLS relocations are replaced with a value that points to a per-compartment memory address that holds all CLS variables of that object (see §4.2).

When a compartment calls `orc_request()`, it passes the hash  $H$ . If an object with hash  $H$  exists in the Intravisor, i.e., it was previously registered with `orc_register()`, the Intravisor returns the capabilities for it, which are ready to use by the calling compartment.

The object hash  $H$  is computed by the Intravisor before any location-dependent relocations, and so it is also known by the requesting compartment. If an object with hash  $H$  exists in the Intravisor, we know that its integrity and isolation are ensured. The Intravisor does not ensure object correctness beyond relocation resolution, which should be handled through other means, e.g., attestation checks as part of the software supply chain, for which hash  $H$  can be helpful.

### 3.4 Discussion

With ORC, components are shared by design via capabilities. Component sharing by design could also be implemented by other systems, e.g., traditional hypervisors with MMU mappings, but end-to-end performance would vary due to the different hardware mechanisms for enforcing isolation. Capabilities have further benefits e.g., their ability to provide spatial memory protection within components.

We also note that ORC only de-duplicates read-only mem-

ory contents, while traditional hypervisors also de-duplicate writable pages. This is not necessarily an issue: ORC de-duplicates application instances in less time than hypervisor-based approaches, which makes it better suited for short-lived instances, as often found in cloud environments. Our evaluation results also show that de-duplicating small amounts of writable memory leads to little practical benefit.

Finally, ORC requires the recompilation of applications, because applications must use capability instructions for code and data access and ORC's compiler pass for the required CLS functionality. ORC also executes all compartments in a single virtual address space, but we expect this to not be a problem: virtual addresses are an abundant resource, and it is possible to use large blocks to make allocations scalable and resistant to side channels e.g., via core-local caches.

## 4 Implementation

We implement ORC on the Morello platform [42], a development board from Arm that supports the CHERI capability extensions. In this section, we describe how we: build ORC compartments by extending CAP-VMs [49] with our own library OS to maximize object sharing; add CLS support through a new LLVM compiler pass; and implement the necessary logic to load shared objects securely.

Both the Intravisor and the host OS are implemented as hybrid capability code using the existing CAP-VM and CheriBSD [22] projects. We extend the Intravisor to support pure-cap compartments, i.e., using the pure-cap CHERI ABI, and the program loading operations, which adds 530 and 240 lines of C and assembly code, respectively.

For our evaluation, we also port the SQLite database [56], FFmpeg [21] with the libav libraries, and Redis [48] to support the pure-cap CHERI ABI and ORC. In total, the porting requires approximately 350 lines of code. Note that, besides adding the system functionality specific to ORC, the main effort went into porting code to the pure-cap model.

### 4.1 Library OS and standard C library

To increase object sharing across compartments, we make the library OS and low-level C library support a pure-cap build, as no such software components exist with the necessary functionality. We implement our own pure-cap library OS kernel, which is based on Unikraft [32] and CubicleOS [50], from which we use 40 system calls and 9,061 lines of code. We extend it with support for the CHERI ABI and add a capability-aware memory allocator.

We also use a pure-cap version of the C library for our evaluation applications. It is based on musl libc [43], whose pure-cap support is maintained by Arm. Our fork has 494 functions and 19,717 lines of code. We modify it to introduce a capability-aware memory allocator based on `d1malloc`, and a few extra changes for compatibility with our library OS.

### 4.2 Compiler support and CLS

We implement our ORC compiler support as an LLVM pass. It replaces all references to global, writable, non-TLS variables with a call to function `__cls_get_addr()`, which returns a compartment-local version of that variable. Internally, `__cls_get_addr()` is implemented using regular capability-aware instructions (`cgetaddr`, `cincffset`, `csetlen`, etc.). The function retrieves the address of the variable from the input capability and makes it relative to the beginning of the data section. After that, it applies the relative offset to the capability that points to the shadow data section. Finally, it creates the replaced capability by limiting its size to match that of the original capability.

The `__cls_get_addr()` function works similarly to how TLS is supported, i.e., through `__tls_get_addr()` in ELF [17]. It takes the shared object identifier (assigned at load time) and the variable offset within the CLS (assigned at compile time), and returns a capability that grants access to the calling compartment's copy of that variable.

For ease of implementation, the compiler pass inlines `__cls_get_addr()` into the generated code – a production implementation should use a separate CLS relocation type – and it uses a TLS variable to point to the compartment's CLS buffer for that object. This means that the loader (see below) only needs to implement TLS variables, accessed through the `tp` register in Arm, to support both TLS and CLS.

### 4.3 Secure object loader

To simplify application deployment, we implement a loader that takes deployment configurations, i.e., a list of binary paths to load into memory. The program deployment logic loads binaries into the target memory regions, resolves relocations, and generates all capabilities needed in the PLT and GOT of a pure-cap program [63].

The deployment configuration also identifies shareable objects and provides their hash, so that they can be reused if previously loaded by `orc_register()` and `orc_request()`.

### 4.4 Discussion

Our prototype implementation showcases ORC's core ideas, but it has shortcomings:

*Performance.* The CLS implementation uses TLS variables for simplicity. This results in new capabilities fetched from TLS and adjusted to the corresponding variable on each call to `__cls_get_addr()` (except for reuse optimizations in the compiler). In a future version, we would pre-calculate the per-variable capability at dynamic link time, so that no new capabilities are created at runtime by `__cls_get_addr()`.

*Compatibility.* Since we use a compiler pass, we cannot support pre-initialized variable references on other data structures,

e.g., a statically-initialized array entry pointing to a CLS variable address. In our library OS (Unikraft), we found only a single place where this was necessary. Adding compiler support for new CLS relocations would solve this problem by adjusting data structure addresses at dynamic link time.

Our `__cls_get_addr()` implementation assumes a per-compartment CLS. We plan to support per-process CLS, allowing for multiple processes within the same compartment.

## 5 Evaluation

We ask the following questions when evaluating ORC: (1) how efficient is ORC compared to KSM? (2) what is the impact of ORC on tail latency compared to KSM; and (3) what is the execution and compilation overhead of ORC, as a function of the degree of binary object sharing?

### 5.1 Experimental setup

**Workloads.** We evaluate a real-time video transcoding micro-service that scales out to a large number of clients. The micro-service uses *FFmpeg* [21] to perform transcoding. A single *FFmpeg* instance consumes a fraction of the CPU and memory resources on the machine, allowing multiple instances to be run. By de-duplicating memory, we can support more *FFmpeg* instances and thus more concurrent clients. We compare the deployment of the micro-service using ORC to one that uses Linux KSM as a baseline for memory de-duplication.

We also consider other workloads to evaluate specific characteristics of ORC: (1) we use Redis [48] with the *memtier* benchmark [37] to understand the impact of ORC and KSM on request tail latencies; and (2) we use the SQLite database system [56] and its *speedtest1* benchmark [55] to compare the performance of different object sharing scenarios.

**Testbed.** We deploy ORC on a Morello board [42], which has an Armv8-A CPU with hardware support for CHERI [66]. The board has 4 CPU cores running at 2.5 GHz, with 16 GB of DDR4 memory (64 KB L1, 1 MB L2, and 1 MB L3 caches).

The experiments compare two OSs: (1) Ubuntu 22.04.1 LTS with Linux v5.15.0, which only runs native arm64 binaries with no CHERI support; and (2) Hybrid CheriBSD version 14 (release/22.05p1) [22]. The Linux OS is used to measure KSM, and can also run the entire ORC stack without isolation guarantees (i.e., disabling our compiler pass and eliminating capability management instructions in the Intravisor and loader). The CheriBSD OS is used to run ORC with all its isolation guarantees, as described in this paper. All ORC results use CheriBSD unless stated otherwise.

Note that the same source code executes on all compartments, so that we can compare ORC and KSM despite the different compiler options and underlying OS support.

**Fig. 4: Throughput over time when de-duplication of the video transcoding micro-service happens** (The shaded area indicates the difference between ORC and KSM-Tuned, which is the best-performing KSM configuration.)

### 5.2 Efficiency and performance overhead

We now evaluate the trade-off between memory de-duplication efficiency and application performance overhead when comparing ORC and KSM. We deploy the video transcoding micro-service, which increases application throughput with higher memory density – i.e., it increases the number of processed frames by increasing the number of deployed transcoder instances.

The experiment deploys new transcoder instances until it reaches one of two limits: (i) memory limit – when the instances consume all available physical memory, but there are still spare CPU resources to support more instances; and (ii) CPU limit – when at least one of the instances can no longer transcode at real-time due to a lack of CPU resources.

Each micro-service instance contains *FFmpeg*’s main program and libraries, our library OS, and the standard C library (see §4.1). It occupies around 111 MB of memory (11 MB in binaries and read-only data, shareable by ORC, and 100 MB of heap). The transcoded video has a resolution and frames-per-second configuration such that, without de-duplication, the experiment reaches the memory limit after 127 instances; optimal de-duplication can run more instances: it eventually reaches the CPU limit after 180 instances.

We deploy multiple KSM configurations with different de-duplication and overhead trade-offs:

KSM-Tuned is the default policy of the *ksmtuned* daemon [70]. Every 60 secs, it checks the share of free memory, and starts KSM if it is below 20%. It also adjusts KSM parameters: the number of scanned pages in each iteration (*pages\_to\_scan*) is increased gradually when the de-duplication rate is too low. KSM-On is a hand-tuned policy that achieves good memory efficiency in the shortest time for our workload, but it consumes significant CPU resources. With this setting, KSM operates constantly and uses 20,000 *pages\_to\_scan*.

**Fig. 5: Throughput over time when de-duplication of the video transcoding micro-service happens using larger binaries** (The shaded area indicates the difference between ORC and KSM-Tuned.)

**Micro-service instances.** Fig. 4 shows the number of active micro-service instances over time, with ORC and the various KSM configurations. Given the performance of one instance, there are sufficient CPU resources for 180 instances, but only enough memory for 127 instances without de-duplication.

The plot shows that KSM-Tuned first reaches the memory limit (127 instances) after 119 secs, and it does not de-duplicate memory until 58 secs later. It then reaches the memory limit again at around 227 secs, and, after 23 secs, it is able to de-duplicate enough memory to deploy 180 instances.

In contrast, ORC is designed to optimize for density almost instantaneously: it creates 142 instances in just 11 secs, which is a 20 $\times$  speedup over KSM-Tuned for the same number of instances. Note that the 142 instances deployed by ORC correspond to 11% more than the 127 instances without de-duplication. This is expected, because code and read-only data occupy only 11% of the memory of each instance (see above). In contrast, KSM can de-duplicate additional pages by also considering writable memory.

ORC thus deploys and de-duplicates instances much faster than KSM-Tuned, which gives it an advantage over KSM on the aggregate performance over time, expressed as the total number of processed frames (highlighted by the shaded areas in Fig. 4). Although KSM-Tuned deploys more instances than ORC within 300 secs, at this point, ORC has processed 15%–35% more frames than the various KSM configurations. To outperform ORC, KSM-Tuned would require a total execution time of 441 secs – an extra 141 secs after reaching 180 instances. None of the other policies outperform ORC.

KSM-Tuned limits its de-duplication speed, as it tries to minimize CPU overheads – it operates only under memory pressure (80%), and at a limited memory scanning rate (`pages_to_scan`). This negatively impacts environments in which processes are frequently created and destroyed, so we also evaluate the case in which KSM maximizes de-duplication rate with KSM-On. Since KSM is probabilistic in

**Tab. 1: Impact of memory de-duplication on Redis tail latency**

	set requests		get requests	
	p50	p99	p50	p99
Linux	0.5 ms	9.7 ms	0.5 ms	9.3 ms
Linux+KSM	0.5 ms	20.9 ms	0.5 ms	20.8 ms
CheriBSD	2.1 ms	3.7 ms	2.2 ms	3.6 ms
CheriBSD+CC	2.1 ms	4.2 ms	2.1 ms	4.3 ms
CheriBSD+CC+ORC	2.1 ms	4.9 ms	2.1 ms	4.8 ms

nature, we show the best and worst results of twenty different runs of the same KSM-On experiment.

KSM-On (best) deploys more instances than KSM-Tuned within the first 170 secs, but instances are created more slowly and peak at just 140 (98.6% of ORC), because KSM is constantly consuming more CPU resources. KSM-On (worst) creates instances at the same rate as KSM-On (best), until its heuristics stop at only 100 instances (70% of ORC).

*Conclusions:* The results show that instance creation and de-duplication in ORC are substantially more efficient than in the baseline system with KSM. Although KSM-Tuned de-duplicates more (writable) memory, given enough time, ORC retains an advantage with shorter-lived application instances, which are prominent in the cloud. In addition, more aggressive de-duplication with KSM-On is not viable, because higher de-duplication rates are hidden by higher CPU overheads, resulting in a 30% throughput overhead compared to ORC.

**Large binary instances.** We now evaluate how a larger amount of shareable memory affects ORC and KSM, given that language runtimes and programming frameworks can easily consume hundreds of megabytes.<sup>1</sup> To this end, we run the same experiment after manually injecting an additional 100 MB of code into the FFmpeg binary, resulting in 53% of shareable code and read-only data contents on each instance.

Fig. 5 shows the results for this experiment, which supports 68 and 136 instances without and with perfect de-duplication, respectively. In this case, the ability to de-duplicate writable data in KSM has no long-term advantage over ORC, because KSM has further CPU overheads that prevent spawning additional instances; ORC reaches 136 instances in 18 secs, while it takes KSM-Tuned 377 secs to reach the same maximum. In this case, we also report the best results for KSM-On with two fixed values for `pages_to_scan` (1,200 and 20,000), which reach 132 instances 52 secs earlier than the default policy.

*Conclusions:* With a larger proportion of directly shareable contents, ORC reaches optimal de-duplication effectiveness at a 20 $\times$  faster rate than any of the KSM configurations.

Fig. 6: Query execution times for different compartments using ORC (SQLite)

### 5.3 Impact on service tail latency

Next, we investigate the impact of ORC and KSM on the tail latencies in a typical cloud service. We observe that KSM consumes up to an entire CPU core when active, and it issues TLB shutdowns when scanning and de-duplicating pages.

We spawn 4 instances of the Redis key-value store service [48] and use the *memtier* benchmark [37] as a workload: it pre-fills each instance with 2.5G GB of data and then executes a 1:10 set/get request workload, using 4 threads with 4 concurrent connections for each instance.

Tab. 1 shows the results of five deployments: (1) Linux acts as our baseline (arm64 binaries without using CHERI or KSM); (2) Linux+KSM adds memory de-duplication with an always-on KSM; (3) CheriBSD is our baseline with a CHERI-capable host OS but without ORC or enabling capabilities when compiling Redis; (4) CheriBSD+CC uses ORC to compartmentalize Redis but disables de-duplication; and (5) CheriBSD+CC+ORC uses ORC for de-duplication.

We run both Linux and CheriBSD to decouple the impact of KSM and ORC from the intrinsic differences between the two OSs. CheriBSD shows worse throughput and tail latencies than Linux on all operations, which can be attributed to the different device driver and network stack implementations.

Linux+KSM matches the 50<sup>th</sup> percentile (p50) latencies of Linux, but the CPU overheads and TLB shutdowns due to KSM more than double the 99<sup>th</sup> percentile (p99) latencies. In contrast, ORC has a small impact on tail latencies: support for compartmentalization alone (CheriBSD+CC, i.e., compiling the program in pure-cap mode and crossing isolation boundaries results in a 13% and 19% increase in p99 latencies

<sup>1</sup>For example, the MongoDB database system uses 104 MB; the PyTorch machine learning stack with CUDA uses over 200 MB; a Python-based data science pipeline with TensorFlow uses over 300 MB.

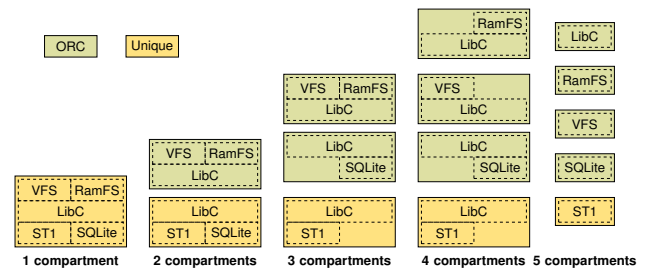

Fig. 7: Decomposition into capability compartments (SQLite)

for set and get operations, respectively. Fully enabling ORC (CheriBSD+CC+ORC) leads to an 17% and 12% increase in p99 set/get latencies, respectively, which can be attributed to the overheads of our current CLS implementation.

*Conclusions:* The page table management and memory hashing overheads of KSM’s page de-duplication lead to a more than 2× increase in p99 latencies; the explicit sharing of binary objects in ORC reduces these overheads to 12%–17%.

### 5.4 Cost of isolation

We also investigate how increasing the number of shareable binary objects in an application affects performance. We control both the overheads introduced by the compiler pass, and those of capability-based crossings between binary objects.

To measure the cost of isolation, we execute a single compartment with the *speedtest1* benchmark and its embedded SQLite instance, and incrementally make some of its components separate binary objects (see Fig. 7). We start with one compartment that contains all components in a single binary object. Since CLS support is unnecessary here, we disable the compiler pass. We then incrementally build further compo-

nents into separate shareable objects (2 to 5 compartments), compiled with CLS support. The *VFS* and *RamFS* components correspond to internal components of the library OS; *STI* is the benchmark binary.

Fig. 6 shows the execution times of the benchmark for different SQLite query types, varying compartment numbers. We observe that all configurations, except for 5 compartments, have only a minor performance overhead. The average difference between one compartment (everything monolithic; no CLS support) and 4 compartments (all system components but LibC are shareable objects) is 10% (median of 3%). Even when isolating all components into separate shareable objects (5 compartments), which adds many cross-compartment calls, the average slowdown is 53% (median of 39%).

*Conclusions:* We draw two conclusions: (1) the overhead of supporting CLS is small, especially when compared to the performance cost of cross-object calls; and (2) while the cost of cross-object calls exists, it is sufficiently small that it becomes possible to share across multiple fine-grained objects.

## 6 Related Work

**Page-level memory sharing.** Modern hypervisors support dynamic page sharing among VMs. VMware ESX [61] pioneered inter-VM page sharing without guest OS support by periodically scanning physical pages and transparently discovering pages with identical contents using their hash values. KSM [1] also periodically scans physical pages but uses a balanced tree to find duplicated pages (see §2.1). Dynamic page sharing by hypervisors, however, results in an inflexible sharing granularity due to the lack of OS semantics, unpredictable latency spikes due to runtime scans, and vulnerabilities to side-channel attacks due to copy-on-write semantics.

Hypervisors can also perform page sharing on disk reads. Disco [5] intervenes in DMA to support copy-on-write shared disks and copy-less NFS shares among VMs, allowing page sharing without runtime scanning. Satori [41] uses similar sharing-aware block devices that enable copy-on-write sharing as well as content-based sharing through enlightenment (para-virtualization). Sharing in these systems is still page-based, and copy-on-write issues remain.

VM introspection (VMI) or graybox approaches can be used to improve the efficiency of de-duplication by extracting semantic information from in-VM memory data. Sindelar et al. [53] used VMI techniques to identify memory pages belonging to free memory pools in Windows and Linux without making kernel version-specific assumptions. They are treated as zero pages to improve de-duplication and VM migration efficiency. Singleton [52] uses KSM page information to de-duplicate pages in the guest page cache by dropping them from the host page cache. VMI, however, cannot always obtain semantic information reliably without cooperation from the guest, and these techniques are still page-based.

Overall, ORC has the advantage over page-level sharing in that it allows for reliable, flexible, and efficient sharing that leverages semantic information about objects.

Efficient inter-VM page sharing techniques can be applied to optimize inter-server VM placement for cloud-wide memory density. *Memory buddies* [65] aggregate memory fingerprint information into a centralized control plane to determine VM placements for increased sharing and to optimize VM placement dynamically with live migration. Sindelar et al. [53] show that inter-VM sharing largely occurs hierarchically, and they propose a tree structure to manage sharing. ORC leverages semantic knowledge about shared memory objects and could be applied to improve memory density in the cloud through optimal VM placement.

**Mixed-granularity sharing.** Sharing at a granularity finer than pages can help increase memory density, as many pages are found to be nearly identical with only some differences. Gupta et al. [28] propose a *difference engine* as an extension to Xen [2], which supports sharing at the sub-page level in addition to page level. The difference engine stores patches against reference pages for similar but not identical pages, and compresses pages that are unique but accessed infrequently. Several studies on VM live migration also leverage sub-page granularity for differentiation, compression and write detection [15, 46, 71]. Although such proposals could increase memory density, unlike ORC, they do not reason about what should be shared across tenants.

Prior work on improving scanning efficiency groups pages based on access characteristics and uses a granularity finer than pages. CMD [8] identifies page access characteristics by measuring the distribution of writes per subpage using dedicated hardware, in addition to the address and number of writes to the page. UKSM [68] proposes adaptive partial hashing, which hashes only a portion of the page and gradually changes its size. These approaches allow for fine-grained sharing and reduce the cost of hashing, but still lack semantic information, making sharing opportunities non-deterministic.

In modern cloud environments, it has become important to leverage large page sizes that minimize the overhead of TLB misses. The opportunity for page-level memory sharing decreases with the page size. SmartMD [27] splits large cold pages with high repetition rates for de-duplication, while re-consolidating small hot pages for improved access performance. GLUE [47] attempts to maintain large-page performance in regions that are broken into small pages for de-duplication. It extends the hardware to perform speculative large-page translation using normal-sized TLBs. While these approaches leverage finer granularities than a page, ORC has an advantage in its ability to share objects at byte granularity.

## 7 Conclusions

We have described ORC, a new memory de-duplication approach that improves the memory density of cloud environments using capability-protected compartments. Our motivation was to create a practical, capability-based cloud stack, in which tenants can enjoy strong isolation and cloud providers benefit from more efficient use of memory resources.

Unlike conventional hypervisors, which blindly scan memory for identical pages, ORC takes advantage of a semantic separation into sharable and non-sharable objects. Therefore, it is not subject to the performance overheads of existing runtime methods. Due to its use of capabilities, ORC can share objects more precisely at a word granularity (i.e., spatial precision), while avoiding unintentional sharing of runtime objects (i.e., temporal precision). The loading of objects is done via a narrow interface with a small TCB, providing strong isolation.

**Source code availability.** The source code of ORC and our evaluated sample applications can be downloaded from <https://github.com/llds/intravisor>.

Meta Platforms

## Abstract

Customers of both private and public clouds must wrestle with the problem of *regionalization*: how should service capacity be apportioned across a large number of geo-distributed datacenter regions? This problem is further complicated by the complex service dependency graphs that arise from microservice architectures, as well as capacity availability and hardware mix that can vary greatly by region.

Historically, regionalization has been solved through a slow-moving and manual process, whereby owners of large services directly negotiate capacity allocation and distribution with the cloud provider. However, as both service and cloud footprints continue to grow, these manual processes are becoming untenable, and often result in excessive labor for all parties involved, as well as suboptimal outcomes.

At Meta, we have built a system called *Flux* to automate capacity regionalization, transitioning it from a bottoms-up, manual process, to a top-down, automated one. Flux employs RPC tracing to identify service capacity models, and uses these to compute an optimal joint capacity and traffic distribution plan that spans thousands of services across tens of products, and involves millions of servers. These plans are orchestrated by a system that safely and efficiently rebalances service capacity and product traffic across tens of regions on a continuous basis.

## 1 Introduction

Meta's private cloud consists of millions of machines and hosts products serving billions of users. It must provide the products with a growing, geographically distributed capacity footprint, so that they can scale and remain fault tolerant while their usage grows and new features are introduced.

Our products employ large microservice architectures [29] comprising thousands of services, globally deployed in tens of datacenter regions. Most of these services are *shared* by multiple products, and hence the sizing of one service needs to consider the demands of all products. Moreover, the services are *interdependent*. It is not uncommon that a service calls tens of other services and the depth of the call graph can

go beyond 10 levels. As a result, capacity distributions for services must be managed in concert: the growth of one service may cause the growth of tens more, which in turn places further capacity demands on their downstream services, and so on. Thus, it is a daunting task to manage capacity at scale, as service operators must answer questions such as: How to size my service? How and where do I provision capacity for organic growth, or to enable a new feature? Are downstream services correctly provisioned for the demand generated by my service?

To avoid the above complexities getting out of control when planning capacity jointly across tens of regions, service owners often prefer the simplicity of reasoning about their capacity on a per-region basis: a service responds to demand increases by requesting that new capacity be delivered to the regions where the service is already running.

However, this local optimization leads to many issues:

- Services in mature regions cannot grow as those regions have no available space or power to add capacity.
- Hardware utilization becomes imbalanced as some regions may provide more capacity than others.
- Hardware ordering is overly constrained by specific services requiring specific hardware to be placed in specific regions.
- Capacity imbalances lead to excess disaster-readiness buffers as we must have enough buffers for the potential loss of the single *largest* region.

Before Flux, these issues were solved by lengthy negotiations between service owners and cloud providers. For example, in order for service A to grow in region X, the service owners might negotiate to trade the service's excess capacity in region Y for service B's capacity in region X. This laborious process does not scale well with the number of regions and services, and leads to suboptimal capacity allocation. Moreover, even after capacity negotiations, rebalancing services and traffic across regions in order to match capacity supply is still a daunting task, requiring coordination across many services and traffic distribution systems.

Finally, this region-centric capacity management process leads to tight coupling between specific products and specific regions. The *capacity mix* (i.e., the ratio of different hardware types) of any given region often reflects the products that have historically been deployed to that region. As a result, the capacity mixes of our regions have already diverged significantly, further exacerbating the problem as this regional heterogeneity limits the flexibility of moving services across regions to rebalance demands and supplies.

**Global capacity management.** Our key insight to solving these issues is to elevate capacity management to a *global* problem, decoupling global service placement from global hardware placement. This paper describes our global capacity placement system, called Flux, which runs continuously on weeklong timescales, redistributing service capacity and product traffic to best utilize our global capacity footprint.

Flux utilizes RPC tracing to identify a model that predicts service capacity demands given a traffic mix for our products. This model is then used to formulate a mixed-integer-programming (MIP) problem that jointly distributes service capacity and product traffic across all of Meta’s regions. Flux’s service placement distributes service growth capacity, rebalances existing service capacity to meet infrastructure goals, and manages projected regional capacity deficits such as those caused by regional hardware refresh.

A *capacity orchestrator* works with our existing autoscaling and traffic management systems to safely and efficiently execute global capacity redistribution plans. The orchestrator also allows human-in-the-loop operations as needed by escalating low-quality estimates to be vetted by human operators, or delegate orchestration for services that have not yet onboarded to our autoscaling systems.

Flux has been running in production at Meta for 2.5 years, continually allocating service capacity quotas and performing cross-region shifts of service placements and traffic for our largest products. Currently, Flux covers about 50% of the servers in our private cloud that consists of millions of servers supporting online, batch, and AI training & inference workloads. We expect Flux to cover more than 90% of our capacity as we increase adoption. Flux has also enabled dramatic simplification of our hardware planning process, as it allows us to plan for capacity globally, while gradually homogenizing our current heterogeneous regional hardware mixes.

Besides Flux’s usage in our private cloud, the ideas presented in this paper can potentially be adapted to public cloud settings as well. Public cloud providers also similarly negotiate with their large customers directly to match capacity demands with supplies. This sometimes entails providing capacity outside of the customer’s preferred regions, which in turn may require customers to relocate their workloads.

**Contributions.** We make the following contributions:

- To the best of our knowledge, this paper is the first to conduct a comprehensive study of global capacity manage-

ment and global service placement, which are important issues for public and private cloud providers. We hope that by sharing our firsthand experiences, we can help the research community better understand this important problem and the constraints involved in solving it.

- We propose *global* capacity contracts, whereby service owners only need to reason about their global capacity demands, leaving it for Flux to optimally *regionalize* service capacity and product traffic distributions. By contrast, cloud providers still mostly operate in a mode where large services require specific hardware to be placed in specific regions, and traffic distribution is not integrated with capacity management.
- We use RPC tracing to build a service-capacity regionalization model, which calculates a service’s regional capacity distribution as a function of the traffic mix for different products. We are not aware of any prior work that attempts to use models to regionalize service capacity. Moreover, although RPC tracing has been used for debugging and performance modeling, we are not aware of any prior work that uses it for capacity modeling, not to mention doing it at our scale and in production.
- We formulate a MIP problem to optimally distribute service capacity under constraints of capacity supply as well as service and infrastructure objectives. Despite the widespread use of MIP, our approach is novel in its application to joint capacity and traffic regionalization, a problem that has not been considered before. We also use load-test-induced nonlinear models to complement MIP-based linear models, improving modeling accuracy.
- We describe our *capacity orchestrator* which integrates across autoscaling and traffic management systems to safely implement capacity and traffic redistribution plans. Automating joint service placement and traffic redistribution at our scale is highly risky and may negatively impact site reliability. To our knowledge, this has not been attempted before.
- Finally, the effectiveness and robustness of Flux is demonstrated by the fact that we use it every quarter to assign hundreds of thousands of new machines to services.

## 2 Background

In this section, we provide background on our datacenters, workloads, capacity management practices, and the capacity management challenges that are addressed by Flux.

### 2.1 Datacenter Regions

Meta operates 10s of datacenter regions, each comprising multiple datacenter buildings in the same local geography, typically located on a single campus.

Our existing infrastructure abstractions generally operate at the level of regions. For example, our cluster management

systems [37, 45] manage all machines in a region as a single pool. Services are expected to be oblivious to the placement of their tasks within a region, and they may be spread across multiple datacenter, network segments, or power domains. Our regional infrastructure abstractions are supported by a network fabric that provides sufficient regional cross-sectional bandwidth for all but a few workloads

## 2.2 Traffic Management

We maintain a global network of small edge datacenters that are connected to our backbone network. User traffic (e.g., those from apps or web browsers) are terminated in these edge datacenters. Requests from clients connected to our edge datacenters are forwarded to front-end servers in one of our geo-distributed regions. A traffic distribution system [18] manages the distribution of requests from edge datacenters to our large datacenter regions, typically by considering a combination of factors including front-end utilization and geographic proximity to the end-user.

## 2.3 Service Workloads

Traffic enters a region through a front-end web service, typically an HTTP reverse proxy that routes the request to an appropriate application server based on the request URI. The application server implements some business logic, and typically makes RPC calls to tens to hundreds of services, which in turn fan out to yet more services. While some of these services implement functionality used by just a single product, most are shared across many products. Thus, our services are highly interdependent, and we cannot partition our services into product-specific silos.

Figure 1 illustrates the complexity in our request serving paths, with a large fanout and deep call depth. The complexity of service interdependencies [29] motivated us to use precise RPC tracing to attribute resource consumption when designing Flux, rather than using indirect methods such as statistical analysis [2] or heuristics [3, 38, 43].

Figure 1: **Service RPC fanout.** An example of how to read the curves: when a request for the web product reaches the call depth of 10, it fans out to call 158 services on average.

## 2.4 Service Capacity Management

Meta’s capacity management systems provide quotas in the form of regional reservations [37], which provide strong guarantees of regional capacity availability and sub-regional failure tolerance. Thus, the various hardware buffers required to reliably operate services within a region are encapsulated by the regional capacity management systems, and hidden from higher-level capacity management systems like Flux. The number of service replicas in a region is usually determined by our autoscaling systems which combine service capacity models with demand forecasts and disaster scenario simulations to ensure the job is sized correctly.

Most RPCs occur within the same region due to strict latency requirements imposed by applications. Additionally, our complex service dependency graphs often contain critical paths with tens of hops, which can quickly amplify cross-region RPC latencies. Finally, by hosting both the caller and callee in the same region, we can limit cross-region dependencies and improve disaster readiness [31, 52].

Figure 2 illustrates regional caller-callee affinity by showing the latency distribution of RPC calls across thousands of compute services, denominated by total capacity. The inflection point at around 25ms represents calls going cross-region; observe that  $\approx 80\%$  of capacity is reached by in-region requests.

Figure 2: **Cumulative distribution of capacity by RPC latency.** Note the y-axis begins at 80%.

All of our products are located in multiple regions to improve disaster readiness, access a large capacity pool, and achieve wide geographic distribution. However, the distribution of service capacity across regions is uneven. This is due to the organic growth of both service capacity demand and regional capacity supply. Service capacity demand responds to new features and world events, while regional capacity supply depends on factors such as power availability and datacenter construction timelines. Additionally, geographic skew in product usage exacerbates the issue as we try to place service capacity close to end users.

Over time, this has led to a negative feedback loop, wherein services prefer to grow proportionally to their existing regional footprints, causing regional hardware mixes to reflect these historical workloads. This in turn makes it difficult to move these workloads to other regions, causing services to continue preferring the regions in which they are already deployed to receive capacity growth. We can see this specialization reflected in the regional hardware mix, as shown

Figure 3: **Regional hardware type distribution.** A histogram of the compute, flash, HDD, and other hardware deployed across a subset of our regions. Note that the y axis starts at 50%. The right-most region is dominated by flash, because it is a small region that recently underwent a large retrofit, leaving a lot of database workloads in place.

in Figure 3. For instance, the percentage of servers of the compute type ranges from 55% to 80%.

Regions also vary in their power headroom, i.e., the difference between used and available power. Observe in Figure 4 that six regions have little available power, implying that if service deployments in those regions need to grow, they must expand their capacity footprint in other regions as there is little additional power to support additional racks. This is similar to the situation in public clouds where users cannot acquire new capacity in a given region [10–12, 21, 22, 47].

Figure 4: **Power headroom per region for capacity growth.** The y-axis is power, normalized to our largest region.

## 2.5 Capacity Management Challenges

Service capacity management presents significant challenges for both service owners and infrastructure operators. While service owners wish to grow freely where they already are deployed, infrastructure operators must reconcile these wishes with constraints associated with operating physical infrastructure, as well as goals around efficient fleet operations.

These problems are amplified as regions reach maturity—when there is no longer additional power available to allocate to new racks—and infrastructure owners cannot accommodate service capacity growth without shrinking the footprint of other services. The complex dependency graphs between services in a typical online product make this a more challenging problem still.

We refer to this challenge as the *service regionalization problem*: How can we optimally allocate capacity to a set of services across multiple regions? Additionally, how should product traffic be appropriately distributed based on this allocation? Finally, considering that cluster and capacity management systems usually operate at the regional level, how can we effectively rebalance services according to the regionalization plan?

## 3 Design and Implementation

Our global capacity management system, *Flux*, continually rebalances a large number of interdependent services across regions in response to demand changes (e.g., product growth) and supply changes (e.g., hardware refreshes). By decoupling the management of capacity demand and supply, Flux enables service owners to focus on their global capacity demand without considering regional needs, and allows cloud providers to evolve each region’s capacity supply independently.

### 3.1 Overview of Flux’s Workflow

As illustrated in Figure 5, Flux solves the regionalization problem through the following workflow.

**Product-to-service capacity attribution via RPC tracing.** Flux uses RPC request tracing [30, 40] to construct a regional *baseline* ① that attributes each service’s peak capacity footprint to the products that are served directly or indirectly by the service. This baseline is used to construct a service placement model ② that determines how service capacity should be distributed given a product traffic distribution.

**Joint regionalization of service capacity and product traffic.** Using inputs from our budgeting systems, Flux then creates a capacity *target* for each service, which specifies the amount of global capacity that is needed for each service. These service targets are jointly regionalized with product traffic by formulating an assignment problem that is solved using mixed-integer programming (MIP) ③. The result of this stage is a *placement plan* that redistributes service capacity and product traffic across regions. The optimization problem also encodes a number of infrastructure objectives, such as minimizing the total amount of disaster-readiness buffer required to operate services safely.

**Global capacity orchestration.** Flux introduces a global capacity orchestrator, responsible for executing placement plans safely and efficiently ④. The orchestrator drives automation through several capacity and traffic management systems, and also supports human-in-the-loop operations to handle exceptions or uncertainties in execution.

The overall Flux workflow runs continuously in weeklong cycles to rebalance service capacity across regions according to changing hardware supplies and service demands. It measures the current state of service and hardware placement, computes a desired state, and then executes a plan to move

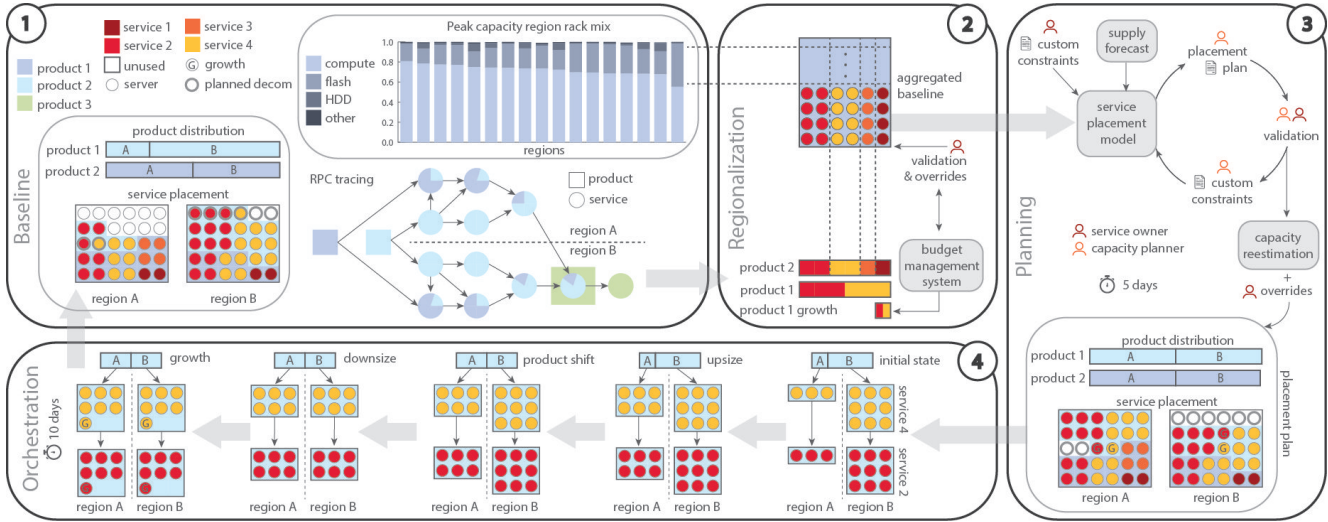

Figure 5: Flux's end-to-end workflow.

towards the desired state. It tolerates imperfect execution of the plan by repeating this self-correcting reconciliation loop.

Next, we describe the details of the steps above.

### 3.2 Service Modeling

The goal of service capacity modeling is to determine the optimal distribution of a service's capacity across regions in concert with product traffic. This is challenging because many of our services are shared by multiple products, and each product may invoke different call paths within the service. This can result in significant differences in the cost per request depending on the product being served (see §2.4).

#### 3.2.1 Baseline

Flux defines a *baseline* for each region, attributing portions of each service's peak capacity footprint to different products. This baseline is created by combining two other baselines:

**Capacity usage baseline.** We run profilers on every server in our fleet to produce a dataset that attributes resource usage to specific services. Profiles are sampled every minute, and we process this dataset to identify the daily peak time window<sup>1</sup> and peak resource usage per service and per region, covering different resource types such as CPU and SSD.

**Demand baseline.** Flux uses sampled RPC traces to reconstruct the call graphs for requests that are handled by each service. We identify a set of *product gateways* that act as traffic entry points for each product. Importantly, the traffic destined for these gateways is globally and independently routable, and is usually managed by Meta's shared traffic management systems [18]. Each sampled RPC call is attributed

<sup>1</sup>Demand spikes due to new product launches or special events such as New Year's Eve are handled separately. During daily off-peak periods, many of our services are automatically scaled down to donate unused capacity to our elastic capacity pools, which are used to run preemptible services.

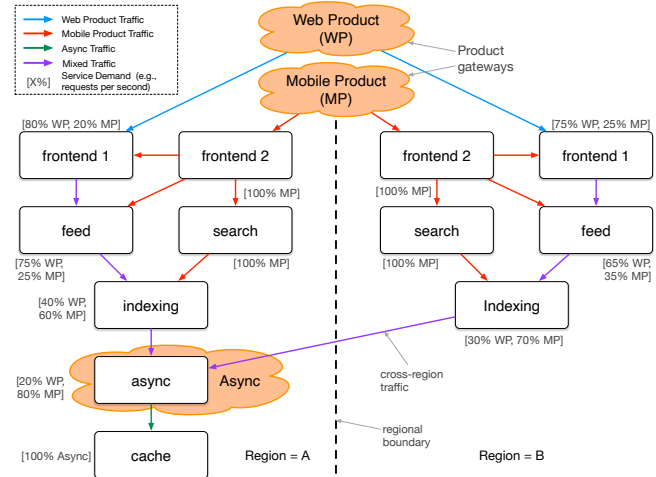

Figure 6: **Demand attribution.** Attribution of capacity usage to three Products: Web Product, Mobile Product, and Async. For the indexing service in Region A, the annotation “[40% WP, 60% MP]” means that 40% and 60% of the indexing service's capacity consumption is attributed to the Web Product and Mobile Product, respectively. Note that while demand attribution is relative, the capacity usage baseline is defined in terms of absolute capacity.

to the product handled by the nearest upstream gateway in the call path. The demand attribution process is illustrated in Figure 6. Sampled traces are aggregated to compose the demand attribution dataset for each service, dividing a service's total demand among the set of products served by it. Traces collect multiple demand metrics, including call counts as well as CPU instructions. The next section discusses how we select the demand metric that minimizes the overall model error.

### 3.2.2 Modeling

Flux’s service models predict the amount of service capacity required in a region to serve that region’s product traffic mix. We assume that each product’s traffic is fungible across regions, and thus that capacity requirements for serving a fixed portion of the product’s traffic is also the same across regions.

This suggests a model where capacity for service  $s$  in region  $r$ ,  $c_{s,r}$ , is given by a linear combination of the capacity contributions from each product:

$$c_{s,r} = \sum_{p \in P} (\alpha_{s,p} * \rho_{p,r}) + \delta_{s,r}, \quad (1)$$

where  $\alpha_{s,p}$  is the amount of capacity for service  $s$  attributed to product  $p$ ;  $\rho_{p,r}$  is the *presence*, or the proportion of global traffic for product  $p$  assigned to region  $r$ ; and  $\delta_{s,r}$  is the model residual for service  $s$  in region  $r$ .

Modeling residuals may be due to an existing capacity imbalance, or due to nonlinear effects not captured by the model. We allow service owners to be involved in managing the treatment of residuals during planning.

The baseline includes multiple demand metrics. In the modeling step, we select the metric that minimizes modeling error. For example, many large services have per-request costs that vary significantly across different products (because they invoke different internal code paths), and are well-modeled using CPU instructions as a demand metric. On the other hand, some services perform very little computation for each request. Therefore, call counts are a more appropriate demand metric for these services due to the CPU overhead of tracing.

### 3.3 Joint Capacity & Traffic Regionalization

Flux computes joint service capacity and traffic regionalization plans by formulating an assignment problem that is solved by a MIP solver. This section provides the intuition behind the problem formulation.

The formulation, detailed in appendix A, is an optimization problem that jointly assigns capacity for each service in each region and product traffic in each region, corresponding to  $c_{s,r}$  and  $\rho_{p,r}$  from equation 1. The assignments are subject to a set of constraints imputed from the service placement model described in §3.2, which determines the service capacity mix required to serve each product.

Initial capacity and traffic assignment are given by the baseline. The capacity residual ( $\delta_{s,r}$  in equation 1) is interpreted as capacity that is unexplained by the model, and is thus excluded from reassignment, unless directed otherwise by the service owner. We provide an analysis of capacity residuals in §6.3.

**Baseline adjustments.** Flux adjusts the existing *baselines* to match planned capacity and product distribution changes. These planned changes are encoded as events and maintained in a *capacity ledger*. Flux commits its plans to the ledger

along with other capacity planning systems. Thus, Flux can overlap planning and execution, as we can adjust the baseline to account for planned changes between the plan generation time and the start of its execution cycle.

**Regional capacity pools.** Flux divides each region’s capacity into a shared pool per hardware type. Our capacity reservation system, RAS [37], provides these pools as a regional abstraction that we build upon, and lets us treat the capacity in each pool fungibly.

Each hardware type is assigned a capacity measure that represents the common bottleneck for that hardware type. For example, the generic compute pool is denominated by a normalized CPU throughput measure, while our SSD hardware is generally I/O bound. The capacity measure is normalized across all generations of the same hardware type. Some services can run on multiple hardware types: we encode this knowledge through a set of fungibility rules that establish a service’s conversation ratios between different hardware types.

**Service capacity demand.** The *global* capacity demand for each service is computed by querying our budgeting systems which mandate service capacity budgets in terms of a normalized cost measure. Flux converts this normalized budget to a hardware-type specific capacity demand using a conversion ratio specific to the service and hardware type.

**Service placement model.** Flux imputes placement constraints from the service capacity model. Specifically, for each service, the model determines a *lower bound* of service capacity assigned to a region as a function of the product traffic mix to that region (see §3.2.2). The product traffic assignments are also optimization variables, and hence the service and traffic placement is jointly optimized. The baseline model residual (see Equation 1) is codified as an explicit term in the formulation to offset capacity imbalances that exist at baseline. Flux gives service owners the choice to reduce the model residual, which is often used to correct baseline capacity imbalances; see §6.5 for an example.

**Optimization constraints.** The MIP assignment problem constrains (1) the capacity assignment in each region to be no more than its available supply; and (2) the global capacity demand for each service to be met. The latter constraint is a soft constraint, which allows us to prioritize capacity fulfillment among services if necessary. Flux prioritizes *baseline* capacity footprint (i.e., the capacity present when the baseline was measured) over *growth* capacity (i.e., additional capacity granted by the budget systems), to ensure that already granted service capacity is not taken away.

**Optimization objectives.** The MIP assignment problem includes several infrastructure objectives that help us manage our global capacity footprint more effectively. First, a balancing objective spreads service capacity evenly across regions, which reduces the amount of buffer capacity needed

for disaster readiness. Second, unused capacity is also distributed evenly based on region size, making extra capacity available to account for discrepancies or defects in Flux’s placement. Third, a stability objective minimizes the amount of capacity reassignment in each placement cycle, simplifying the placement plans and reducing infrastructure churn.

**Timesteps.** Regionalization is simultaneously computed for multiple future timesteps in increments of future execution cycles. This serves three purposes. First, multi-timestep plans can incorporate large changes in supply or demand ahead of time, allowing for a plan that anticipates these changes with small, individually feasible adjustments over multiple timesteps. Second, we can set stability objectives that span multiple timesteps to prevent undue oscillation in placement plans. Finally, this multi-timestep approach prevents the solver from optimizing a short-term solution at the expense of long-term negative impacts.

While Flux computes plans for multiple timesteps, we only execute the plan for the next timestep. Flux runs in a self-correcting reconciliation loop as the baseline can change between executions for a number of reasons, including: (1) execution may have deviated from the placement plan; (2) supply and demand forecasts may change in the interim; (3) manual capacity operations may affect the baseline; (4) service code changes or new services may affect the service models.

The formulation is detailed in appendix A.

### 3.4 Execution Planning

Flux derives an *execution plan* from the joint service and traffic placement plan. The plan is a directed acyclic graph (DAG) of service capacity assignments and product traffic assignments. The plan ensures that services are always sufficiently provisioned for the traffic during the transition stage.

Flux provides this guarantee through a three-phase plan. First, all upsizes are executed, i.e., each service is sized to the maximum of its baseline size and its target placement size. Second, all product traffic is reassigned. Third, downsizes are executed by sizing each service to its target size.

The advantage of this approach is its simplicity and the ability to execute it quickly by parallelizing actions in each phase. A disadvantage is that it requires temporarily overprovisioning services, which takes up capacity that could be used by other services. To address this limitation, we explored using more sophisticated multi-step plans. However, we found that these plans were both complex to execute and difficult to explain to service owners. As a result, we decided to continue using the simple approach.

### 3.5 Orchestration

The execution plan is fulfilled by Flux’s capacity orchestrator which: (1) executes capacity and traffic assignments in the

Figure 7: End-to-end orchestration workflow.

correct dependency order; (2) continuously monitors product-level and service-level metrics to ensure that they remain healthy; (3) delegates exceptions and actions to human operators as needed; and finally (4) performs load tests to validate the placement.

Figure 7 illustrates the orchestration workflow. A *capacity ledger* stores a timeline of *capacity events*. These events are timestamped, and each reflect a proposed capacity related change. Capacity and traffic management systems query the ledger for future events, but only execute them once they are marked by the orchestrator as *active*. After execution, the same systems store their status (success or failure) back into the ledger.

The ledger acts as a central repository of all anticipated capacity changes, and allows multiple systems to simultaneously propose and coordinate changes, while decoupling *capacity planning systems* from *capacity management systems*. While Flux is the primary writer to the ledger, we sometimes write manual events to make temporary capacity changes in support of product launches or experimentation.

The ledger provides three important properties. First, we can compose events from different writers, so that the underlying management systems can consider the combined effect of a set of events. Second, by providing events ahead of time, we accommodate services that require a long lead time to provision capacity and scale. For example, our caching systems need a significant warm-up period before newly provisioned capacity can handle production traffic. By providing future events, the control plane gives the management systems enough time to ensure that services are ready for future traffic shifts. Third, the ledger serves as an authoritative forecast of future capacity changes, and is used by Flux to incorporate future and ongoing events during planning. This allows Flux to overlap planning with execution, and to compose well with other capacity planning systems.

The orchestrator ensures that events are executed in dependency order by verifying that all antecedent events have

completed before marking an event as active. RF delegates any exceptions to human operators through its UI. The UI is also used when (1) the service owner has configured the service to require validation before execution, or (2) the capacity estimates for a service are considered low confidence in the modeling stage and require operator validation. By providing this progressive path towards full automation, Flux offers transparency and explainability, and allows service owners to gain comfort with the system.

Finally, before downsizing service capacity, the orchestrator initiates product load tests [52] to validate that the sizing is correct and that the site as a whole remains disaster ready.

### 3.6 Stateful Services

Flux integrates with Shard Manager [32] to handle stateful services within our platform. Shard Manager is responsible for managing most of our stateful workloads. Shard Manager continuously queries the capacity ledger for relevant capacity events, and builds new replicas after upsize capacity has been provided by Flux. This is done by migrating or replicating data from other regions. Shard Manager then acknowledges the capacity event, allowing Flux to safely proceed with execution. After the demand shift, Shard Manager safely removes the old replicas from downsized regions before Flux reclaims capacity.

The primary challenge with integrating stateful services today is that the default demand attribution algorithms do not always accurately capture requests costs. Such systems often exhibit interaction between requests, where processing of one request can affect the cost of subsequent requests. Our default attribution algorithms also do not capture persistent storage costs, the effects of caching, etc. We work with service teams to update our algorithms to better capture their capacity cost models. For example, TAO [16], Meta’s social graph store, maintains a custom cost model, which captures many of the above effects across their complex, distributed system. We integrate this cost model into Flux’s attribution models to correctly capture TAO’s capacity needs.

## 4 Design Alternatives

In this section, we discuss the major design alternatives.

### 4.1 RPC tracing

Flux relies on RPC tracing for gray box measurements of product-service capacity attribution. Meta has invested in a unified RPC stack [39], leading to high out-of-the-box tracing coverage without any additional instrumentation needed from service owners. Moreover, all our main traffic ingestion systems [30, 52] already implement sampled trace origination.

As of 2022, we have 52% of capacity usage covered by RPC tracing. For services that are not yet covered by RPC tracing, we have been working closely with the the service

owners to drive the adoption, because distributed tracing [40] as a fundamental capability in a large infrastructure has broad usage beyond capacity management, such as problem determination [17] and performance debugging [2].

Black box methods like statistical analysis [2] or heuristics [3, 38, 43] can be used to infer service call graphs without needing service-specific instrumentation. However, our highly interdependent microservice architecture makes employing such techniques less accurate. Since many of our backend systems are shared among multiple frontends, which invoke distinctly different callpaths, often with substantially different cost per request.

Black box methods were previously only evaluated on simple three-tier applications, while in our complex environment, the depth of call graphs reaches 14 and the RPC fanout is as high as 742, and hundreds of different upstream services may call a given service at varying call-graph depths. The full complexities of Meta’s service topology and call graphs are reported in detail in a recent work [29]. These complexities make statistical or heuristic methods less applicable to our environment.

Furthermore, because we can mandate high tracing coverage in our services, we can expect higher quality models, which in turn helps us provide greater levels of automation in global capacity management.

### 4.2 Nonlinear Service Models

The core service model used by Flux is linear: it assumes that capacity usage is linearly related to a chosen demand metric (see Equation 1) and a product traffic mix. While such models are simple to identify and to apply broadly, many services exhibit nonlinear capacity behaviors. When available, Flux can update its estimates by using more accurate nonlinear models such as those produced by load testing [55], queuing analysis [41], or by simulation.

Many of our services use continuous load testing to maintain an accurate model of the relationship between a service’s capacity usage and its RPC throughput. These models are used by our *Capacity Estimator* (CE) [14] to ensure that services are sized correctly for demand and remain disaster ready as determined by simulating various failure scenarios. However, simulations introduce nonlinearities that cannot be represented in a MIP assignment problem. To solve this problem, Flux invokes CE with the traffic distribution produced by the MIP solver. CE then runs its simulations against the proposed traffic distribution, and provides updated capacity estimates that incorporate planned failure scenarios.

We have found that using a combination of a default linear model for regionalization, along with a load-test-induced nonlinear model for improving estimates, works well in practice. Linear models provide upper bounds and are amenable to MIP optimization, while the nonlinear models provide higher accuracy, and usually operate within the bounds of the linear

models. Additionally, the simpler linear models are easier to explain and diagnose. Currently, 9.2% of services using Flux have load-test-induced models, and these services account for 46.4% of the total capacity allocated by Flux. This suggests that larger services are more concerned about capacity and are more likely to build their load-test-induced nonlinear models.

## 5 Discussion

In this section, we discuss the challenges of doing capacity planning in a complex real world and several ways of applying ideas in Flux to public clouds.

### 5.1 Practical Challenges

**Flawed baselines impact modeling accuracy.** Because Flux started with a baseline that was the result of many years worth of ad-hoc capacity management, the baseline itself does not reflect an ideal placement. Thus, when modeling capacity, we have to take extra care when interpreting model residuals: they could be due to imperfect modeling, or baseline itself not well-balanced. Flux provides *rebalancing* to service owners wishing to correct these imbalances in a controlled manner.

**Complete capacity models are hard to come by.** We have found that many capacity management practices rely on tribal knowledge, ad-hoc modeling, and implicit agreements between services. These are not captured in the service capacity models that Flux operates with, and thus cannot incorporate various de facto objectives or constraints. We work with service owners to codify these, but often find that we need to work around these with manual planning adjustments. We have also introduced tools like the capacity ledger (see §3.5) that help capture and mechanize previously ad-hoc capacity management practices.

These realities mean that there isn't a clear ground truth for capacity distribution, and require a nuanced interpretation of both modeling residuals and execution errors.

### 5.2 Applying Flux in Public Clouds

Many large public cloud customers maintain “virtual private clouds”, whereby they acquire large capacity pools of reserved instances. For example, Netflix has reported [36] that it runs thousands of services on hundreds of thousands of geo-distributed reserved instances [9] in AWS. These customers can apply Flux to manage these pools of reserved instances, and intelligently place services so that they are maximally utilized. These customers can also use Flux to extract recommendations about the type, location, and amount of capacity to acquire in order to accommodate growth, and to optimize the customer's capacity footprint.

Cloud providers could provide a new kind of capacity contract, whereby customers are guaranteed low-cost capacity, but are not guaranteed specific regional placement. The cloud provider offers an online capacity-planning tool through

Figure 8: **Automated actions in total and by services.** Actions are nodes in the Flux's capacity placement plan, and include capacity and traffic management operation, such as adjusting regional quotas or resizing services.

which their customers continually update their aggregated placement constraints. The cloud provider then regularly re-regionalizes the capacity for customers that use this form of capacity, calling into customer's control planes to execute service and traffic rebalancing. This is similar to existing preemption APIs for spot instances [8].

## 6 Evaluation

Our evaluation answers the following questions:

1. How long does it take for Flux to execute its plan (6.1)?
2. Do Flux's service models help accurately assign global workloads to hardware in individual regions (6.2, 6.3)?
3. To what extent does Flux help meet the growing needs of out-of-region hardware refresh (6.4)?
4. How does Flux plan capacity and service placement for a specific service in practice (6.5)?

### 6.1 Execution Automation

Our goal for Flux is to maximize automation across both planning and execution, while incorporating humans-in-the-loop to review proposed actions and catch defects. We have granted Flux increasing autonomy as we gain confidence in the completeness and accuracy of Flux's models, its solvers, and automated execution systems. Currently, not all services support automation when adjusting their deployments across regions; Flux compensates by incorporating human-in-the-loop manual actions.

Figure 8 plots the degree of automation in Flux's execution plans, showing a handful of service groups as well as the overall automation. The drastic improvement in “total” around July 2021 was due to the introduction of a fully automated capacity distribution mechanism that integrates with our autoscaling system [14]. Over the past 2.5 years, we have increased automation in Flux from 27% to nearly 100%.

Figure 9 shows Flux's plan completion times. When Flux was first introduced, execution was dominated by operations requiring human feedback or execution. As we have simultaneously improved automation coverage and model quality,

Figure 9: **Plan completion times.** The “total” curve represents the end-to-end plan execution time. The boxplots represent the distribution of individual service resize operation’s completion time. From bottom to top, the markers on a box represent, excluding outliers, the minimum, lower quartile, median, upper quartile, and maximum. Outliers are shown separately as small circles. The spike in the “total” curve represents a large shift in the complexity of Flux’s placement plans, which caused service automation coverage to lag Flux’s capacity coverage. We spent the ensuing months improving the coverage of our capacity automation tooling.

fewer operations require human-in-the-loop intervention and scrutiny, and most operations are now fully automated. Recently, executions take roughly 1 week. Even with model and automation improvements, some limits still remain. For example, cross-region data replication or cache warmup may still require long execution times for stateful services even if they support full automation.

## 6.2 Capacity Sizing Error

We define Flux’s capacity sizing *error* as the service capacity eventually used in production, minus Flux’s recommended capacity assignments, which include improvements from using load-test-induced models when available (§4.2). The errors exist for several reasons. First, since capacity-planning mistakes can be costly, service owners often review and sometimes revise Flux’s recommendation based on their domain knowledge of their services. Second, after Flux executes its capacity plan, our autoscaling system [14] may resize services in production, if it finds that additional capacity is needed to support Flux’s traffic shift, or that a service is left with a capacity surfeit.

Figure 10 shows the proportion of upsize and downsize capacity executed in each plan. A value of 100% means that execution was (in aggregate) exactly to plan. Over the course of the last year, we have improved planning accuracy significantly, primarily by working with service owners to improve their attribution and capacity models. We use execution his-

tory to incorporate expected error rates into Flux’s planning assumptions, and thus are able to tolerate this error by ensuring that we both (1) have sufficient capacity to support anticipated (aggregate) upsizes; and (2) are able to reclaim sufficient capacity where this is needed for refresh.

Figure 10: **Capacity-sizing error,** the percentage of Flux’s recommended assignments executed in production. Each data point represents the proportion of the total capacity in a Flux placement plan that was actually executed. The error is split by upsizes and downsizes.

Unless service owners explicitly opt out, we require them to review Flux’s placement plans through a UI tool. An Oct 2022 execution plan had 377 resize nodes. The total number of nodes available for Flux to execute on is about 3000. Of these, 81 nodes were for services that opted out of review; of the remaining 296 nodes, 84, or 22% of the total nodes, were revised by service owners. These revisions modify the resize node directly; Flux continues execution with the updated node. Our tool captures the reason given by service owners for each override, and we present the most frequent reasons below, with the number of each kind of override shown in parentheses.

**Insignificant capacity (15).** The service owner rejected the plan as the service does not have fully automated capacity management and the plan moved an insignificant amount of capacity. Therefore, the overhead to the service owner is too high to justify the benefits of execution.

**Service should not be rebalanced (13).** The service owner rejected the plan because the service should not be rebalanced by Flux. The remedy is to add the service to Flux’s execution blacklist.

**Insufficient headroom (10).** The plan would leave a service without enough headroom capacity, usually to accommodate anticipated growth. The remedy for this is to capture this requirement as a capacity event, so that it can be incorporated into Flux’s capacity plans.

**Deprecated service (8)** The service is deprecated, and should no longer be managed by Flux.

**Bad estimates(4)** The service owner judges the estimates to be incorrect, usually due to one of two reasons. First,

Flux has incorrectly attributed product demand to the service. In these cases, we repair the demand baselines, for example, by choosing another demand metric. Second, the linear model is inaccurate for the service. In these cases, we work with the service owner to adopt the load-test-induced model (see §4.2).

These overrides highlight the complexity of operating in a large-scale production environment. These results show that, with supervision, it is feasible for Flux to operate in a complex environment. Over time, as bugs are fixed and new features (e.g., headroom modeling) are added to Flux to cover a broader set of scenarios, we expect Flux to perform with higher accuracy and gain greater autonomy.

### 6.3 Model Residuals

The model *residual*  $\delta$  (expression 1 in §3.2.2) measures the portion of baseline service capacity distribution not explained by Flux’s service model. While the previously presented *error* metric reflects plan defects that could cause inefficient placement or operational risks,  $\delta$  merely reflects the imbalance between traffic and capacity distribution. Large residuals often reflect pre-existing capacity imbalance or inherent limitations in services which prevent the system from achieving an ideal balance.

Figure 11 shows the residual for several representative services. *Web product*’s residual varies between 3% and 5%. Such stateless services are usually well-modeled by Flux.

The residual for *feed infra* was initially higher at  $\approx 8\%$ , because its capacity distribution was uneven before Flux was applied. Over multiple placement cycles, we have used Flux to reduce this capacity imbalance, which is reflected in recent residuals that match those of *web product*. Due to limited capacity supply during COVID, Flux’s optimization objective has been dominated by supply constraints, and once Flux is able to meet decommission and growth objectives, we limit the infrastructure changes that Flux is allowed to introduce. As capacity supply improves in the future, we plan to use Flux

Figure 11: **Aggregate model residual.** We show  $\frac{\sum_{r \in R} |\delta_{s,r}|}{\sum_{r \in R} c_{s,r}}$ , for several representative services.

to more aggressively rebalance service capacity and reduce the residual. The short-term variance of the residual curves in Figure 11 correspond to load tests [6] and drain tests [52], as well as Flux traffic shifts. These events temporarily distort the relationship between traffic and capacity distribution, and are filtered out of Flux’s baseline.

Figure 12 shows the distribution of *feed infra*’s model residual across regions. This kind of plot guides us to work with service owners to improve their service balance by applying more aggressive balance objectives in Flux. The figure also demonstrates that, while the aggregate residual is higher at  $\approx 5\%$ , the per-region residual is generally less than 1%.

In Figure 11, *database infra*’s model residual is the highest due to some unique challenges associated with stateful services. For example, if a subset of hot data shards are the bottleneck, naively adding more capacity may not improve the service’s throughput proportionally. Many stateful services also have substantial capacity requirements for internal data replication [5], which fall outside of the usual request-response RPC regime, making it difficult to apply RPC tracing. We have been continuously improving Flux’s support for stateful services. In Figure 11, the initial reduction of residual from 22% to 15% was primarily due to improved attribution accuracy and coverage for *database*. The later regression coincides with deployment of new *database* systems into just a subset of regions, and for which we need to define new product attribution rules to capture correctly.

Overall, we deploy many stateful services, including databases, storage, and caches. Of the capacity currently managed by Flux, 14% is for stateful services. Our long-term strategy is to migrate stateful services to a common stateful framework called *Shard Manager* [32], which solves many common problems (e.g., hot shards) that impact stateful-service modeling. Moreover, *Shard Manager* is integrated with Flux so that the services it manages are automatically covered by Flux. Finally, *Shard Manager* intelligently places data shards onto the capacity allocated by Flux to minimize data-access latency [1,4].

### 6.4 Accelerating Out-of-Region Refresh

Figure 4 shows that as regions mature, they may have minimal power headroom to accommodate new hardware. Accordingly, the “quarterly OORR demand” data points in Figure 13 shows the rapidly increasing need for performing out-

Figure 12: **Model residual for feed infra by region.**

of-region hardware refresh (OORR). Prior to 2020, a negligible amount of OORR was performed, and even then OORR was already a significant planning challenge. This was due to the lack of planning tools to compute global workload shuffling and traffic shifting for interdependent services, as well as lack of automation to execute such plans even when it was manually built. The benefits of Flux go far beyond OORR, but the imminent increase in OORR demand and the unsustainable toil in performing OORR motivated us to develop Flux. Flux has helped scale OORR planning and execution by  $\approx 950\%$  year-over-year. Currently, we perform global workload shifts once every 6 weeks; each shift typically reshuffling capacity for 100k-300k servers globally. The shifted capacity exceeds OORR demand because (1) the decommissioned capacity may not reflect the overall workload hardware composition, meaning that Flux must perform larger reshuffles to utilize the underlying hardware; and (2) Flux also allocates growth capacity and optimizes other infrastructure goals such as reducing disaster-readiness buffers.

### 6.5 Case Study: FeatureStore

As a detailed case study, we present the impact of Flux on FeatureStore, a flash-based key-value store serving features of machine learning models, deployed across thousands of servers, with a 99th percentile read latency of under 15ms, and a read request rate of 10s of millions per second. In September 2020, Flux was used for the first time to generate a service-placement plan for FeatureStore. Prior to that, its service placement was performed by humans.

A key event that took place during the September 2020 planning cycle was large-scale decommissioning of servers in three regions A, B, and C, resulting in a reduction of supply in those regions. Accordingly, we expect Flux to perform out-of-region hardware refresh and shift traffic away from those regions to others in order to accommodate this regional supply reduction, which is confirmed by Figure 14.

Figure 13: **Volume of out-of-region refresh (OORR).** This figure shows OORR planning and execution volumes handled by manual processes as well as Flux. The uptick in manual OORR in 2022 was due to a one-time large-scale decommissioning of data-warehouse hardware. Over all, Flux has helped scale our yearly OORR volume by  $\approx 950\%$ .

To understand Flux’s capacity assignment, we focus on two sets of services: (1) the frontend Web service that serves as the traffic gateway for FeatureStore, and (2) all backend services that support or consume FeatureStore. Figure 15 shows the ratio of capacity for these two sets, which varies due to different workload mixes across regions. Specifically, regions A and B show a lower capacity ratio, because they are data-warehouse heavy and have a larger FeatureStore footprint to support additional training workloads that are co-located with data warehouse but do not go through Web to access FeatureStore. Before Flux was applied to FeatureStore, capacity planners needed to explicitly take this into consideration, whereas Flux’s MIP formulation is able to automatically account for this and other factors affecting placement.

Recall from §3.3 that one optimization objective is to minimize deviation from the ratios in the globalized service model. This deviation is partially reflected in Figure 15 as the Web-to-FeatureStore capacity ratio’s variances across regions. Before Flux was applied to FeatureStore, the variances across regions C, D, and E were partially due to sub-optimal planning done by humans. Flux is able to reduce the variances by lowering the ratio for region D and increasing the ratio for region E, thus leading to better balance across regions C, D, and E. The improvement was small as this was the first time that Flux was applied to FeatureStore and was configured to be more conservative in introducing changes.

Deviation from ideal service capacity ratios is also reflected in the service’s unbalanced CPU utilization across regions. Note that, if FeatureStore’s capacity increase in a region is bigger than FeatureStore’s traffic increase in the region, we expect FeatureStore to have a lower CPU utilization

Figure 14: **FeatureStore traffic changes computed by Flux.** An example of how to read the figure: region A’s traffic change is  $\frac{\text{new traffic for FeatureStore in region A}}{\text{old traffic for FeatureStore in region A}} - 1 = -37\%$ . Only 5 out of 10s of regions are shown for readability.

Figure 15: **Ratio of capacity for Web and FeatureStore.** Only 5 out of 10s of regions are shown for readability.

in the region after the change. This type of change can be applied to lower the CPU utilization of more heavily loaded regions, which is precisely what Flux did. For each region  $r$ , we calculate the average CPU utilization  $u_r$  of `FeatureStore` during its daily peak time window. Then we calculate the median of  $u_r$  across 10s of regions, and call it  $\hat{u}$ . Before and after Flux was applied to `FeatureStore`,  $\hat{u}$  was 55% and 50%, respectively. This indicates that Flux is effective in matching traffic distribution with capacity distribution to balance load across regions.

Figure 16 shows  $u_r$  for some sample regions. Overall, Flux reduces the CPU utilization of more heavily loaded regions such as regions A and D. In this instance, Flux was unable to increase CPU utilization in C due to the other constraints and objectives. This example shows that there are many factors to be considered during optimization, which is better suited to a MIP solver than humans.

## 7 Related Work

**Capacity management.** Capacity management impacts service performance and reliability as well as an organization’s capital and operating expenses. Two USENIX *login*: articles [27, 48] provide an overview of this topic. Misbah et al. provide a survey of resource management in federated cloud [33]. Several publications report capacity-management practices for internet services such as LinkedIn [53, 56], Uber [15], Google [34], and Netflix [36]. They focus on forecasting demand and capacity headroom, and are complementary to our work focusing on global service placement.

**Service tracing and modeling.** Several systems [13, 17, 30, 40, 46] insert unique request IDs into RPC calls to discover end-to-end service dependency. Our work adopts this approach. Some systems use statistical analysis [2] or heuristics [3, 38, 43] to infer service dependencies. Although these techniques are easier to deploy, they have not been proven to be robust enough to be used for internet-scale complex services. Both analytical models [51] and profiling techniques [41] have been applied to build performance models for three-tiered applications, but our environment is much more complex (see Figure 1). Endo *et al.* [20] call out the challenges of operating

Figure 16: CPU utilization of `FeatureStore` per region before and after Flux is applied. Only 5 out of 10s of regions are shown for readability.

a distributed cloud, including resource modeling, but do not propose solutions.

**Service placement.** Yang *et al.* [54] propose joint service placement and traffic routing in mobile cloud, without considering service interdependencies. Malet and Pietzuch [35] propose placing services across datacenters to minimize network latency without considering the constraints of capacity supply and demand.

**Constrained optimization.** Constrained optimization has been used for resource allocation in different scenarios, including hardware-to-reservation assignment within a region [37], data-shard-to-container placement [32], and job scheduling within a cluster [19, 23–26, 42, 44, 49, 50]. None of them tackle the problem of global service placement.

**Infrastructure orchestration.** Cloud infrastructure orchestrators like Terraform [28] and CloudFormation [7] coordinate changes across multiple infrastructure systems in public clouds. These could be used to implement the orchestration component of Flux in a public cloud setting.

## 8 Conclusion

We identified the *regionalization problem* associated with managing customer services on large, global cloud footprints. We presented Flux, which solves regionalization by (1) using RPC tracing to build service regionalization models; (2) jointly solving service and traffic placement, growth capacity distribution, and infrastructure objectives; and (3) introducing a capacity orchestration system that safely and automatically rebalances services and traffic according to the computed plan. We shared our experience of using Flux at Meta’s large private cloud and discussed ways in which the ideas in Flux can be applied to public clouds.

## 9 Acknowledgements

This paper presents many years worth of work by multiple teams at Meta. They include: the Regional Fluidity, Capacity Engineering, Capacity Automation, Shard Manager, and Algorithmic Optimization teams. We would like to thank the current members of the Flux team who are not already on the author list: Kiryong Ha, Alex Cauthen, Chris Zheng, Hossein Tajik, Lin Xiao, Xiaomeng Shen, Austin Hendy, Daniel Boeve, Jikai Zhang, Tejash Shah, Kevin Lin, Partha Roy Chowdhury, Caroline Tony, Junjie Qian, Anand Saggi, Sebastiano Peluso, David Xu, Yichen Zhou, and Peter John Daoud.

We would also like to thank the following for their insightful comments, honest feedback, and partnership during the development of Flux: Maria Kacik, James Kneeland, Nasser Manesh, Haying Wang, Ariel Rao, Ash Shroff, and Alp Elci.

Finally, we thank Yunqi Zhang, Dimitrios Skarlatos, all reviewers, and our shepherd Z. Morley Mao for their help and insightful feedback.

$S$	Set of all services.
$R$	Set of all regions.
$H$	Set of all hardware types.
$P$	Set of all products.
$T$	Set of all timesteps.
$t_0$	Baseline timestep, i.e., infrastructure's current state.
$t_1$	Target timestep, i.e., the timestep for which we are executing.

### Inputs

$m_{r,h,t}$	Capacity pool: amount of type $h$ hardware available in region $r$ at time $t$ . It is generated by capacity forecast and includes the current capacity and net incoming and outgoing supply.
$\phi_{s,h,p}$	Globalized service baseline: output of the service-modeling process described in §3.2, indicating the fraction of service $s$ ' consumption of type $h$ hardware being attributed to product $p$ . We also scale the globalized service baseline by service growth, derived from our capacity budget management system, leading to varying values at different timesteps $t$ .
$\gamma_{s,h,t}$	The total growth capacity, indicating the global amount of type $h$ hardware allocated for service $s$ at time $t$ to support service growth. It is derived from Meta's budget management system, and is used to support product growth and launches.
$\tau_{p,t}$	The total traffic growth indicating the global increase in traffic to product $p$ at time $t$ , represented as the percentage above 100% global baseline traffic.
$e_n$	The penalty coefficient for objective $n$ . Penalty coefficients dictate how tradeoffs are compared.

### Assignment variables

Variable	Baseline	Distribution	Description
$x_{p,r,t}$	$\xi_{p,r}$	$X_t$	Traffic assignment, indicating the fraction of traffic from Regionalization Entity $e$ assigned to region $r$ at time $t$ . $X_t := \{x_{p,r,t} : p \in P, r \in R\}$ Invariant: $\forall p \in P \sum_{r \in R} \xi_{p,r} = 1$
$c_{s,r,h,t}$	$\kappa_{s,r,h}$	$C_t$	Capacity assignment, indicating the amount of type $h$ hardware allocated to service $s$ in region $r$ at time $t$ . $C_t := \{c_{s,r,h,t} : s \in S, r \in R, h \in H\}$
$g_{s,r,h,t}$	-	$G_t$	Growth assignment, indicating the amount of additional type $h$ hardware allocated to service $s$ in region $r$ at time $t$ for the purpose of growth. $G_t := \{g_{s,r,h,t} : s \in S, r \in R, h \in H\}$
$d_{r,h,t}$	-	$D_t$	Deficit assignment, indicating the amount of additional type $h$ hardware needed in region $r$ at time $t$ . $D_t := \{d_{r,h,t} : r \in R, h \in H\}$
$s_{r,h,t}$	-	$S_t$	Spares, indicating the amount of unallocated hardware of type $h$ in region $r$ at timestep $t$ . $S_t := \{s_{r,h,t} : r \in R, h \in H\}$
$o_{r,h,t}$	-	$O_t$	Double occupancy capacity. See explanation for Expression 14. $O_t := \{o_{r,h,t} : r \in R, h \in H\}$
$r_{s,r,h,t}$	$\rho_{s,r,h}$	-	Model residual, the difference between the observed baseline capacity distribution and the capacity distribution implied by the globalized service baseline, $\phi$ , distributed according to the baseline traffic distribution $\xi$ . $\rho_{s,r,h} := \kappa_{s,r,h} - \sum_{p \in P} \xi_{p,r} \times \phi_{s,h,p,t_0}$

Table 1: Notation used in the MIP formulation. *Baseline* means the current state of the infrastructure.

## A MIP Formulation in Flux

This appendix presents the MIP formulation used by Flux.

The core of the formulation is an assignment problem, represented by the assignment variables enumerated in Table 1. Each variable shares a region ( $r$ ) and timestep ( $t$ ) dimension; while capacity related assignments also include dimensions for the service being assigned ( $s$ ) and hardware type of the assignment ( $h$ ).

Next, we present the MIP problem formulation and explain each expression. The MIP problem is to minimize:

$$e_1 \times \sum_{p \in P, r \in R, t \in T} |x_{p,r,t} - x_{e,r,t_0}| \quad (2)$$

$$+ e_2 \times \sum_{t \in T, p \in P} \max_{r \in R} x_{p,r,t} \quad (3)$$

$$+ e_3 \times \sum_{r \in R, h \in H, t \in T} d_{r,h,t} \quad (4)$$

$$+ e_4 \times \sum_{r \in R, h \in H, t \in T} o_{r,h,t} \quad (5)$$

$$+ e_5 \times \sum_{p \in P, r \in R, h \in H, t \in T} |r_{p,r,h,t}| \quad (6)$$

$$+ e_6 \times \sum_{r \in R} \left| s_{r,h,t} - \frac{s_{r,h,t}}{\sum_{r \in R} s_{r,h,t}} \right| \quad \forall h \in H, t \in T \quad (7)$$

Subject to:

$$c_{s,r,h,t_0} = \kappa_{s,r,h} \quad r_{s,r,h,t_0} = \rho_{s,r,h,t_0} \quad (8)$$

$$x_{p,r,t_0} = \xi_{e,r} \quad o_{r,h,t_0} = 0 \quad (8)$$

$$c_{s,r,h,t} \geq \sum_{p \in P} (x_{p,r,t} \times \phi_{s,h,p,t}) + r_{s,r,h,t} \quad (9)$$

$$r_{s,r,h,t} \geq \min\{\rho_{s,r,h}, 0\} \quad (10)$$

$$m_{r,h,t} + d_{r,h,t} = s_{r,h,t} + \sum_{s \in S} c_{s,r,h,t} + \sum_{s \in S} g_{s,r,h,t} \quad (11)$$

$$\forall p \in P, t \in T \quad \sum_{r \in R} x_{p,r,t} = 1 + \tau_{p,t} \quad (12)$$

$$g_{s,r,h,t} = \frac{\gamma_{s,h,t} * c_{s,r,h,t}}{\sum_{r \in R} c_{s,r,h,t}} \quad (13)$$

$$o_{r,h,t} = \sum_{s \in S} c_{s,r,h,t-1} - c_{s,r,h,t} [c_{s,r,h,t} < c_{s,r,h,t-1}] \quad (14)$$

$$s_{r,h,t} + \sum_{s \in S} g_{s,r,h,t} \geq o_{r,h,t} \quad (15)$$

Below, we explain the intuition behind the MIP expressions.

**Stability objective.** Expression 2 penalizes traffic shifts to reduce churn in the infrastructure.

**Disaster-readiness objective.** Services have a disaster-readiness buffer to cope with any single-region failure. Expression 3 minimizes this buffer, by minimizing the size of the largest region.

**Objective to minimize deficits.** Expression 4 minimizes the additional hardware needed. Technically, a feasible solution requires that  $\forall r \in R, h \in H, t \in T \quad d_{r,h,t} = 0$ , and we use a high penalty  $p_4$  to ensure that deficits are non-zero only if a solution requires it.

**Objective to minimize deviation from service model.** Pre-existing placement imbalance, attribution inaccuracies, or traffic routing imbalances can cause baseline capacity assignments to deviate from the service model. Expression 6 minimizes deviation from the global service model defined by the globalized service baseline.  $r_{p,r,h,t}$  is the residual of the service model, which is further discussed in §6.3.

**Objective to balance spare pool distribution** Expression 7 encourages balancing unused capacity across regions to reduce hardware stranding. Sufficient unused capacity placement can also act as a buffer for capacity estimation discrepancies.

**Baseline.** Expression 8 establishes timestep  $t_0$  as the baseline, i.e., the current state of the infrastructure.

**Product attribution ratio constraint.** Expression 9 ensures that each service is allocated according to the ratio imputed from the service model (see §3.2). The model residual  $r_{s,r,h,t}$  is used to offset the placement.

**Residual-regression constraint.** Expression 10 prevents model residuals from regressing. Specifically, negative residuals (i.e., underprovisioned services per the model) are prevented from becoming more negative, while positive residuals may not become negative. Together, objective 6 and this constraint cause Flux to better balance service utilization across regions. Flux provides fine-grained controls (per service, region, hardware type) that let the service owner tune how aggressively Flux is allowed to rebalance a service. §6.5 provides a case study of this benefit.

**Capacity-sufficiency constraint.** Expression 11 ensures that each region has sufficient capacity to support the capacity assignment, as determined by expression 9. This also assigns additional hardware as deficits, if required for feasibility. Unallocated capacity is assigned to the spare pool  $S_t$ .

**Full-placement constraint.** Expression 12 ensures that each RE is fully placed.

**Organic growth constraint.** When  $\tau_{p,t} \geq 0$  Expression 12 places additional traffic demand which Expression 9 then allocates the organic growth capacity to each service according to its globalized service model. Organic growth is used to model increased traffic where all dependent services must be sized up proportionally.

**Inorganic growth constraint.** Expression 13 distributes the growth capacity proportionally to a service's placed capacity. Inorganic growth is used to distribute growth capacity to an individual service such that dependent services don't necessarily need to be resized, such as product launches.

**Double-occupancy constraint.** We execute the capacity upsizes before capacity downsizes (see §3.4) and cannot count on future released capacity to fund an ongoing upsize operation. Expression 14 defines the amount of capacity needed during an upsize operation, whereas Expression 15 ensures a valid intermediate state by enforcing sufficient capacity is available to prevent an upsize from using still occupied capacity. Growth is given out as a final step of execution, and can be used during the upsize stage. Expression 5 minimizes double occupancy.

**MIP Solver Scalability.** Flux uses the MIP solver well within its scalability limit. Our latest service placement run generated a problem with 24K assignment variables and 36K constraints. Solving the problem took only 5 seconds.

# Defcon: Preventing Overload with Graceful Feature Degradation

## Abstract

Every day, billions of people depend on Internet services for communication, commerce, and entertainment. Yet planetary-scale data center infrastructures consisting of millions of servers experience unplanned capacity outages and unexpected demand for resources; how can such infrastructures remain reliable in the face of capacity and workload flux?

In this paper, we introduce Defcon, a system for improving the availability of large-scale, globally-distributed Internet services using graceful *feature* degradation. In response to overload conditions, Defcon enables site operators to gradually disable less-critical features in order to reduce resource demand. Defcon presents a common interface to product developers to define feature *knobs* that represent degradation capabilities. Defcon automatically tests knobs to understand each knob’s product- and infrastructure-level trade-offs. At Meta, we have used Defcon to improve global product availability in the face of worldwide demand-surges in addition to large-scale infrastructure failures.

## 1 Introduction

Large-scale, globally-distributed Internet services, such as those operated by Alibaba, Amazon, Google, Meta, Microsoft, and Netflix, power modern human life by providing access to communication, commerce, entertainment, and many other experiences. At the same time, rapid advances in finance, artificial intelligence, machine learning, and virtual/augmented reality have solidified the utility of Internet services for much of humanity for the foreseeable future.

Internet services consist of *features* – functional building blocks that make up a larger product. For example, a video product consists of a search feature, a playback feature, a recommendation feature, and so on. Features are hierarchical: A *top-level* playback feature may itself consist of a video quality feature and a closed-caption feature, for example. Features, and the *products* they make up, power Internet services.

Products (and, by extension, features) run in data centers distributed around the planet. Analogous to the familiar von

Neumann architecture, computing at a planetary scale requires input/output (in the form of HTTP and RPC requests), computation (in the form of front-end servers), interconnect (the network backbone), caching, storage, and so on. Site operators deploy these resources within geographically-distributed data centers with the goal of ensuring that the workload *demanded* by users does not exceed the resources *supplied* by the network, servers, and so on.

Planning data center resources well requires predicting the future – or at least trying to. Capacity engineers rely on detailed user demand forecasts and server supply models to decide how and where to purchase and deploy resources, but alas, prophesy yet remains elusive: Errors and inaccuracy creep into models and forecasts, making data center capacity planning at times more of an art than a science. In addition, unpredictable world events – like global pandemics – can render even the most sophisticated predictions obsolete overnight.

At the end of the day, the people that use Internet services care about *availability*: Can they use the product that they want to use when they want to use it? Toward that end, companies work hard to ensure their products remain highly available. But what happens when things do not go according plan, such as during a persistent product demand increase due to a global pandemic, or when recovering from a global outage? Can we achieve high product availability without sacrificing additional resources? Can we be more efficient for rare – but inevitable – partial outages and survive them without additional server resources?

For example, Figure 1 shows a *real-world* surge in demand for one of Meta’s products, Facebook (measured on the y-axis in mega-instructions per second, or MIPS, executed by front-end servers for the product), that occurred over several hours on October 27, 2022. Localized peaks toward the left and right of the chart illustrate software deployment on the front-end systems, which consumes additional resources due to idle hosts updating their binaries and cold cache effects – these are expected behaviors. At around 5AM PDT, however, an unexpected increase in demand for the product happened to coincide with the daily peak usage of the product (shown

**Figure 1:** Defcon in action during a real-world site event. (See Section 1 for explanation.)

from a previous day as “reference signal”) leading to constructive interference and causing the product to run out of capacity and dangerously approach an *overload* condition (approximately  $1.15 \times 10^{10}$  MIPS) at which point fail-slow behavior and overload would occur. At around 6:35AM PDT (vertical dotted line), site operators engaged a system, which we present in this paper, in order to safely and efficiently reduce resource consumption (MIPS), *while still preserving access to core product functionality for all users*, avoiding an outage. Around 7:15AM PDT, as demand for the product continued to increase, site operators further engaged a next *level* of the system – leading to a correspondingly larger decrease in resource consumption, *bending the traffic (MIPS) surge curve* to restore it to nominal amounts of resource demand. After the surge had passed, at around 8:00AM PDT, site operators disengaged the system, restoring the product’s features to their original state.

In this paper, we present *Defcon*, a system to provide graceful *feature* degradation for Internet services. Defcon achieves high availability without sacrificing additional server resources by allowing site operators to *dynamically turn off product features* in response to rare (e.g., monthly or yearly) demand spikes or even unpredictable product demand increases. The key insight of Defcon is that *not all product features provide equal value* – many features can safely be turned off for short periods of time without altering a product’s fundamental behavior. Human guidance is used to define and actuate “knobs” – control flow annotations that represent the best capacity savings and user experience trade-offs.

We characterize the overload problem and solution space, apply a rigorous data-scientific methodology to analyze knob behavior, and describe a real-world at-scale testing methodology to validate the efficacy of Defcon. We also shed light on the design and organization of large-scale, real-world systems from the field as our approach accurately reflects the trade-offs involved in designing and implementing an initial solution to an emerging problem under realistic constraints. A key contribution of this paper is to prove the efficacy of feature degradation to help solve the overload problem in distributed systems.

We describe the design and implementation of Defcon and

our experience operating Defcon in production over the course of three years. We evaluate our approach using a combination of continual at-scale controlled tests as well as case studies from production incidents, including during a sustained demand surge. Overall, we find graceful feature degradation to be a powerful design pattern for system architects to efficiently improve the availability of large-scale distributed systems.

## 2 Background

Graceful degradation pervades the natural world: Removing ballast to prevent a ship from capsizing, escalators losing power and becoming ordinary stairs, starfish reproducing a lost limb, and so on. We observe analogous patterns of graceful degradation in the realm of computing and provide a brief overview of these techniques as well as a backdrop for why graceful degradation matters in large-scale Internet services, next.

### 2.1 Data Center Capacity Management

Modern hyper-scale data center infrastructures rely on server *capacity* distributed across the planet in order to support the diverse resource needs of the services that run in the data centers. Capacity Engineers rely on two inputs in order to make data center capacity planning decisions: *workload resource demand* and *server resource supply*.

Workload resource demand models the resource needs of a product in order to support its set of features. Capacity engineers normalize resources to a common unit baseline in order to plan resources across different server architectures or generations (e.g., Relative Resource Units, or RRUs) where resource types include computational throughput, storage capacity, memory bandwidth, and network bandwidth. Modeling workload resource demand involves understanding how many RRUs of different resource types are required to support product features. To accurately model future resource demand, engineers scale current resource demand based on feature growth projections.

Of course, in reality, resource supply and demand can behave in unpredictable ways. For example, a workload pattern change can change resource demand, while a data center outage can decrease resource supply. A key challenge, therefore, is *how to allocate resources in the face of constant infrastructure and workload flux*<sup>1</sup>. In many traditional systems, scenarios where resource demand > resource supply leads to fail-slow – and, eventually, overload-induced – system unavailability.

<sup>1</sup>Note that systems in Meta’s infrastructure are already equipped to automatically scale up and down capacity in response to predictable (e.g., diurnal) demand changes. Even so, there still comes a point when there is no remaining capacity to elastically expand a service into (such as during unpredictable load spikes or large outages).

Potential Solution	Description	Additional Resources	Engineering Effort	User Impact
0. Do Nothing	Allow overload to happen, leading to product outages.	None	None	Very High
1. Overprovision Resources	Increase server resources, leading to lower steady state utilization. Cannot fully predict future traffic patterns.	Prohibitively High	None	Potentially None
2. Drop User Requests	Reduce work by discarding user requests at a load balancer level (L4 or L7) before they enter into a data center.	None	Medium	High
3. Shed Server Load	Modify micro-services to decide when and which requests to drop for their service.	None	High	Medium
4. Degrade Product Features	Annotate control flow and avoid executing certain features on-demand.	None	High	Low

**Table 1:** Potential solutions to the overload problem and their associated trade-offs.

## 2.2 The Overload Problem

System *overload* occurs when the requested throughput of a service (e.g., measured in queries per second, QPS) exceeds the capabilities of the system, leading to a phenomena known as *congestion collapse* whereby *goodput* (a measure of the rate of successful responses from the service), decreases [2, 38]. Systems of any size can become overloaded, but the overload problem is especially acute in large, geographically-distributed Internet services, which can cause cascading failure scenarios, and can lead to widespread outages [12]. *Overload remains a fundamental problem in the operation of distributed systems.*

Meta’s infrastructure is organized around a collection of geographically-distributed data center failure domains, each representing around 5–12% of the overall capacity. Common failures such as bugs, network/power outages, and incorrect configuration happen within these failure domains and we have found 5–20% of savings to be a sweet spot for capacity savings for mitigating the risk of cascading failures due to overload. In this work, we assume a baseline of an overload-induced metastable failure state that leads to product outages for large portions of users for minutes to hours at a time.

Table 1 summarizes some potential solutions to the overload problem and how they trade off the amount of hardware resources (Server Resources), the amount of effort required of engineers to implement and maintain (Engineering Effort), and the potential impact to users (User Impact). For example, one way to attempt to solve the overload problem is to simply allocate more server resources for a distributed system (option 1). While potentially effective, simply allocating more resources can be inefficient, leading to low resource utilization when traffic is not at its infrequent (e.g., on the order of months or years) projected peak.

Furthermore, we can never perfectly predict traffic patterns and real-world events can often thwart even the best preparations. Take the COVID-19 pandemic as an example: In 2020, as more persons began to shelter in place, communication

that was once in-person began shifting to occur online. Figure 2 shows an example of how traffic for one product at Meta greatly exceeded its pre-pandemic resource plans. During global crises, Internet services often become more important than ever for humans to communicate and remain connected with each other. And while at Meta we were able to survive the COVID-19 demand surge, we wondered: “*Can we build systems that are inherently resilient in the face of unforeseen overload?*”

To answer this question, we found options 2–4 compelling. Note that options 2 and 3 both reduce work, but whereas option 2 reduces work at its *source*, option 3 reduces work at its *destination*. Specifically, for option 3, we considered a fine-grained backpressure-based approach, which led to noticeable user impact when capacity demand exceeded capacity supply and requests could not be processed. After evaluating the potential trade-offs at Meta, we opted for a technique to minimize user impact and found option 4, Degrade Features, to achieve the best trade-off: No additional server resources and low impact to users, albeit with an investment in engineering effort (which we qualify in Section 5).

**Figure 2:** Real-world events can often thwart even the most sophisticated preparation techniques, as shown by this graph of actual versus forecasted demand for Facebook in 2020 during the onset of the COVID-19 pandemic.

## 2.3 Related Work

Degradation is a self-adaptation technique that reduces the amount of work that servers need to perform to stay resilient during resource shortages, spiky load, and reduced hardware performance [12] that would otherwise cause a distributed system to enter a failure state [6, 16]. Degradation has been considered in many different contexts of system design, such as storage systems [8, 22, 31, 39], processor design [4, 17], cloud computing infrastructure [9, 11, 20, 25, 29], edge computing systems [21], web server applications [1, 2, 14], search engines [10], and mail services [27]. In network systems, graceful degradation is used to handle overload of network resources through intelligent connection management [36], traffic prioritization [3], traffic handover control [5], security hardening [15, 34], as examples.

Degrading the static content of a website was proposed in [2] and relevant techniques have been extended to dynamic content [26]. Degradation has also been proposed by cloud Infrastructure as a Service (IaaS) providers as a feature to increase cloud utilization [29] and used for adapting to the high network variability and possible network disruptions in edge computing infrastructure [21]. Defcon contributes to this area of research by developing a product-level, *feature-centric* framework to perform configurable *graceful* degradation of large-scale geo-distributed micro-services during spiky load and disaster events and providing real-world insights on how to build and operate such a system from its global of deployment in products at a large scale.

One alternative approach for surviving resource shortages during load spike or outage events is load shedding [11, 37, 38], which drops a proportion of load by dropping request traffic when a server approaches overload. However, load shedding sacrifices availability guarantees and broadly impacts user experience. In contrast, degradation techniques aim to provide high availability of products and services to users around the globe, which is critical to minimize impact.

Another area of related research is on specifying and realizing degradation for distributed systems. A relaxation lattice method was proposed for specifying the behavior of degradation [13]. Furthermore, specifications and implementations of degradation were presented in [39] as a complementary mechanism to fault tolerance in the design of highly-available distributed systems. Availability Knob [30] was proposed to provide a variety of availability guarantees, improving the utilization of reliability-heterogeneous infrastructures. In this work, we adopt the “knob” nomenclature, although for different means. Whereas Availability Knobs specify availability SLA flexibility, knobs as used in this work describe source code control flow annotations which can be enabled or disabled at-will.

Client-managed degradation was explored in the context of features like low power modes [18]. Our approach differs from client-managed degradation in three key ways. First, in

contrast to an ad-hoc approach to define individual points of degradation in client code (which, like a low power mode, then effectively become new “features” to maintain in the client), our approach provides a framework (knobs) that developers can use to efficiently encapsulate existing features, significantly reducing the development cost of degradation. Second, our approach provides developers with a framework to automatically test, analyze knob savings, and manage the lifecycle of knobs. Third, our approach extends to both client-side and server-side knobs, as it abstracts the knob control plane into configuration management as opposed to custom client (or server) code.

## 2.4 Graceful Feature Degradation

In this work, we ask the question, “Can we design distributed systems that remain available even when resource demand  $>$  resource supply?” While such systems would violate traditional system design assumptions, our key insight is that *not all features of a product are equally important* – if we can identify *essential* features (such as the ability to send a message in a messaging product) versus *fungible* features (such as an online status indicator for whether the message recipient is currently online), then we can gracefully *trade off fungible features for on-demand server resources*, while still preserving *essential features*. For example, the number of results can be considered as an adjustable *feature* for a search product.

In this paper, we introduce the qualifier graceful *feature* degradation to refer to the property of a large, globally-distributed system to dynamically modify its behavior (features) in order to dynamically (i.e., *at runtime, without* recompilation or changing binary flags) alter its control flow for the purpose of reducing the system’s resource requirements. From here on, we use the terms “graceful degradation” and “graceful feature degradation” interchangeably.

## 3 Defcon

Defcon is a system to implement graceful degradation in large-scale distributed systems. Defcon is designed to be used during infrequent site emergency situations where demand is greater than supply. There are many reasons why a system may encounter situations where demand for the system’s resource exceeds the supply of resources for the system. Some examples are data center outages, load spikes during special events like New Year’s Eve, service overload due to a bug in a software deployment, and so on. We provide an overview of Defcon and discuss the design and implementation of its key system components, next.

### 3.1 Overview

Figure 3 shows an overview of Defcon. *Knobs* annotate program control flow eligible for degradation and follow a well-defined API. Product engineers use a Knob Definition Framework to annotate source code that can be degraded. These knobs are controlled using a Knob Actuator Service by site operators according to a policy. Not shown in the figure, a *Knob Testing Framework* registers knobs defined in the code base and automatically tests them to understand the sensitivity of product experience and resource consumption when the knob is turned on. We discuss each of these components next.

**Figure 3:** Overview of Defcon system architecture. Product software engineers use a *Knob Definition Framework* to label sections of control flow corresponding to specific features to conditionally execute. A *Knob Actuator Service* controls which knobs (and their corresponding features) are enabled or disabled in response to real-time events. Mobile clients, web clients, and micro-services all communicate via configuration with the Knob Actuator Service to dynamically determine control flow. A Degradation Portal provides insights for site operators to understand which knobs to enable in response to server resource shortages and a Degradation CLI allows humans to rapidly control knobs *en masse*.

### 3.2 Knob Definition Framework

A *knob* is a switch to enable or disable a feature in the code. Unlike feature flags, which require a binary restart in order to take effect, knobs are controlled dynamically while a binary is running. Knobs are implemented by a client library (or sidecar service) that determines the current state of each knob and are controlled using a configuration management system [32]. Software developers provide each knob a unique name, which they then can reference in their code. Thus, knobs can span multiple source code files, or even multiple binaries. Knobs come in two flavors:

**1. Server-side knobs** are implemented in binaries running on the servers in data centers. The advantage of server-side knobs is that we can adjust the knobs' state in seconds without any propagation delays.

**2. Client-side knobs** are implemented in client code running on phones, tablets, wearables, and so on. The advantage of client-side knobs is that they have the capability to reduce network load by stopping requests sent to the server along side reducing server load due to the request. Client-side knobs can also be controlled conditionally based on device metadata, such as cache state and network bandwidth availability. For example, Meta's mobile apps maintain a client-side cache response freshness threshold value. We update this freshness threshold value during Defcon to control incoming traffic. At Meta, we use server-side configuration to control these values. We use two approaches to propagate knobs state changes to clients, each with its own pros and cons:

**2.a. Silent Push Notification (SPN):** This approach uses a push notification system to propagate knobs state changes. At Meta, we have large numbers of client devices and the system takes around 30 minutes to finish all push notification jobs to propagate knobs state changes. SPN works like a typical app notification mechanism but instead of showing a notification to a user, the client app updates corresponding configuration fields.

**2.b. Mobile Configuration Pull (MCP):** In this approach, clients pull updated mobile configurations from servers through an API. At Meta, every client application implements two kinds of configuration-pull mechanisms: (1) A *full configuration pull* happens every 6 hours and pulls updated configuration data for every configuration definition. Full configuration pull is more thorough, but requires more network bandwidth and server resources. (2) During *Emergency Mobile Configuration (EMC) pull*, each client request triggers a server to inspect an emergency configuration file located on the server to fetch updated configuration data for the fields mentioned in the emergency configuration file. EMC consumes less network bandwidth and server resources, but requires manual intervention.

Listing 1 shows an example of defining a knob in Python (although APIs also exist for Rust, C++, Hack [35], and Java). Every knob has a unique name (with a namespace unique for each product name, `Feed` in this example), a *level* corresponding to the magnitude of resource reduction and used for grouping all knobs of a similar magnitude together, and a Boolean enabled state. The `export` statement instructs the build system to generate/update knob source code definitions in the code base.

**Listing 1:** Knob definition.

```
from configs.knobs import KnobConfig
disableCommentsRanking = KnobConfig(
    name = "Feed/DisableCommentsRanking",
    oncall = "owner_team_oncall",
    level = 2, # Impact magnitude.
    enabled = True)
export(disableCommentsRanking)
```

Listing 2 shows an example of using a knob in Python. To

use a knob, a developer must inspect the `enabled` field for the knob:<sup>2</sup> If the knob is disabled (the common case), the binary follows its normal control flow; if the knob is enabled (e.g., during an emergency), the binary follows a work-reducing control flow to reduce server resource consumption for every request served.

**Listing 2:** Knob usage.

```
from configs import ConfigReader
disableCommentsRanking = ConfigReader(
    "Feed/DisableCommentsRanking")
comments = fetchComments()
if (disableCommentsRanking.enabled == False)
    comments.RankUsingModel()
else # Knob enabled: do less work.
    comments.RankChronologically()
```

At Meta, knobs are not implemented haphazardly, but are instead carefully planned for by product teams with target resource savings set for different knob levels. Even so, the flexibility and ease of knob definition has enabled some products to implement and manage hundreds of knobs. Usually product teams choose the design of their knobs (i.e., server side knobs or client side knobs) based on the product behavior and the trade offs from controlling the demand at different places. Generally, knobs are defined at product feature level to stop the entire control flow across different surfaces.

Defcon knobs are added to both existing and new features. At Meta, features are deployed gradually with server-side controls and experiments. Meta’s deployment process requires product engineers to have a single-server side configuration to enable/disable their features. In Meta’s infrastructure, features are typically implemented as separate RPCs and therefore there is strong isolation between the control flow of each feature. For shared library code, product engineers have the choice to degrade at the library level or at a finer-grained RPC request level.

This process provides an advantage for developing knobs as a product team can simply extend these feature controls to check for Defcon configuration. Integrating knobs with feature development and deployment processes has other advantages: Ease of running experiments to test a knob for side-effects, measuring the capacity savings from disabling a knob, and measuring the impact of a knob on users (Section 3.4). User impact is then used to classify a knob into the correct Defcon level (Section 3.5). Once a product engineer is satisfied with a knob’s behavior, they will explicitly choose to include it in the Defcon system.

To aid product teams in understanding the breadth and behavior of the knobs they have defined, a browser-based graphical user interface is provided to help developers understand target level resource saving expectations, manage knob

<sup>2</sup>Knob configuration state is cached within memory on the server a binary is running on and accessed either by a shared library or a sidecar binary, typically requiring no more than microseconds to access.

metadata, visualize knob savings against the target expectations, and understand any user experience trade-offs (using a measurement methodology we discuss later). In turn, emergency responders use this user interface to understand Defcon level savings and the associated impact of enabling knobs.

### 3.3 Knob Actuator Service

We believe it is important to have a highly reliable tool with minimal dependencies to control Defcon, so that we can use Defcon even when most other systems are unavailable. The Knob Actuator Service is responsible for enabling or disabling (actuating) sets of knobs. Knobs are grouped into three categories: (1) By service name, (2) by product name, and (3) by feature name (such as “search,” “video,” “feed,” and so on).

The Knob Actuator Service also manages metadata for knobs, stored in a geographically-replicated relational (MySQL) database. Knob metadata includes: (1) The engineering oncall responsible for the knob’s definition, (2) the engineering team responsible for the knob’s usage, and (3) a cache of recent resource and user experience test results (discussed later in this section).

Finally, the Knob Actuator Service is responsible for changing the state of knobs. Knob state changes can be performed for individual knobs or for sets of knobs grouped using one of the three categories (service, product, or feature name). State changes occur in seconds for server-side knobs and in a couple of minutes for client-side knobs (due to the EMC pull cycle duration mentioned before).

While state changes across sets of knobs are used during site events that require additional capacity supply, state changes for *individual* knobs are used for testing knob impact. Knobs can be further selected for only a fraction of users participating in controlled A/B test experiments (discussed in the next sub-section).

At Meta, emergency responders receive notifications for various overload scenarios (including increased demand, decreased capacity, etc.) for services. The emergency responders use a Degradation Policy (defined in Section 3.5) to evaluate if Defcon can and should be used to reduce the load. Once the emergency responders decide on a course of action, they use capacity savings data from recent tests (which are available in a dashboard) to estimate what Defcon level should be enabled, and use the Knob Actuator Service to enable Defcon knobs to reduce the demand to the desired amount.

### 3.4 Knob Testing Framework

As an emergency response tool, we must test Defcon periodically to ensure its reliability and performance. Since Defcon will incrementally degrade product features when enabled, we go to great lengths to minimize its impact during testing.

Our strategy is to execute frequent, but *small scale* A/B tests to get continuous signals for Defcon knob resource savings as

well as potential issues, and infrequent large-scale exercises to validate these signals at scale and observe how the knobs for a product, service, or feature (and downstream services) behave when Defcon is enabled for all of the product's, service's, or feature's requests.

We classify production tests into two categories:

**1. Small scale tests.** A/B testing measuring user behavior metrics helps us quantify the impact on users and products. These tests are conducted across a product, but with a very small user base, (e.g., 0.01–2%) of a population over a certain duration (e.g., 15 minutes to 36 hours). The main goals from these tests are validating the knob set-up for the product, measuring the impact from the knobs, and measure the savings on downstream services using TRU. During A/B testing, we define four groups. One control group without any impact from Defcon and three treatment groups with different Defcon levels. We compare the resource consumption between the different groups with the control group as a baseline to measure the impact from Defcon on the service and the downstream services. To understand the impact of the Defcon knobs at a more granular level, we also run A/B tests at a service level (for any services that have knobs defined) and at a feature level.

We run server-based tests for multi-tenant backend services when per-user annotation is not propagated (e.g., for batch-processing services or multi-tenant services, where requests may belong to the system or several users simultaneously). In this case, we randomly select a small number of hosts for a particular service, and split these hosts in 4 groups, testing as described above.

We compare host metrics with the control group and store the results. The downside of this approach is that user experience may be momentarily inconsistent because consecutive requests from the same user may be served by different hosts. To minimise the user impact, we pick a negligible number of hosts for this test and run it for 5–15 minutes only. We run host-based tests weekly to always have fresh data and make sure that results are consistent. If results are not consistent, we adjust the number of randomly selected hosts. To make sure that our results are statistically significant and reliable we check that they match with empirical *large scale test* results (discussed next).

**2. Large scale tests.** Since Defcon is an emergency tool, we must test Defcon at scale to ensure its reliability and performance. We execute a Defcon service test on 100% of users quarterly to measure the resource savings at the product and service level and the demand reduction on the downstream services. Since during an emergency situation we may need support from Defcon for multiple products at the same time, we also execute combined degradation tests for multiple products together to measure the impact on Meta's infrastructure. During such tests, we enable Defcon knobs across products at levels 3, 2 and 1 for a short time and we monitor behavior similar to individual product tests.

### 3.5 Degradation Policy

Graceful feature degradation provides a trade-off between resource savings and product behavior. When designing the policy for when – and to what extent – to enable degradation, we must understand the trade-off between capacity savings from enabling a knob or collection of knobs and the user or product impact that comes from doing so. Product teams are responsible for defining key performance indicators that are closely measured and monitored during tests. Infrastructure teams provide a distributed tracing framework [19] to measure resource savings not only on the product, service, or feature where the knob is implemented, but also along the transitive closure of services affected by the knob.

Meta implements a four-level Defcon policy scheme whereby smaller-numbered levels correspond to *higher* amounts of degradation. Levels can be applied across the same features supported by the Knob Actuator Service (product, service, and feature). To ground the policy in reality, care has been taken to design each level around handling a specific set of failure scenarios:

**Level 4 (L4)** is the default state: All knobs are disabled.

**Level 3 (L3)** is used for handling overload situations resulting from relatively small-scale load spikes such as those seen during New Year's Eve or sporting events like World Cup. The Level 3 target savings is 5% of a product's overall demand.<sup>3</sup>

**Level 2 (L2)** is used for handling overload situation that arise from full data center region failures. Target savings is 10% of a product's overall demand (but can vary up or down based on a product's data center deployment model).

**Level 1 (L1)** is used during rare emergency events such as unforeseen global system outages. Target savings is 20% of a product's overall demand.

For setting target level savings, recall from Section 2.2 that Meta's infrastructure is organized around a collection of geographically-distributed data center failure domains, each representing around 5–12% of the overall capacity, making 5–20% of savings to be a sweet spot for mitigating the risk of cascading failures due to overload.

The Knob Definition Framework allows product developers the freedom and flexibility to explore potential knob resource savings and trade-offs in order to arrive at a portfolio of knobs that attempt to maximize the resource savings while minimizing the potential impact to users. When setting these level targets, service owners will translate demand reduction numbers to whichever resource they bottleneck on, like CPU,

<sup>3</sup>Most front-end services at Meta have CPU utilization as the bounding resource, and so target CPU savings is the most salient metric to focus on.

memory, network. We rely on historical data for the amount of demand increase typically seen during similar past scenarios.

Figure 4 illustrates the four-step policy that emergency responders follow when operating Defcon in production. Emergency responders:

1. *Analyze* the state of the product resource demands and potential Defcon knob resource supplies using a system monitoring dashboard. The dashboard lists critical system resource utilization metrics described in Degradation Policy.
2. *Decide* if the situation can be mitigated by applying a Degradation Policy. A degradation policy specifies the resource and impact trade-offs associated with enabling knobs at a particular level for a product.
3. *Check* the current state of Defcon and adjust it in accordance with the desired Degradation Policy (e.g., enable L2 knobs for a product).
4. *Degrade* fungible product features using a command line interface (CLI). Continue at step 1, adjusting Defcon level as necessary.

**Figure 4:** Emergency responders rely on a well-defined *Degradation Policy* in order to engage Defcon effectively.

We next evaluate the efficacy and trade-offs associated with operating *Gratuit* in a real-world large-scale environment.

## 4 Evaluation

At Meta, we have operated Defcon across three products – Facebook, Instagram, and Messenger – for over three years. Defcon has been used to avert or avoid many dozens of situations that would have otherwise led to resource exhaustion and overload. We next evaluate Defcon to demonstrate its efficacy, both during tests as well as during real-world events.

### 4.1 Measurement Methodology

We relied on four main sources of data for our analysis:<sup>4</sup>

1. A *Real-time Monitoring System (RMS)* for measuring hardware counter statistics across the entire fleet of servers at Meta to measure real-time demand for server resources.
2. A *Resource Utilization Metric (RUM)* source of truth data set for available server resource supply, measured using load-test data. Supply metrics include available request throughput, CPU MIPS, memory bandwidth, and so on.
3. A *Transitive Resource Utilization (TRU)* system that uses a distributed tracing framework to measure resource changes across the transitive closure of services involved in serving requests from a particular service.
4. A *User Behavior Measurement (UBM)* framework for quantifying any user workload changes that occur during a test.

Using these systems, we measure two *system-level* metrics during testing: (1) The global savings in resource utilization on the product, service, or feature under test using RMS; and (2) the savings in resource utilization on back-end services that receive traffic from the product, feature, or service under test using a combination of RMS, RUM, and TRU.<sup>5</sup>

We rely on controlled UBM experiments in order to measure the non-system-level effects of Defcon in a statistically significant manner. Requests to a product, service, or feature under test are divided into two groups: A control group (group A) and a test group (group B). Resource usage and user behavior is measured and then compared between group A and group B. Tests are run on a small fraction of users (typically a fraction of a percent) and over a long enough period to obtain statistically-significant results (typically minutes to hours).

In addition, for large-scale tests that involve large collections of knobs, we utilize various data science approaches to model each of our metrics both before a test (a forecast) and after a test (a backcast). Through linear modeling and time-series forecasting/backcasting, we construct a source-of-truth signal during the test period. Resource savings are subsequently computed by taking the percentage difference between the real signal captured during the large-scale test and the constructed source-of-truth.

As an example of this methodology, Figure 5 shows the measured global request throughput for the Facebook product before a product-level Defcon test. This experiment was performed as the product was nearing its peak moment of

<sup>4</sup>Due to space constraints, we do not detail the design of these systems in this paper.

<sup>5</sup>Whether to use RMS or RUM depends on the resource consumption to measure.

**Figure 5:** An example of timeseries forecasting. The measured global request throughput (QPS, y-axis) over time for the Facebook product immediately prior to enabling Defcon. A raw signal is converted to a smoothed signal and a forecast is generated from the smoothed signal.

request throughput (i.e., the highest organic load that we can test upon). Raw signal obtained prior to switching on Defcon (“raw signal”) is first smoothed (“smoothed signal”) and several time-series forecasting models are applied to obtain an estimate of what the raw signal would have looked like if Defcon was not turned on. Examples include linear, exponential, and Auto-Regressive Moving Average (ARMA) [28] models that are fitted using sections of the test signal before and after the Defcon degradation period.

**Figure 6:** An example of timeseries backcasting. Methodology is similar to Figure 5.

Aside from the forecasting models, we also reference past days’ signals in the steady state. The model which gives the smallest Median Percentage Error (MAPE) [23] is then chosen. Similarly, Figure 6 shows a time-series backcasting method applied to the smoothed signal gathered when Defcon is turned off. Note that the forecast and backcast use a somewhat conservative approach to ensure that measured savings are not over-estimated and to factor in headroom for the spikes observed in the raw signal. Finally, combining both the forecasted and backcasted signals (Figure 7), we derive a baseline which tells us what the metric would have been under normal circumstances when Defcon is not enabled. Savings are subsequently computed by taking the difference between the actual signal gathered during a Defcon test and the baseline.

**Figure 7:** By combining forecasts and backcasts during a Defcon test, we can construct a baseline to compare to the behavior when Defcon is enabled during a test.

## 4.2 Individual Product Tests

To continuously validate Defcon savings and reliability, we regularly perform A/B tests with a small percentage of users (0.01%, 0.05% and 0.5% for Level 1, Level 2, and Level 3 experiment groups respectively). The user percentages are set based on required population size of A/B test statistical analysis. Figure 8 shows the results of A/B test applied across different product areas. The y-axis shows the CPU resource consumption (measured in relative MIPS) and each bar corresponds to a group under test. As we expect, enabling lower levels of knobs generally results in more resource savings.

**Figure 8:** Results for Defcon tests for different sets of knobs (Product Areas) with different Defcon levels enabled. The y-axis plots the percentage change in CPU resource consumption, MIPS. Lower values indicate greater resource savings. Tests at each level are *inclusive* of higher levels (i.e., L1 tests also include L2 and L3 knobs). Notice that, generally, L1 knobs have larger resource savings than L2 knobs, and the same for L2 and L3. However, levels correspond to *impact* and not necessarily *savings*, and so some products, such as Storage, can achieve higher savings at lower levels of impact (L2 > L1).

Table 2 provides a detailed example of user impact metric data measured using the UBM framework described in Section 4.1 while testing at Level 1 for: (1) an individual knob, (2) a collection of knobs for a feature, and (3) all the knobs within all the features that make up a product. We observe

that degradation generally leads to relatively small user interaction changes, especially when compared to the alternative of an overload event leading to a site-wide outage. We also observe that enabling knobs can lead to user interaction *shifts* since user behavior changes in response to feature availability. For example, Video Watch Time at the Feature granularity increases when Level 1 knobs are turned on, as users engage in different ways to interact with a product.

Metric Name	Knob	Feature	Product
User Interaction	-1.82%	-4.3%	-5%
News Feed Usage	-0.6%	-1.1%	-1.6%
Video Watch Time	-0.6%	+2.37%	-0.93%
App Usage Time	-0.36%	-1.9%	-11.0%

**Table 2:** Example UBM metrics when enabling Defcon Level 1 for a selected Knob, Feature, and Product. User Interaction measures high level user engagement metrics for an app, like the number of comments, reactions, posts, and so on over the test interval. News Feed Usage is a composite metric measuring feed views and feed interaction time. Video Watch Time is a composite metric aggregating time spent watching videos, count of live viewers, engagement with live videos, and so on. The Knob granularity is for an individual knob defined for the product. The Feature granularity is the feature that contains that individual knob and all other knobs that make up the feature. The Product granularity is for the product that contains that feature and all other features that make up the product.

### 4.3 Combined Product Tests

At Meta, we regularly run combined degradation tests for multiple products. Figure 9 shows a combined Defcon test for three products: Facebook, a multi-tenant asynchronous compute platform (Async), and Instagram on 100% of traffic. The main goal of these tests is to accurately measure the combined transitive resource savings for shared backend services (here we illustrate the savings for Memcache, an in-memory key-value store [24]). As we can see, enabling Defcon across these three products leads to a compounding resource reduction for Memcache.

Of course, even when core product behavior remains unchanged, users may not expect to see changes in product features. At Meta, a user can submit a report when the user encounters something unexpected. Figure 10 shows user reports for four products during a combined test. As the figure shows, changing the features within products does not go unnoticed by users, with users submitting higher than nominal reports when Defcon is enabled. Note that this volume of reports – while keeping core product functionality available – is much preferred compared to fail-slow or overload conditions which could be several orders of magnitude larger without Defcon enabled.

**Figure 9:** An example of transitive resource changes on a multi-tenant backend system (Memcache), measured in QPS (y-axis). Requests are tagged according to which source of traffic sent the request: Facebook, an asynchronous compute platform (Async) and Instagram. We see that Facebook and Async contribute the most to the reduction in overall QPS (All of the Above).

**Figure 10:** Number of reports submitted by users for different products during a combined product test.

### 4.4 Transitive Resource Savings

We next explore in more detail how transitive savings affect dependent services. Figure 11 shows an example of the resource savings achieved on the Memcache service (the same service from Figure 9) as measured *only* for the requests originating from the Feed product. Knobs of decreasing level were enabled incrementally during the test and then removed later in the test.

Note that knobs for the Feed product were only enabled during the first half of the annotated test range, and while other products participated in this test, using TRU, we were

able to observe the resource changes for only a single source of requests. Crucially, this savings is a beneficial *side-effect* of the reduction in workload from the front-end service and *not* a result of knobs defined in the Memcache service.

**Figure 11:** Resource savings, measured in QPS on the y-axis, on the Memcache service by enabling Defcon on upstream products, despite the Memcache service having no knobs defined. Reducing the request throughput to the Memcache service leads to corresponding reductions in resource consumption for the service *and its dependent services*.

Figure 12 shows an example of resource savings for TAO (a social graph caching service [7]) when Defcon is enabled across the three products under test. In addition to showing another service that achieves savings despite not having *any* knobs defined, it also shows an example of how resource savings can remain relatively stable over long periods of time (hours).

**Figure 12:** Another example of transitive resource savings on a social graph (TAO) service that has no knobs defined. We find resource savings from Defcon to be stable over long periods of time (e.g., hours).

Figure 13 adds annotations to the results for TAO, showing the distinct phases involved in a large-scale test. As we can see, products enable knobs of decreasing level until reaching Level 1, remain at Level 1 for a small period of time, and then return to a disabled state. In this case, we can clearly see in Phase III, IV, and V that most of the demand for the TAO service comes from the Async product. We record insights

such as these as metadata for knobs and use the insights to inform decisions during real-world site events.

**Figure 13:** A detailed timeline of events during a typical multi-product Defcon test. This figure illustrates the complexity of testing Defcon at-scale in a production environment.

Interestingly, we also find that enabling Defcon across multiple products can achieve more resource savings for a product than enabling Defcon for that product alone. This occurs because some front-ends (such as the Facebook product) also serve RPC requests from other products (such as the Instagram product) so enabling Defcon on the other products reduces the resource consumption of the Facebook product. Figure 14 shows such an interaction for the Facebook product during a test when Defcon is applied to the asynchronous compute product, Async. We can see that even after Facebook knobs are disabled (around 17:50 UTC), Facebook still sees reduced resource consumption compared to its baseline due to reduced requests from the Async product.

**Figure 14:** An illustration of the inter-dependent resource savings of knobs: Enabling knobs for the asynchronous compute product, which sends requests to the Facebook product, leads to additive savings compared to enabling knobs for the Facebook product alone.

## 4.5 Outage Simulation Testing

At Meta we also simulate the conditions posed by large-scale outages such as natural disasters by redirecting traffic away from data center regions in order to concentrate more traffic

on the remaining regions, akin to what could happen during a fiber cut, hurricane, or power grid failure [33]. This reduces the available resource supply, effectively simulating load spike events such as New Year’s Eve or World Cup.

In Figure 15 we show the results of running a large-scale test on the Facebook product through the Facebook product’s peak moment of traffic. At the beginning of the test, we sequentially redirect traffic from multiple data center regions (labeled C and A) in order to concentrate enough load on the remaining regions. This operation continued until site operators began to detect a small volume (measured in very low parts per million of requests) of failed requests due to overload, whereupon Defcon was enabled at Level 2.

**Figure 15:** We regularly run tests to test the efficacy of Defcon under large-scale outages. In this test, we start by redirecting product traffic away from two data center regions in order to reduce the amount of server resource supply for the same amount of user demand, thereby increasing the resource utilization of the remainder of the fleet. We then enable Defcon in order to validate resource savings when products are in a highly-loaded state.

Moreover, after enabling Defcon at Level 2, we *continued to redirect traffic* until the second data center region was completely drained of traffic. This example illustrates how Defcon can effectively avert overload conditions that could ultimately lead to fail-slow behavior and wide-spread cascading failures. Tests such as this also provide valuable validation of the measured resource savings in a realistic environment: At-scale, at peak, and using the real production workload.

To illustrate the importance of at-scale testing, in Figure 16, we show an example of measured resource savings on a separate day, during a similar time, using the same knobs as the previous example. We can see that while the mean resource savings during this test is similar to the real-world increased load simulation, it is not exactly the same. A major reason for this is cold cache effects from traffic being redirected among data centers, a realistic concern during real-world outages.

To illustrate the generality of our approach, Figures 17–20 show similar results across four different products – Feed, TAO, Memcache, and Graph Search – during a different two-data-center region drain test at peak levels of traffic with L2 knobs enabled. The y-axes of these figures have been normalized to compare the relative sensitivity to knobs across different products, with the measured savings corresponding

**Figure 16:** We find that resource savings (measured in MIPS on the y-axis) are *load-dependent*. In this example, having warm caches *increases* the amount of resource savings (corresponding to lower values of MIPS) compared to when outages are simulated (cf. Figure 15).

to 3.2% for Feed, 2% for TAO, 8% for Memcache, and 6% for Graph Search.

Notice that while different products achieve different levels of savings (these are reflections of their own target savings for L2 knobs), their response to enabling Defcon can vary due to caching effects and workload pattern changes in response to enabling knobs. The figures also illustrate how different products can customize their demand metrics used to measure and track their target Defcon savings (e.g., by using CPU Cycles or Power consumption).

**Figure 17:** Results for L2 knobs enabled during a two–data-center region drain test for the Feed product.

## 4.6 Real-World Large-Scale Outage

Since Defcon is an emergency tool used during large-scale outages, we must ensure that unknown unknowns are minimized. Based on the different degradation tests that we execute for products, and by measuring the impact on users and downstream services, we work closely with Site Reliability Engineers (SREs) to come up with degradation policies and guidelines for the scenarios where Defcon can help. During a real-world outage, SREs work with a lead emergency responder, the *Incident Manager (IM)*, who decides on which options from the Degradation Policy to pursue to mitigate an outage.

**Figure 18:** Results for L2 knobs enabled during a two–data-center region drain test for the TAO product.

**Figure 20:** Results for L2 knobs enabled during a two–data-center region drain test for the Graph Search product.

**Figure 19:** Results for L2 knobs enabled during a two–data-center region drain test for the Memcache product.

Figure 1 from Section 1, showed one such outage where the IM applied the principles listed in the Degradation Policy to avert a site-wide overload event and outage (please refer to Section 1 for an detailed explanation). During this event, the IM made the call to first engage L3 knobs for the product before eventually engaging L2 knobs. The fact that different levels of knobs – with different amounts of impact – existed, provided the IM with a spectrum of options to pursue in order to eventually arrive at the right degradation trade-off in real-time.

To ensure that we could mitigate this real-world event smoothly, we needed to ensure that the degradation policy discussed in Section 3.5 has been practiced by SREs and the IM. To make sure all the responding members are trained on using the policy, we frequently execute mock fire drills where we come up with potential scenarios, and role play the necessary steps to mitigate the risks. We have found such testing to be largely beneficial in ensuring emergency responders are prepared when disasters strike.

## 5 Lessons Learned

Over the past several years of using Defcon, we have learned several key lessons to consider for graceful feature degradation:

### 1. Understand business goals and customer perception to determine what to degrade.

Prior to implementing knobs, product engineers first decide on which features to degrade. Core product functionality must remain intact, but among the non-core features, we find that there exists a spectrum of resource savings compared to user impact. For this reason, product designers perform A/B tests (cf. Table 2) and make a decision about which knobs to keep and which to pass on. While this process requires human interaction, the Knob Definition Framework and Knob Testing Framework allow developers to quickly explore the knob definition space in order to determine the set of knobs that provide the most resource savings for the least user impact.

### 2. Leveraging graceful degradation during emergencies requires regular testing and an easy-to-consume understanding of the business and customer impact.

To provide an easy-to-consume understanding for emergency responders to use in the heat of the moment, product engineers provide a high-level *functional* summary of what is affected at each Defcon level. Using this summary, site incident managers can quickly determine whether enabling knobs for a product at a given level is an adequate response. Additionally, this summary benefits the public relations and communications team, who may need to respond to inquiries from customers or the media about product feature changes.

### 3. Degradation systems require high and regular commitment from product teams.

To motivate product engineers to work on Defcon knobs, we built mechanisms to provide recognition for investing in this technique for product reliability. We organize monthly Defcon meetings per product to showcase each team’s work to their organizational leader (e.g., a vice president). We also

leverage the concept of Defcon champions. A Defcon champion is someone who is passionate about reliability that can drive Defcon throughout the organization. Defcon champions identify and recruit people in their organization to work on Defcon.

#### **4. Knobs, once built, need to be regularly maintained.**

Implementing and maintaining knobs requires engineering effort. Identifying candidate features involves coordination with product developers to run experiments to understand the capacity savings and user impact of knobs. Developers, however, have provided feedback that controlling and testing knobs using a standardized framework has helped them to rapidly develop and deploy knobs. While automated systems measure and report knob behavior, regressions in capacity savings and user impact require manual investigation. We intend to explore automating this area of knob maintenance in future work.

#### **5. Low dependence and high availability actuation.**

To ensure that Defcon is ready to be deployed during disasters, we iterated on improving our operations and operational availability. As an example, we developed a CLI with minimal dependencies on other systems in our infrastructure to make sure that Defcon is ready to be enabled during partial failures and disasters. Having a low dependence and highly available mechanism for knob actuation is critical for facing real-world disasters.

#### **6. Developer experience and efficiency are key.**

Before Defcon existed, there were scattered independent efforts to try to achieve similar goals. By unifying these disparate efforts and providing tools to support teams in a structured manner, we were able to increase the coverage of Defcon and simplify knob maintenance. Since Defcon is built on top of existing tools at Meta, such as Configurator [32], developers do not need to learn new technologies to implement new Defcon knobs.

Safety is handled by ensuring that features are isolated at the RPC layer (a design practice at Meta) and thus knobs typically encapsulate control flow between RPC callers and callees. While fine-grained degradation within a binary serving an RPC request is possible, safety and consistency must be validated by product developers during initial knob testing. We note that such validation is similar to what developers must do when routinely modifying binary control flow (i.e., not for the purpose of Defcon knobs) – a common practice at Meta. To aid developers in knob definition, we provide guidance on how to properly implement and maintain knobs, as well as provide developers with a Knob Testing Framework to measure Defcon savings and track regressions.

The main challenge for developers in maintaining Defcon knobs is capacity savings regression tracking. Systems at Meta are constantly evolving, so the impact of existing knobs can drift over time. Because of this, we make sure that each

team tests Defcon savings at a limited scale in production at least once every three months (an interval chosen to balance knob impact with the need to understand behavior changes) using the Knob Testing Framework. We are actively exploring ways to test knobs more frequently at lower impact.

## **6 Conclusion**

We presented Defcon, a system for graceful feature degradation to prevent overload in large-scale Internet services. We hope that by characterizing the overload problem, the corresponding solution space, and our approach to graceful feature degradation, we will spark discussion within the research community about how best to tolerate overload-induced system behavior and advance reliable and available distributed system design.

## Abstract

Traditional systems for allocating finite cluster resources among competing jobs have either aimed at providing fairness, relied on users to specify their resource requirements, or have estimated these requirements via surrogate metrics (e.g. CPU utilization). These approaches do not account for a job’s real world performance (e.g. P95 latency). Existing performance-aware systems use offline profiled data and/or are designed for specific allocation objectives. In this work, we argue that resource allocation systems should directly account for real-world performance and the varied allocation objectives of users. In this pursuit, we build Cilantro.

At the core of Cilantro is an online learning mechanism which forms feedback loops with the jobs to estimate the resource to performance mappings and load shifts. This relieves users from the onerous task of job profiling and collects reliable real-time feedback. This is then used to achieve a variety of user-specified scheduling objectives. Cilantro handles the uncertainty in the learned models by adapting the underlying policy to work with confidence bounds. We demonstrate this in two settings. First, in a multi-tenant 1000 CPU cluster with 20 independent jobs, three of Cilantro’s policies outperform 9 other baselines on three different performance-aware scheduling objectives, improving user utilities by up to  $1.2 - 3.7\times$  and performs comparably to oracular policies. Second, in a microservices setting, where 160 CPUs must be distributed between 19 inter-dependent microservices, Cilantro outperforms 3 other baselines, reducing the end-to-end P99 latency to  $\times 0.57$  the next best baseline.

## 1 Introduction

The goal of cluster resource managers is to allocate a finite amount of scarce resources to competing jobs. When doing so, we should ensure that the allocations fulfill the users’ and the organization’s overall goals. Traditionally, resource allocation policies have aimed to provide fairness [16, 24], maximize resource utilization [61], maximize the amount of

Figure 1: Two users, U1 and U2, serving TPC-DS benchmark queries with different resource-throughput mappings and performance goals (SLO). A user’s demand is the amount of CPUs needed for her SLO.

work done [24], or minimize queue lengths [47, 66]. However, these policies miss, or at best are imperfect proxies for what matters most to the users: the performance of their jobs in terms of real-world metrics that impact business (e.g. P99 latency or throughput for a serving job). Barring some recent exceptions [10, 18, 35, 64], resource allocation systems have traditionally focused on the resources requested by a job rather than the job’s real-world performance from using those resources (henceforth, simply *performance*).

To illustrate the pitfalls of performance-oblivious scheduling, consider an example where two users, U1 and U2, are sharing a cluster of 100 CPUs. They are each serving different sets of TPC-DS [43] queries and care about their throughput: U1’s service level objective (SLO) is 120 queries per second (QPS), while the U2’s SLO is 62 QPS. If the goal is to satisfy all user’s SLOs, how should CPUs be allocated? If it were known that the resource-to-throughput curves of the two users’ jobs were as shown in Figure 1, a scheduler can allocate 40 CPUs to the first job and 60 to the second. However, in practice, this mapping is usually not available and performance-oblivious scheduler will likely be suboptimal. For instance, a CPU-based fair allocation algorithm would allocate 50 CPUs to each user, which would result in U2 getting just 59 QPS, thus missing its SLO.

\* Co-primary authors.

Despite extensive theoretical work [16, 24, 28, 37, 38], performance-aware scheduling has remained challenging since the *resource-to-performance mappings* are usually unavailable in practice. To obtain these mappings, past work [15, 58, 64] profile their workloads before execution. Such profiling has three limitations. First, offline profiled resource-to-performance mappings may not reliably reflect a job’s performance in a production environment, as it may not capture the interference from other jobs [14] and the server’s performance variability [19]. Second, jobs’ resource requirements change with time due to varying load (e.g., arrival rate of external queries) and profiling typically cannot account for these changes. Third, such profiling is burdensome for users and expensive for organizations as it requires a large pool of resources to exhaustively profile a wide range of resource allocations. This informs the *first requirement* for this work: obtain the resource-to-performance mappings in the production environment where the job will be run.

Even if the resource-to-performance mappings are known, the choice of scheduling policy depends on the objective of the end-users (e.g. organization, developers). For instance, suppose in Figure 1, we wished to maximize the total throughput of the cluster, instead of trying to satisfy each user’s SLOs. In this case, we would allocate ~64 CPUs to U1 and ~36 to U2 for a total throughput of ~212 QPS. As more realistic examples, in multi-tenant clusters, we may wish to use policies which balance between performance and fairness [16, 24, 38]. In contrast, when we provision resources to different microservices of the same application, we are more interested in some end-to-end performance objective, such as application latency, and may wish to allocate more resources to critical microservices which bottleneck performance. These objectives can vary from organization to organization and optimizing for such different objectives requires different allocation policies. However, while end users may find it relatively easy to state their objective (e.g., satisfy all SLOs, maximize throughput), it is harder to design a policy to achieve it. This informs our *second requirement*: support a diverse set of user-defined scheduling objectives.

To address these requirements, we introduce Cilantro, a framework for performance-aware allocation of a single fungible resource type (e.g. CPUs, containers) among competing jobs (Figure 2). In Cilantro, end users first declare their desired scheduling objective. To satisfy the first requirement, a pool of performance learners and load forecasters analyzes live feedback from jobs and learns models to estimate resource-performance curves and load shifts for each job. To satisfy the second requirement, Cilantro’s scheduling policies, which are automatically derived based on the users’ objectives, leverage these estimated models to compute allocations for each job. As the learned models become accurate over time, Cilantro is able to eventually achieve the users’ objectives. This obviates the need for an offline model to estimate the required

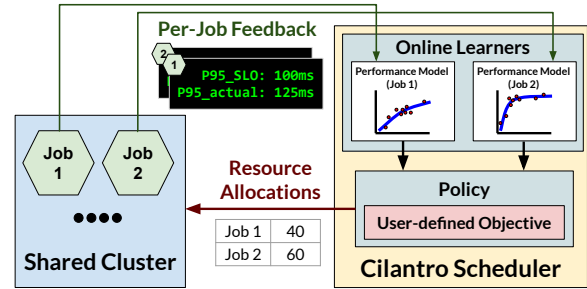

Figure 2: Cilantro overview. Cilantro uses continuous feedback to dynamically learn each job’s resource-to-performance mappings. An uncertainty-aware resource allocation policy, instantiated for the user’s objective, uses these mappings to determine allocations.

resource allocation for a given performance target, and allows Cilantro to optimize for custom objectives, such as various fairness or performance criteria. This is a marked departure from performance-oblivious policies, those based on unreliable proxy metrics such as CPU utilization and queue lengths, and other heuristic-based policies (using either surrogates [51] or performance metrics [10, 18]) which are designed for very specific scheduling objectives. Cilantro seamlessly enables the implementation of performance-aware policies in two settings: (i) multi-tenant resource allocation for independent jobs, and (ii) resource allocation for inter-dependent jobs (microservices) within an application.

Our proposed solution solves two key challenges. First, estimating resource-to-performance mappings online can be notoriously difficult due to highly stochastic nature of real-time production environments, unexpected load shifts, especially in the early stages when there is insufficient data. To operate without accurate estimates, Cilantro informs scheduling policies with confidence intervals of its estimates. Policies are designed to account for this uncertainty when making allocation decisions until the estimates become more accurate. Accounting for this uncertainty helps Cilantro conservatively explore the space of allocations making it robust to environment stochasticity and also to the idiosyncrasies specific to the performance models used.

Second, supporting a diversity of objectives in the same framework is challenging. The monolithic design of end-to-end feedback-driven approaches [34, 49, 64] restricts them only the objective they were originally designed for. Instead, Cilantro achieves generality in supporting custom objectives by decoupling the learning mechanisms from the allocation policy. This decoupling is necessary as it allows us to account for the effect of each job’s performance and load shifts on the objective individually. Moreover, this decoupling has other intangible benefits: it leads to a more transparent design which is easy to debug than monolithic systems which directly optimize for end-to-end performance, and if online job feedback cannot be obtained for a particular job, it is easy to swap the learners with profiled information or other sensible defaults.

We have implemented Cilantro as an open-source extension to the Kubernetes core scheduler, available at <https://github.com/romilbhardwaj/cilantro>. To evaluate Cilantro, first we deploy it on a 1000-CPU multi-tenant cluster which includes a diversity of real-world, latency and throughput-sensitive jobs. On three different allocation objectives, Cilantro’s policies are able to outperform 9 other baselines, and is able to compete with oracular policies which know the resource-to-performance mappings a priori on resource efficiency and fairness. When compared to resource-fair allocation, it is able to increase the performance of 1/3 of users in the clusters by  $1.2 - 3.7\times$ . Second, we evaluate Cilantro on a 160 CPU cluster where we wish to allocate CPUs to constituent microservices of an application. Here, Cilantro is able to minimize the end-to-end P99 latency of the application to  $\times 0.18$  the latency of a resource-fair scheduler and to  $\times 0.57$  of the next-best performance-aware baseline.

## 2 Background & Related Work

In this section, we compare Cilantro with prior work. Table 1 summarizes the key differences of Cilantro against other resource allocation systems and methods.

**Performance oblivious methods:** The simplest, yet popular approach to allocating finite resources among competing jobs, is to adopt a *resource fair* policy, which simply divides the resource equally (or proportional to weights) [2, 30, 32, 42]. As this does not account for jobs’ resource requirements, it is inadequate in all but the most trivial settings.

Several scheduling frameworks, such as Kubernetes [9], Mesos [29] and YARN [57], relies on users to submit their own resource demand. To execute resource allocations from policies, Kubernetes and YARN use resource reservations while Mesos negotiates through resource offers. This requires users to estimate their jobs’ resource needs, which can be difficult. They focus on one-way resource allocations and do not provide any mechanisms for the policy to get feedback on application performance. However, recognizing that end users may have varied scheduling objectives, these frameworks support and implement multiple policies.

**Methods based on proxy metrics:** The most common approach to account for resource requirements relies on proxy metrics (e.g. CPU utilization, work-queue lengths). Quasar [15] offline profiles jobs’ proxy metrics, and has a fixed operator-centric policy to maximize cluster utilization. Paragon [14] accounts for resource heterogeneity and inter-job interference to achieve performance guarantees. AGILE [46] models the resource pressure, and uses demand prediction to minimize SLO violations. The above works do not directly account for users’ performance goals and optimize for singular objectives.

**Methods which use offline profiling:** Some work has explored directly incorporating job performance via profiled his-

torical data. Morpheus [33] aims to mitigate performance unpredictability by defining SLOs and satisfying their resource demands by using models based on historical data. Ernest [58] provides methods for estimating performance curves using limited amount of data, but does not study using these estimates for resource allocation under scarcity. Sinan [64] partly uses profiled information for auto-scaling in a cloud environment. Quincy’s [30] min-cost flow formulation aims at providing fairness, but relies on offline estimates of data movement costs. For reasons explained in §1, offline profiling can be problematic and it is desirable to rely on real-time feedback to determine resource allocations.

**Methods which use online feedback:** Among related work, some feedback-driven systems account for performance metrics and SLOs in resource allocation. Jockey [18] focuses on meeting latency SLOs for a single job by modeling internal job dependencies to dynamically re-provision resources. Henge [35] defines new utility functions for stream processing workloads and aims to maximize a singular objective – the sum of utility of all jobs. [48] uses application hints in for prefetching disk blocks in the OS kernel. Gavel [44] is a scheduler for ML training workloads in heterogeneous environments with varying objectives. Since Gavel is focused on ML training, it’s policies are designed for throughput and a greedy optimizer computes the optimal allocation for each round. On the other hand, Cilantro supports any metric specified by the user and employs online learning to eventually converge on the optimal allocation. Finally, in a video streaming application, Minerva [45] studies methods for resource allocation so that all end users have the same quality of service. The highly customized policies used in the above works, while adequate to the allocation objectives set out by the authors, are not applicable for diverse cluster objectives which is our goal here.

**Variable resource amounts:** In other related work, PARTIES [10] allocates resources to jobs within the same server while always satisfying SLOs. If the SLOs of all jobs cannot be met, it evicts one of them to a different server; thus, it does not apply to our setting where there is a fixed amount of resources and eviction is not possible. Indeed, in §7 we show that a straightforward adaptation of PARTIES does not work as well. Sinan [64], DS2 [34], Autopilot [51] and FIRM [49] consider performance-aware resource allocation using online feedback when there is elasticity in resource availability, e.g. the cloud. Because these works can scale up to more resources than originally provisioned, they are not directly comparable to Cilantro which operates in a fixed cluster setting. While the cloud is an emerging use case, traditional fixed resource cluster management remains pertinent for privacy and cost reasons. Moreover, the above work focus on specific goals and are not designed to handle general allocation objectives. As an example, FIRM [49] focuses on autoscaling resources for single applications deployed as microservices to

minimize end-to-end SLO violations, Cilantro operates differently, reallocating a fixed number of resources according to user-specified objectives, which can include fairness considerations. Additionally, FIRM uses Reinforcement Learning with anomaly injection, in contrast to Cilantro, which focuses on resource-allocation under uncertainty and is agnostic to the learning method used.

### 3 Cilantro Architecture

Cilantro is a performance-aware scheduling framework that can optimize for various scheduling objectives without requiring any a priori knowledge of the resource-performance mapping of the workloads. The design of Cilantro is informed by the following two key insights.

**[I1] Offline profiling of resource-performance is insufficient.** Performance-aware policies rely on accurate estimates of resource-to-performance mappings and load shifts. Offline profiling of these resource-performance mappings can be inaccurate due to unpredictability in server and application performance [19] and changing traffic patterns [50]. Adapting to these changes necessitates continuously learning and predicting these unknowns in an online manner.

**[I2] Decoupling learning mechanisms and policies enables diverse scheduling objectives.** As different scheduling policies optimize different criteria, it may be challenging for a scheduling framework to generally support different policy types. Prior work on feedback-driven resource allocation [34, 49, 64] uses an end-to-end model for allocating resources for a fixed objective, such as total utility or cost. Optimizing for a different objective in these systems may require a complete redesign of the system and policy, or at the very least an expensive retraining of their models. Decoupling learning mechanisms from policies allows the model to be learned once and applied to multiple allocation objectives. This decoupling also increases transparency in the allocation decisions made by the scheduler and facilitates debugging.

We leverage these learnings to build Cilantro (Figure 3). Cilantro is composed of two key components: the central-

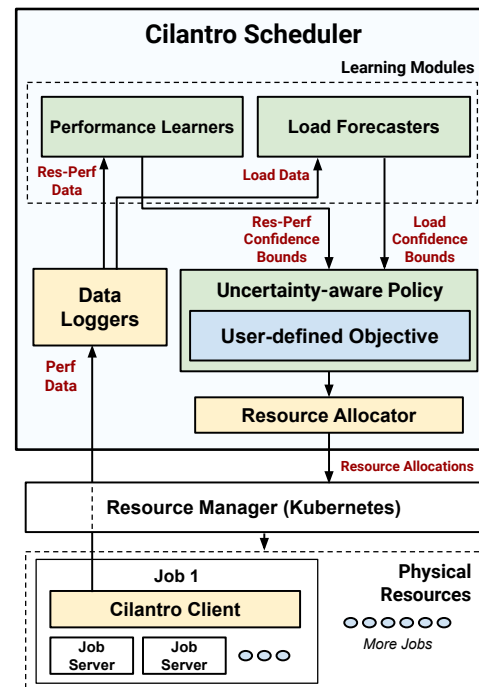

Figure 3: The Cilantro scheduler and client architecture. The scheduler generates resource allocations for jobs and the clients collect performance feedback to report to the scheduler.

ized Cilantro scheduler, which is responsible for generating resource allocations, and the Cilantro clients—lightweight sidecars co-located with each job—which fetch a job’s performance metrics and send them to the Cilantro scheduler. Informed by [I1], the Cilantro scheduler employs online learning to create increasingly accurate models of job performance and load. Guided by [I2], the policy optimizes a user-defined objective by polling these models for a resource-performance estimates to produce a resource allocation.

**Assumptions & terminology.** In this work, we will focus on jobs which can scale elastically with the number of resources with corresponding gains in performance. Examples of such workloads include stateless or stateful distributed

services (e.g., prediction serving [13], memcached [21], Cassandra [40]), distributed computation (ML training, MPI jobs) and distributed frameworks (e.g. Hadoop [52], Spark [62]). Some of these can be viewed as a collection of several tasks whose job size may vary with time, such as in serving jobs. Each task may refer to a query whose arrival rate may change with time. For jobs with such varying query rates, we will refer to the instantaneous rate of external query arrival as the *load* (measured in queries per second (QPS)). Finally, we assume there is a *fixed amount* of a *single, fungible* resource type that must be allocated.

**Cilantro scheduler:** The Cilantro scheduler is designed as a centralized asynchronous event driven system. Event sources include timers, performance updates received from the Cilantro clients, and cluster state updates from the underlying resource manager. Below, we describe the scheduler’s modules. Specific implementation details are available in §6.

**1. Data loggers.** Application metrics pushed from Cilantro clients are stored in memory-backed tables. They relay these metrics to the performance learners and load forecasters.

**2. Performance learner.** The performance learner learns a job’s performance as a function of the resource allocation and the load using an associated model. It periodically polls the data logger for new data and updates the model. The learner’s update frequency is constrained only by the velocity at which the model can be updated. One instance of a performance learner is maintained per application. A performance learner provides `get-perf-ucb` and `get-perf-lcb` interfaces for a policy, which return upper and lower confidence bounds for the performance as a function of the resources and load.

**3. Load forecasters.** In many real-world deployments, the job size could vary with time depending on the real-time traffic, which should be accounted for when allocating resources. The goal of the load forecaster is to estimate this load for the duration of a future allocation based on past observed loads via an associated time series model. It offers `get-load-ucb` interface for a policy which returns an upper confidence bound for the future load. Load forecasters are periodically updated by polling from the data loggers.

**4. Uncertainty-aware Policy.** Policies compute allocations in order to optimize for a user-specified scheduling objective. In an online setting, using direct estimates of the performance may fail as it does not reflect the uncertainty in the model. Therefore, Cilantro’s policies leverage confidence intervals of these estimates to account for this uncertainty in a principled manner when making allocation decisions (§4).

**5. Resource allocator.** The resource allocator is responsible for executing the resource allocations by interfacing with the underlying cluster manager. This module is driven via an allocation expiry event, upon which it invokes the policy’s `compute-alloc` method and allocates the resources. Allocation

expiry events are raised based on a timeout, resulting in a new round of allocations. In practice, the duration of an allocation round is limited by the agility of the environment. Since scaling jobs requires time, changing resource allocations too frequently can result in job thrashing (having to scale down before it has a chance to utilize new resources).

**Cilantro client:** The Cilantro client is a lightweight side-car container whose purpose is to poll the job to get its current performance, process it, and publish it to the scheduler’s data loggers. The primary task for the client is to extract metrics from their assigned job. Many systems expose REST endpoints to query system performance [3, 4], but often the applications also use monitoring tools such as Prometheus or Grafana. Depending on the job, the performance metric extraction logic is specified by the users. In §5, we describe built-in fallback options if job metrics are not available.

## 4 Policies

We now describe our policies for performance-aware resource allocation in two settings: multi-tenant resource allocation in a fixed cluster (§4.1), and allocating finite resources to constituent microservices of an application (§4.2).

**Set up & notation:** We will denote the number of jobs (or microservices) by  $n$ , the amount of resources by  $R$ , and an allocation by  $a = (a_1, \dots, a_n)$ , where  $a_j$  is the amount of resources allocated to job (or microservice)  $j$ . A scheduler should allocate these resources so that  $\sum_{j=1}^n a_j \leq R$ .

### 4.1 Resource allocation in shared clusters

Cilantro supports two classes of performance-aware allocation objectives in the multi-tenant setting: welfare-based, and demand-based. Our primary contributions are in §4.1.2 where we derive uncertainty-aware online variants of these policy classes. But first, we will review some common examples of such objectives in §4.1.1. For what follows, we will need to define the *performance*, *demand*, and *utility* of a job.

*Performance:* The *resource/load-to-performance mapping* (henceforth simply performance or performance mapping)  $p_j$  of a user’s job  $j$  refers to some raw metric of interest, which, say, can be obtained from a monitoring tool. We write the performance  $p_j(a_j, \ell_j)$  as a function of the resources received  $a_j$  and the load  $\ell_j$ . As we are allocating a single resource type,  $a_j$  is a single number, as is  $\ell_j$ . For example, in a serving job with a P95, 100 ms latency SLO, the performance may be the fraction of queries completed in under 100 ms, and the load may refer to the external arrival rate of queries.

*Demand:* If a job has a well-defined SLO, we define the *demand*  $d_j$  to be the minimum amount of resources needed to achieve this SLO. The demand depends on the job’s performance curve  $p_j$ , SLO, and load  $\ell_j$ .

*Utility:* The *utility*  $u_j$  of a job is the *practical value* derived

Figure 4: Three candidates for SLO-based utility functions. The left-most figure shows a job’s performance  $p_j$  as a function of the resources (for fixed load). In (a), the utility scales linearly with performance until the SLO, i.e.  $u'_j(p) \propto \min(p, \text{SLO})$ , whereas in (b) it scales quadratically  $u'_j(p) \propto \min(p, \text{SLO})^2$ , and in (c) it scales with the square-root  $u'_j(p) \propto \min(p, \text{SLO})^{1/2}$ . Here, (b) captures settings where even small SLO violations are critical while (c) captures settings where small SLO violations are not very significant.

due to its performance. Generally,  $u_j$  is a non-decreasing function of the performance and we can write  $u_j(a_j, \ell_j) = u'_j(p_j(a_j, \ell_j))$  for some non-decreasing function  $u'_j$ .

**Examples of utilities.** The simplest option is to set the utility to be equal to the performance  $u_j = p_j$ , i.e.,  $u'_j$  is the identity. However, we may also choose a utility which is more applicable when there are well-defined SLOs. Fig. 4 illustrates three candidates for  $u'_j$ : the maximum utility for any job is set to 1, which is achieved for any performance greater than the SLO; for performances below the SLO, we may set the utility to (a) decrease proportionally with SLO violation, (b) decrease sharply in settings where small SLO violations are critical (e.g., with external customers where SLO violations can lead to penalties [1] and a loss of credibility), (c) decrease gradually when small SLO violations are not critical (e.g., soft SLOs internal to an organization). Such utility forms which are ‘clipped’ at the SLO provide a simple way to compare jobs with heterogeneous performance metrics and SLOs, such as latency and throughput. Prior work have also used similar forms of utility [23, 35, 60]. For these reasons, our experiments also use these forms, although we emphasize that Cilantro can handle any utility form which increases with performance.

#### 4.1.1 Review of multi-tenant allocation when performance mappings are known

We will first review two classes of multi-tenant allocation objectives supported in Cilantro—welfare-based and demand-based—and three examples of such objectives. In §4.1.2, we will develop online learning policies that achieve the same objectives when performance mappings are unknown.

**Welfare-based objectives:** These policies aim to maximize a given cluster-wide *welfare* function  $W$ , which is a function of the utility of each job, i.e.,  $W = W(u_1, \dots, u_n)$ . Below, we describe two common welfare-based objectives.

(i) *Social welfare (a.k.a. Kelly mechanism [38]):* We choose the allocation  $a$  which maximizes the social welfare (the average utility), i.e.  $a = \text{argmax } W_S$ , where,

$$W_S = \frac{1}{n} \sum_{j=1}^n u_j(a_j, \ell_j) = \frac{1}{n} \sum_{j=1}^n u'_j(p_j(a_j, \ell_j)). \quad (1)$$

As we show in Figure 5, this notion of fairness allocates

more resources to “high-performing” users, i.e those who can generate large utility with a small amount of resources.

(ii) *Egalitarian welfare:* Here, we choose the allocation  $a$  which maximizes the egalitarian welfare (minimum of all utilities), i.e.  $a = \text{argmax } W_E$ , where

$$W_E = \min_{j \in \{1, \dots, n\}} u_j(a_j, \ell_j) = \min_{j \in \{1, \dots, n\}} u'_j(p_j(a_j, \ell_j)). \quad (2)$$

This allocates more resources to “struggling” jobs which need more resources to achieve large utility (Figure 5).

**Demand-based policies:** These policies apply when jobs have a well-defined SLO and it is possible to define its demand  $d_j$ . Such policies will compute allocations based on the demands of all jobs. This requires knowledge of the demand, which in turn depends on the performance mapping.

(iii) *No justified complaints (NJC) fairness [16, 17, 28]:* One class of demand-based policies which adopt the NJC fairness paradigm guarantee an equal share of  $R/n$  for each job. If the job’s demand is larger than  $R/n$ , it is allocated at least (but possibly more than) this share. But, if the job’s demand is smaller, the excess resources may be allocated to other jobs to improve overall resource usage. A user can have no justified complaints since they are either guaranteed to satisfy their SLOs or their utility will be larger than if they were to have  $R/n$  resources. To quantify this, we define the following metric. The term inside the minimum measures the utility achieved by job  $j$  with allocation  $a_j$  relative to the utility when using its fair share of  $R/n$  resources.

$$F_{\text{NJC}} = \min_{j \in \{1, \dots, n\}} \frac{u_j(a_j, \ell_j)}{u_j(R/n, \ell_j)} = \min_j \frac{u'_j(p_j(a_j, \ell_j))}{u'_j(p_j(R/n, \ell_j))} \quad (3)$$

In contrast to metrics such as the Jain’s index [31],  $F_{\text{NJC}}$  accounts for users’ performance when evaluating fairness. This metric has a maximum value of 1. Below, we describe a demand-based policy [16] which achieves  $F_{\text{NJC}} = 1$  while also using the resources efficiently as also shown in Figure 5.

*An NJC policy:* This policy proceeds iteratively. In the first round, it sets each user’s “share” to be  $R/n$ . It allocates  $d_j$  to each user  $j$  for whom  $d_j$  is smaller than the share. If  $n'$

Figure 5: Comparison of the three (oracular) fair allocation criteria described in §4.1.1 in a synthetic example with 60 CPUs. *Left*: Utility curves for three jobs. The y axis is the utility and the x-axis is the number of resources. For simplicity, we have ignored the loads and assumed that utilities increase linearly up to the demand. The total demand is 150, whereas only 60 resources are available. *Right*: The allocations and utilities for each job under the three criteria. We have also shown the  $W_S$  (1),  $W_E$  (2), and  $F_{NJC}$  (3) metrics for each policy.

users were allocated  $R'$  resources in the first round, in the second round it sets each user's share to be  $(R - R')/(n - n')$ . It repeats this until all the remaining users' demands are larger than their share. It then divides up the remaining resources equally among the remaining users. While this policy may not maximize any welfare, it achieves Pareto-efficient user utilities. Another advantage of this policy is that it is strategy-proof, i.e. a user does not gain additional utility by falsely stating their demand [24, 28, 36].

This concludes our review of multi-tenant resource allocation objectives when performance mappings are known. We mention that prior work have used these objectives in various contexts with custom utilities. For instance, social welfare has been used in stream processing [35] and wireless networks [55], egalitarian welfare in video streaming [45], and several NJC policies are implemented in Mesos [29].

#### 4.1.2 Online learning policies in Cilantro

We will now develop our online policies. Our policies will operate on lower and upper confidence bounds obtained from the load forecasters and performance learners instead of the direct estimates; doing so accounts for the uncertainty in the learned models and encourages a policy to conservatively explore the space of allocations until the estimates become accurate. Cilantro's policies will proceed sequentially in allocation rounds. On round  $r$ , Cilantro chooses an allocation  $a^{(r)} = (a_1^{(r)}, \dots, a_n^{(r)})$  based on the feedback from all jobs up to now and the specific scheduling objective.

**Welfare-based online policies:** For welfare-based policies, Cilantro adopts the optimism in the face of uncertainty (OFU) principle [7]. OFU stipulates that, to maximize an uncertain function, we should choose actions which maximize an upper confidence bound (UCB) on the function. Both theoretically and empirically, OFU is known to outperform other strategies which use direct estimates or those which are pessimistic (i.e. maximize lower confidence bound). An in-depth exploration of OFU is beyond the scope of this work, but we refer the reader to relevant literature (e.g. [6, 8, 25, 53]).

While OFU is a well established design paradigm, most OFU policies are designed for end-to-end systems which output

a single reward signal. Adapting OFU for general welfare-based policies requires studying how the uncertainty in the performance and load translate to a UCB  $\hat{W}$  on the welfare  $W$  which we wish to maximize. Since  $W$  is non-decreasing in the utilities  $u_j$ , we can obtain a UCB for  $W$  by plugging in UCBs  $\hat{u}_j$  for the utility  $u_j$ , i.e.  $\hat{W} = W(\hat{u}_1, \dots, \hat{u}_n)$ . Similarly, since  $u_j$  is non-decreasing in the performance we can obtain a UCB by plugging in a UCB  $\hat{p}_j$  for  $p_j$ , i.e.  $\hat{u}_j = u'_j(\hat{p}_j)$ . This leads to the following choice of allocation on round  $r$ .

$$a^{(r)} = \operatorname{argmax}_{a \in \mathcal{A}^{(r)}} W \left( u'_1(p_1(a_1, \hat{\ell}_1)), \dots, u'_n(p_n(a_n, \hat{\ell}_n)) \right) \quad (4)$$

Above, since the exact load cannot be known, we conservatively over-estimate it via a UCB  $\hat{\ell}_j$  on the load. Here,  $\mathcal{A}^{(r)}$  is the allocation space on round  $r$  which is defined by two constraints: first, the total allocation cannot be larger than  $R$ , i.e.  $\sum_j a_j \leq R$ ; second, the current allocation cannot deviate too much from the previous allocation, i.e.  $a_j^{(r-1)} - B \leq a_j \leq a_j^{(r-1)} + B$  for all  $j$ , where  $B$  is a parameter to be specified. We impose the second constraint since large changes to allocations can have unpredictable effects on a job's performance; moreover, they take a long time to actuate, resulting in unreliable feedback while resources are being scaled up/down.

To optimize (4), one can use any off-the-shelf optimizer such as evolutionary algorithms, hill climbing, or integer programming which can handle the linear constraints for  $\mathcal{A}^{(r)}$ . In our implementation, we used an evolutionary algorithm (details in the appendix). Finally, we describe instantiations of this principle for the two welfare-based policies we saw in §4.1.1.

(i) Cilantro-SW: To emulate the social welfare policy in §4.1.1, on round  $r$ , we use the UCB for  $\hat{\ell}$  for load and  $\hat{p}$  for performance. Thus, we choose an allocation

$$a^{(r)} = \operatorname{argmax}_{(a_1, \dots, a_n) \in \mathcal{A}^{(r)}} \sum_{j=1}^n u'_j(\hat{p}_j(a_j, \hat{\ell}_j)).$$

(ii) Cilantro-EW: To emulate the egalitarian welfare policy in §4.1.1, on round  $r$ , we choose an allocation

$$a^{(r)} = \operatorname{argmax}_{(a_1, \dots, a_n) \in \mathcal{A}^{(r)}} \min_{j \in \{1, \dots, n\}} u'_j(\hat{p}_j(a_j, \hat{\ell}_j)),$$

Figure 6: Illustration of Cilantro’s uncertainty-aware demand-based policies. We first obtain a UCB  $\hat{\ell}_j$  from the load forecaster, which ensures that we have a conservative estimate on the job’s load. In the figure, the  $x$  axis is the amount of resources  $a_j$  that could be allocated to job  $j$ . We show the SLO (pink), the slice of the unknown performance curve (blue) when the load is  $\hat{\ell}_j$ , and the confidence region obtained from past data (green). The LCB  $\check{p}_j$  and UCB  $\hat{p}_j$  on  $p_j(a, \hat{\ell}_j)$  are given by the lower and upper boundaries of the confidence region (solid green lines). A confidence interval for the demand (orange) can be obtained by the region where  $\hat{p}_j, \check{p}_j$  intersect the SLO line. To obtain a recommendation, we compute a UCB  $\tilde{d}_j^{(r)}$  on the demand (where SLO intersects  $\check{p}_j$ ) and  $\bar{d}_j^{(r)}$  via equation (5).

**Demand-based online policies:** For demand-based policies, on round  $r$ , we will use the confidence intervals from the performance learners and load forecasters to obtain conservative recommendations  $d_j^{(r)}$  for job  $j$ ’s demand. Then, we compute the allocations  $a^{(r)}$  for this round by invoking the same demand-based policy with the recommended demands  $\{d_1^{(r)}, \dots, d_n^{(r)}\}$  instead of the true demands.

Our method for obtaining demand recommendations is based on [36]. To describe this in more detail, observe that for demand-based policies it is sufficient to accurately estimate the demand well, i.e. it is not necessary to learn the entire performance mapping well. We have illustrated our strategy for obtaining the demand recommendation in Figure 6. First, we will denote by  $\tilde{d}_j^{(r)}$ , the UCB for the demand obtained as shown in Figure 6. As a conservative choice for this demand, we may wish to choose  $\bar{d}_j^{(r)}$  as the recommendation. However, we found that in practice this was overly conservative and the resulting allocations were very slow to adapt to feedback. Therefore, we also wish to use a more aggressive exploration strategy to reduce the uncertainty in our *demand*. We use:

$$\bar{d}_j^{(r)} = \operatorname{argmax}_{a_j} \min(\hat{p}_j(a_j, \hat{\ell}_j) - \text{SLO}, \text{SLO} - \check{p}_j(a_j, \hat{\ell}_j)) \quad (5)$$

To illustrate this rule, consider Figure 6 where  $\min(\hat{p}_j - \text{SLO}, \text{SLO} - \check{p}_j)$  is negative for large allocations when the performance LCB  $\check{p}_j$  is larger than the SLO and for small allocations where the performance UCB  $\hat{p}_j$  is smaller than the SLO. By maximizing (5), we are choosing points inside the confidence interval for the demand where both  $\check{p}_j, \hat{p}_j$  are further away from the SLO; so if job  $j$  were to receive  $\bar{d}_j^{(r)}$

resources, then we are most likely to reduce the demand uncertainty. However, choosing  $\bar{d}_j^{(r)}$  as the recommendation can lead to overly aggressive exploration so our final recommendation  $d_j^{(r)}$  is then obtained via,

$$d_j^{(r)} = \operatorname{clip}(\beta \tilde{d}_j^{(r)} + (1 - \beta) \bar{d}_j^{(r)}, d_j^{(r-1)} - B, d_j^{(r-1)} + B) \quad (6)$$

Here,  $\beta \in (0, 1)$  is a parameter to trade-off between  $\tilde{d}_j^{(r)}$  and  $\bar{d}_j^{(r)}$ . We clip this value between  $d_j^{(r-1)} - B$  and  $d_j^{(r-1)} + B$  to control wide deviations in resource allocations (similar to before). Next, we formally state Cilantro’s instantiation of the demand-based NJC procedure described in §4.1.1.

(iii) **Cilantro-NJC:** Here, we simply compute the recommended demand via (5), and then invoke the NJC procedure described in §4.1.1. In §7.1 we show that Cilantro-NJC retains some of the strategy-proofness properties of NJC.

## 4.2 Microservice resource allocation

Now, we will look another use-case for Cilantro, where we wish to optimize an end-to-end performance metric  $p$  of an application composed of several interdependent microservices (jobs). Examples for  $p$  include the total throughput of the application, the negative P99 latency, or even any combination of the two. Here, the entire fixed set of resources is available to the application and must be allocated between microservices for to maximize  $p$ . There are two main differences in this setting when compared to the multi-tenant setting which introduces new challenges. First, while assuming jobs run by different users are independent is reasonable when we aim to optimize for fairness, this is no longer true now since microservices within an application may have complex dependency graphs (see Figure 12-Left). Second, while an application’s performance is clearly tied to the performance of individual microservices, it is not possible to write it explicitly, as we did for the social or egalitarian welfare.

We overcome these challenges by modeling the end-to-end performance  $p$  as a direct function of the allocation to each microservice and the external load faced by the application. That is, we write  $p(a, \ell)$ , where  $a = (a_1, \dots, a_n)$  is a vector of allocations for each microservice and  $\ell$  is the external load on the application. On allocation round  $r$ , our online learning policy, which adopts the OFU principle, chooses an allocation vector which maximizes an upper confidence bound  $\hat{p}$  on the performance obtained from the performance learners:

$$a^{(r)} = \operatorname{argmax}_{a \in \mathcal{A}^{(r)}} \hat{p}(a, \ell). \quad (7)$$

While this circumvents accounting for individual microservice performance and dependency graphs, we now face the challenge of optimizing for an  $n$ -dimensional allocation with just one feedback signal. In contrast, in the multi-tenant setting we had more feedback (one for each job).

## 5 Discussion

We now present a discussion on Cilantro’s operation under various adversarial conditions that may occur in deployment.

**When online job feedback is unavailable.** Cilantro provides three fallback options when online feedback is not available. First, Cilantro allows a user to use a profiled model (using historical data) instead of online feedback. Second, it allows using proxy metrics from the Kubernetes API instead of real-world performance. In such cases, a user should specify how these proxies are tied to their utility and/or demand. Third, if neither of these is possible, we allow the user to directly submit an estimate for their resource demand which will then be fed to the policy when determining allocations. In such cases, we assume that utility increases linearly up to the demand when computing allocations. We evaluate this fallback option in §7.3. Due to Cilantro’s decoupled design, these fallback options can be effected with simple modifications to a job’s performance learner.

**Learning in unpredictable environments.** Some situations, such as unexpected load spikes for web services or interference between jobs, are fundamentally hard to predict. Cilantro’s uncertainty-aware design provides a degree of resilience against these unpredictable changes, as we show in its robustness to noise in load and resource demand estimates in Section 7.3. However, continued extreme fluctuations in the loads can negatively impact Cilantro’s performance. To avoid hysteresis when reallocating resources, future work can explore averaging loads over dynamically sized windows or including rules to temporarily override Cilantro’s policy.

**Limitations and Future Work.** Cilantro currently supports allocating only a single resource type. In our current implementation, multiple resource types can be bundled into grouping units, such as VM SKUs with a fixed ratio of CPU, Memory and GPUs, which can then be scheduled by Cilantro. However, such bundling is not always possible, especially when different jobs have different resource requirements. Extending Cilantro to handle multiple resource types is possible for welfare-based policies. However, learning and optimization can be challenging since the search space is now very large. Another related limitation is that Cilantro cannot handle non-fungible resource types. Cilantro also does not support online learning versions of market-based resource allocation policies in the multi-tenant setting [39, 56, 63]. These are avenues for future work to improve Cilantro. Cilantro also assumes utilities increase with increasing resources, however some workloads may demonstrate inverse scaling, especially when allocated resources become fragmented across physical nodes. Future work can relax this assumption by applying learning techniques robust to non-convex utility shapes. We also note that Cilantro can support multiple SLO parameters (e.g., for an inference job, ensuring a minimum latency and accuracy) by wrapping them in a single utility function, and

the design of such utility functions can be explored by future work.

## 6 Implementation

The Cilantro scheduler is implemented in 7600 lines of Python code, as a standalone scheduler for Kubernetes. Resource reallocation events are triggered by a timer-based event, which is raised every 2 minutes in our experiments. This window was chosen based on the fact that Kubernetes pods could be created and destroyed in 5-15 seconds. A 2 minute allocation round is long enough for the pod to reach its steady state that performance metrics from the job would be reliable, while at the same time frequent enough to adapt to changes in the load and learned performances.

To execute updated resource allocations received from policies, we horizontally scale the workloads by adding more replicas to their Kubernetes deployment. Newly created pods rely on the Kubernetes service discovery mechanism to connect to the workload’s other servers. The workload is responsible for load balancing queries onto the new servers. Workloads write logs to a volume shared with the sidecar cilantro client. The client parses performance metrics and then publishes them to the scheduler over gRPC. These messages also act as heartbeats to inform liveness to the scheduler.

The frequency of performance feedback depends on the application and the environment. For instance, database serving jobs may report feedback multiple times in a minute, while ML training jobs may do so once every few minutes. To avoid bottlenecks, we use an asynchronous design for Cilantro where each component operates in a push or pull based framework. This allows high frequency components to operate at their maximum rate while allowing slower components, such as learners for low-frequency jobs or cluster managers, to be polled when required.

**Specifying utilities and objectives.** Utilities of jobs are calculated based on the performance metrics collected by the Cilantro clients in the last resource allocation round. To compute the utilities, application developers specify utility as a python method which operates on a list of floating point numbers representing the performance metrics observed in the previous resource allocation round. Similarly, the scheduling objective (e.g., social welfare from §4.1.1) is also defined by the cluster operator as a python method operating on the list of utilities from all jobs.

**Learning models and load forecasters.** For the multi-tenant setting, we used a tree-based binning estimator [8, 27, 36] with Lipschitz constant 10 for each job’s resource-to-performance estimation. This is a simple and computationally efficient estimator, but does not work well in high dimensions. Therefore, for the microservices setting where we have a high dimensional estimation challenge, we use kernel ridge regression [59, 65] with a Matern kernel with smoothness parameter

set to 2.5. In both settings, for the load forecasters, we use an autoregressive moving average (ARMA) model [41] with autoregressive order 1 and moving average order 1. Finally, all confidence bounds were computed at the 90% level, meaning that the probability that the true parameter lies between the upper and lower confidence bounds is 90%. We used the above learning models since they are simple and have few tunable hyperparameters. With Cilantro’s modular design, these can be easily swapped with any other model as long as they provide reliable uncertainty estimates.

**Other policy parameters:** For all our policies, we set the parameter  $B$  which controls the deviation from the previous allocation to 10. For demand-based policies, we set the parameter  $\beta$  which trades off between conservative and aggressive exploration to  $3/4$ . For the welfare-based policies in §4.1 and the microservices use case in §4.2, we use evolutionary algorithms to optimize the UCBs. The exact implementation is described in the appendix.

## 7 Evaluation

We evaluate Cilantro in two settings described in §4.

1. In the multi-tenant setting, Cilantro’s online learning policies, which do not start with any prior data, are competitive with oracular policies which have access to jobs’ resource to performance mappings obtained after several hours of profiling. Moreover, they outperform 9 other baselines on the metrics outlined in §4.1.
2. In the microservices setting, Cilantro is able to support the completely different objective of minimizing end-to-end latency. It outperforms three other baselines and reduces the P99 latency to  $\times 0.57$  that achieved by the next best performance-aware baseline.
3. In our microbenchmarks, we show that Cilantro’s allocation policies are inexpensive, evaluate its fallback options when performance metrics are unavailable, and demonstrate its robustness to errors in feedback and choices for performance learner and forecaster models.

### 7.1 Multi-tenant cluster sharing

We first evaluate Cilantro’s multi-tenant policies (§ 4.1.2) on a 1000 CPU cluster shared by 20 users.

**Workloads.** We use three classes of workloads—database querying, prediction serving and machine learning training—which are used to create multiple jobs. The database querying workload runs TPC-DS [43] queries on replicated instances of sqlite3 database and uses the query latency as the performance metric. The prediction serving workload runs queries on a ML model (random forest regressor) trained on the news popularity dataset [20]. The ML training workload trains a neural network on the naval propulsion [12] dataset using stochastic gradient descent. The database querying and prediction serving workloads use the query latency as the performance

metric while ML training uses batch throughput to measure performance. Resource-performance mappings for informing the oracle baselines in §7.1 were obtained through offline profiling of all workloads. These profiles are visualized in Figure 7. More details of the workloads, including workload-specific parameters are available in the appendix.

**Traces.** Queries to the database and prediction serving workloads are dispatched by a trace-driven workload generator. We use the Twitter API [5] to collect a trace of tweet arrival rates at Twitter’s Asia datacenters; to bring to parity with our cluster, we subsample the arrival rate by a factor of 10. For the ML training workload, we draw queries from an essentially infinite pool to create a constant stream of work.

**Experimental set up.** We use a cluster of 250 AWS m5.xlarge instances (4 vCPUs each). The Cilantro scheduler runs on its own dedicated m5.xlarge instance. We use the above 4 workloads to create 20 jobs as follows: 10 database jobs with P90, P90, P90, P90, P95, P95, P95, P95, P99, P99 latency SLOs of 2s; 3 prediction serving jobs with P90, P90, and P95 latency SLOs of 2s; 7 ML training jobs with throughput SLOs of 400, 400, 450, 450, 500, 500, and 500 QPS. To reflect settings where small SLO violations may be either critical or inconsequential, we discount the utility via one of the three options in Fig. 4 for each job. Detailed information on the users’ jobs is given in the appendix. The estimated total amount of resources based on the median demand was 1637 CPUs; hence, even at full capacity, not all users can satisfy their SLOs. We evaluate all baselines for 6 hours.

#### 7.1.1 Baselines

**Oracular policies.** We implement the three policies in §4.1.1 with oracular access to the true performance mappings (obtained by exhaustively profiling workloads for at least 4 hours). They are Oracle-SW, Oracle-EW, for maximizing social/egalitarian welfare and the Oracle-NJC fairness policy.

**Cilantro policies.** We evaluate Cilantro-SW, Cilantro-EW, and Cilantro-NJC, as described in Sec. 4.1.2.

**Other heuristics.** We implement four methods for fairness and maximizing welfare. While not based directly off specific prior work, such methods are common in the scheduling literature [13,26]. Resource-Fair simply allocates an equal amount of resources to each job. EvoAlg-SW and EvoAlg-EW are evolutionary algorithms for social and egalitarian welfare; the same procedure used for Cilantro’s welfare policies, but now operating directly on the performance metrics. Greedy-EW starts by allocating resources equally; on each round, it evaluates job utilities in the previous round and takes away one CPU each from the top half of the users who had high utility and allocates it to the bottom half.

**Baselines from prior work.** We adapt five feedback-driven methods from prior work - Ernest [58], Quasar [15], Minerva [45], Parties [10] and MIAD (Multiplicative-

Figure 7: Performance vs resource-allocation-per-unit-load obtained after profiling the database querying, prediction serving and ML training workloads. The blue curve is the average performance value and the shaded region is the  $2\sigma$  confidence interval. For the latency-based workloads (DB-0, DB-1, and prediction serving), we show the number of resources per unit load (arrival QPS) on the  $x$ -axis and the fraction of queries completed under 2s on the  $y$ -axis. For the ML training workload, we show the number of resources on the  $x$  axis the amount of data processed per second on the  $y$ -axis. To obtain accurate estimates, we sampled low resources allocations more densely.

Increase/Additive-Decrease) [11]. In particular, we note that applying the Parties notion of migration in our setting would imply moving the job to a different cluster or increasing the size of the cluster, both of which are beyond scope for this fixed cluster setting. Details on the specific adaptations are available in the appendix.

### 7.1.2 Results & Discussion

**Evaluation on performance-aware fairness metrics.** We first compare all 15 baselines on the social welfare (1), egalitarian welfare (2), and the NJC fairness criteria (3). Fig. 8 illustrates the results by plotting the time-averaged NJC fairness vs the two welfare criteria. Table 2 (in the appendix) tabulates these values explicitly with error bars. While the oracular methods perform best on their respective metrics, we find that the online learning policies in Cilantro come close to matching them. Resource-Fair achieves a perfect NJC score by definition, but performs poorly on social and egalitarian welfare as it is performance oblivious.

We found that Greedy-EW, Parties, and MIAD were sensitive to the amount by which we changed the allocations based on feedback; when tuning them, we found that they were either too slow or too aggressive when responding to load shifts. Next, the learning models used by Quasar and Ernest were not able to accurately estimate the demands in our experiment. Finally, the evolutionary baselines were inefficient, taking a long time to discover the optimal solution. They, however, were effective within Cilantro’s welfare policies when you need to optimize a cheap analytically computable function as they can be run for several iterations.

Despite our general approach, Cilantro’s policies are able to outperform Minerva and Greedy-EW which are designed specifically to maximize egalitarian welfare. It also outperforms generically designed evolutionary algorithms for the social and egalitarian welfare. While it may indeed be possible to design more efficient fine-tuned policies for a given objective, the flexibility provided by Cilantro’s approach is beneficial to end users. It should not be surprising that Cilantro outperforms other systems such as Ernest, Quasar, Parties, and MIAD as our policies are designed to explicitly optimize

for these objectives. *But this is precisely the goal of Cilantro.* End-users can declare their desired objective, and Cilantro will automatically derive policies to achieve them.

To illustrate how Cilantro improves with feedback, in Fig. 9, we have shown how the three objectives evolve over time for Cilantro’s policies. Resource-Fair trivially achieves  $F_{\text{NJC}} = 1$  at start since our initial allocation is always 50 CPUs to each job (i.e Resource-Fair). However, it does poorly on welfare due to poor cluster usage. The goal behind Cilantro-NJC is to achieve  $F_{\text{NJC}} = 1$  while also achieving good cluster usage. This causes the initial drop in performance for Cilantro-NJC as it explores better allocations that still maximize  $F_{\text{NJC}}$ .

Table 2 presents the detailed results of our multi-tenant cluster resource sharing evaluation. This table adds a metric which measures the useful resource usage.

$$\text{Useful resource usage} = \sum_{j=1}^m \min(a_j, d_j) \quad (8)$$

Here, the  $d_j$  is user  $j$ ’s resource demand. This demand-based metric, measures how much *useful* work is being done by the cluster as allocations beyond the demand do not increase a user’s utility (see Fig. 4). We find that Cilantro’s policies achieve the maximum useful resource usage in their respective classes. This is because learning resource demands allows Cilantro to reallocate resources from jobs which have already achieved maximum utility to jobs which can benefit from increased resources.

**Individual user utilities.** To delve deeper into the trade-offs of the three paradigms discussed in §4.1, we have shown the individual user utilities achieved by these three policies in Fig. 10. We see that both the social and egalitarian welfare policies result in some users being worse off than receiving their fair allocation of  $1000/20 = 50$  CPUs. This results in an NJC fairness violation. In contrast, in Cilantro-NJC, users are at most marginally worse off than their fair share. However, a third of the users achieve a noticeably higher utility than their fair share utility, with more than  $3\times$  for a few of them. We also see that Cilantro-EW has maximized egalitarian welfare by taking resources away from those who achieve high utility and giving it to those who do not, while Cilantro-SW has

Figure 8: NJC fairness vs the social and egalitarian welfare (see §4.1.1) for all policies. We report the average value over the 6 hour period. Higher is better for all metrics, so closer to the top right corner is desirable. The Oracle-SW, Oracle-EW policies optimize for the social and egalitarian welfare when the performance mappings are known and Oracle-NJC achieves maximum fairness while improving cluster usage. The corresponding Cilantro policies are designed to do the same without a priori knowledge of the performance mappings.

Figure 9: Convergence over time of social, egalitarian welfares and NJC fairness for the three Cilantro policies.

maximized social welfare by allocating more resources to jobs that can quickly achieve high utility.

**Evaluating Strategy-proofness.** We next evaluate Cilantro policies for strategy-proofness. A policy is said to be strategy-proof if an unscrupulous user cannot increase the utility of their job by misreporting their performance metrics to the scheduling policy. For this, we repeat the same experiment set up; all jobs behave exactly as before except the db16 job which lies about its performance by either under-reporting by a factor  $\times 1/2$ , or over-reporting by a factor  $\times 2$ . By under-reporting, the user gives the impression that more resources are required to reach its SLO; in contrast, by over-reporting, a user is deceiving the scheduler to prioritize their job as they can achieve high utility with few resources. In Fig. 11, we report the utilities achieved by db16 under these untruthful behaviors. We see that for Cilantro-NJC, the job’s utility does not increase when over-reporting and decreases when under-reporting, leaving no incentive for the user to be untruthful.

In contrast, for Cilantro-EW, a user stands to gain by under-reporting while for Cilantro-SW, they gain by over-reporting. While a theoretical study of such strategy-proofness properties is beyond the scope of this work, it is interesting to empirically observe that the strategy-proofness properties of NJC fairness policies are retained in Cilantro.

## 7.2 Resource allocation for Microservices

We now demonstrate the use of Cilantro to allocate resources for inter-dependent microservices serving an application. A query to the application triggers multiple queries to different microservices and the final result is returned to the user. Cilantro must observe a single end-to-end metric, the end-to-end query latency, and then allocate fixed cluster resources to different microservices to minimize the P99 latency of the application. We note that Cilantro does not require meta information about the microservices, such as their dependency and control flow graphs; Cilantro directly optimizes the end-to-end metric as described in §7.2.

**Workload.** We use the Hotel Reservation application from DeathStarBench [22]. It has 19 microservices, including 6 MongoDB databases, 3 memcached kv-stores and a nginx webserver running on a consul service mesh. The architecture is shown in Fig. 12-Left. Collectively, these microservices serve search, recommendation, rating, account management and geolocation queries from users. We use wrk2 [54] to process and submit the query workload provided in [22]. We measure the end-to-end latency of queries submitted to the frontend microservice. All microservices experiments are run on a 160 CPU cluster with 20 AWS m5.2xlarge instances.

**Baselines.** We compare Cilantro’s end-to-end policy (§4.2) against three baselines. Resource-Fair always equally allocates the resources among microservices. EvoAlg is an evolutionary algorithm which optimizes for the P99 latency. e-greedy randomly picks a new allocation with probability  $1/3$ ,

Figure 10: The average utility achieved by the 20 jobs for the three online learning methods in Cilantro and Resource-Fair. Here, db0x, mltx, db1x, and prsx refers to jobs using the DB-0, ML training, DB-1, and prediction serving workloads from § 7.1.

Policy	Social Welfare, ( $W_S$ )	Egalitarian Welfare ( $W_E$ )	NJC Fairness ( $F_{NJC}$ )	Useful resource usage
Oracle-SW	$0.892 \pm 0.004$	$0.324 \pm 0.008$	$0.336 \pm 0.004$	$0.964 \pm 0.002$
Oracle-EW	$0.752 \pm 0.003$	$0.412 \pm 0.007$	$0.272 \pm 0.002$	$0.997 \pm 0.000$
Oracle-NJC	$0.828 \pm 0.002$	$0.373 \pm 0.008$	$0.999 \pm 0.000$	$0.991 \pm 0.000$
Cilantro-SW	<b><math>0.864 \pm 0.006</math></b>	$0.337 \pm 0.013$	$0.513 \pm 0.020$	$0.818 \pm 0.012$
Cilantro-EW	$0.760 \pm 0.007$	<b><math>0.390 \pm 0.020</math></b>	$0.426 \pm 0.037$	<b><math>0.954 \pm 0.012</math></b>

Table 2: The social welfare (1), egalitarian welfare (2), NJC fairness metric (3), and the effective resource usage (8) for all 13 methods. Higher is better for all four metrics, and the maximum and minimum possible values for all metrics are 1 and 0. The values shown in bold have achieved the highest value for the specific metric, besides the oracular policies. Resource-Fair has NJC fairness  $F_{NJC} = 1$  by definition.

Figure 11: The utility of db16 under the three online learning policies, when they report truthfully, when they under-report, and when they over-report. The plot normalizes with respect to truthful reporting, but the bars are annotated with the absolute value.

or uses the allocation with the smallest observed P99 latency with probability 2/3.

**Results and Discussion.** Fig. 12 shows how the instantaneous and time-averaged P99 latency (computed in 30s intervals) evolves with time during the course of the experiment. Both Cilantro and EvoAlg explore early on (Fig. 12-Center), but as they find better values, exploration shrinks as they focus

on testing more promising allocations. However, Cilantro’s OFU-based online learning policy is able to do this more effectively than EvoAlg.  $\epsilon$ -greedy explores aggressively even in later stages and is unable to adequately exploit good candidates it may have discovered in the early stages. Overall, Cilantro achieves a mean P99 of 525ms, compared to 930ms for EvoAlg, the next best baseline.

### 7.3 Microbenchmarks

**Cilantro Overhead.** Fig. 13-Left evaluates the time taken for Cilantro to process the feedback and compute the allocations for the three policies described in Sec. 4.1. This shows that Cilantro is fairly light-weight. For comparison, the average time it took to de-allocate a Kubernetes pod and assign it to a different job was on the order of 5-15s.

**Unavailable performance metrics.** In real-world situations, performance metrics of all users may not be available. We evaluate Cilantro’s fallback defaults for such instances. We re-run the same experiment in § 7.1, but for users db01, ml1, and

Figure 12: *Left*: Microservices architecture of the hotel reservation benchmark [22]. Blue boxes are business logic, red boxes are caching services, yellow boxes are databases and purple boxes are networking services. *Center*: Results for the microservices experiment comparing four methods on P99 latency over 6 hours, plotting the instantaneous P99 latency vs time. *Right*: The time-averaged P99 latency vs time.

Figure 13: Cilantro microbenchmarks. *Left*: Mean time taken (in seconds) by Cilantro to update the performance model and for computing a new allocation for each of the three fixed cluster sharing policies. *Center*: Evaluation of Cilantro’s fallback option, where users provide a demand value if they cannot report performance metrics. We evaluate Cilantro-NJC when 5 out of 20 users use this option. Since the true demand cannot be known, we use either half or twice the true demand under the median load from our profiled data. *Right*: The three performance metrics for Cilantro-NJC when we artificially introduce error to the confidence intervals of the performance and load.

mlt2, db11, and prs1, we manually set the demand as described in §5. Since the true demands are not known a priori, users might under- or overstate them. To reflect this, we first compute the true demand for each user under the median load from our profiled data. We evaluate Cilantro-NJC when these five users report either half this value as their demand or twice this value, when compared to providing feedback. Fig. 13-Center presents results on the three criteria given in §4.1. While the fallback options are worse than when reporting feedback, the failures are graceful. Cilantro is still able to learn from the remaining 15 users and achieve efficient allocations with only relatively small drops in social and egalitarian welfare. The NJC fairness criterion is significantly small when under-reporting since these 5 users will have been allocated at most half of their true demand and  $F_{\text{NJC}}$  (3) depends on the single worst fairness violation.

#### Robustness to choice of learners and feedback errors.

While Cilantro’s decoupled design aids with generality, it may be susceptible to the idiosyncrasies of the specific models used for the performance learners and load forecasters. Moreover, in many real environments, the feedback can be very noisy. To show that Cilantro is robust to both these effects, we perform the following microbenchmark in a synthetic 5 user environment (described in the Appendix) with the Cilantro-NJC policy. As both feedback noise and model idiosyncrasies can be modeled with inaccurate confidence intervals, we introduce increasing levels of noise (5%, 10%,

20%, 50%) to the upper and lower confidence bounds returned by the learners and forecasters. The results, given in Fig. 13-Right, show that the social and egalitarian welfare decrease gracefully with noise. Moreover, due to Cilantro-NJC’s conservative approach for demand recommendations, the NJC fairness metric remains relatively high despite the noise.

## 8 Conclusion

We described Cilantro, a performance-aware framework for the allocation of a finite amount of resources among competing jobs. Our motivations were: (i) resource allocation policies should be performance-aware and based on real-time feedback in production environments, (ii) schedulers should accommodate diverse allocation objectives. We designed Cilantro to address these challenges by decoupling the performance learning from the policies and informing the policies of uncertainties in performance estimates, thus enabling the realization of several performance-aware policies in multi-tenant and microservices settings.

Figure 14: Sampled query arrival rate from the twitter trace collected over the duration of a day.

## A Experiment Addendum

### A.1 Workload description

**Database querying:** We use the TPC-DS [43] benchmark suite as the workload backed by replicated instances of sqlite3 database. From the TPC-DS query set, we created two workloads (setting scale factor to 100): DB-0, which had queries that completed in under 100 ms and DB-1 which had queries that had a completion time between 100 and 300 ms. When a query is requested, we randomly pick a relevant query and dispatch it according to the trace. The performance metric of interest is query latency.

**Prediction serving:** In prediction serving [13], a job processes arriving queries to output a prediction, usually obtained via a machine learning model. In our set up, we use a random forest regressor as the model and the the news popularity dataset [20] for training and test queries in a 50:50 split. Queries are picked randomly from the test set and issued in batches of 4. The metric of interest is the serving latency.

**ML training:** We use CPUs to train a neural network with four hidden layers of size 64 each. We train our model on the naval propulsion [12] dataset using stochastic gradient descent (SGD). Each task in this workload consists of training a batch of 16 points for 100 iterations. The performance metric of interest here is the batch throughput.

### A.2 Environment details

**Workload traces.** As described in §7.1, we use traces collected from twitter to generate traffic patterns for our workloads. The query arrival rate of this trace is visualized in Figure 14.

**Multi-tenant cluster jobs setup.** For the multi-tenant cluster resource sharing evaluation, we setup 20 jobs with different workloads and SLOs as described in in §7.1. Table 3 details the exact SLO and utility function for each job. The utility function for each job is either of `linear`, which directly maps performance to utility (Figure 4(a)), `sqrt`, which performs a sublinear mapping of performance to utility (Figure 4(b)), or `quadratic`, which performs a superlinear mapping of performance to utility (Figure 4(c)).

**TPC-DS Query Binning.** The queries used for the db serving workload in §7.1 were selected from the TPC-DS benchmark suite. The TPC-DS suite consists of 99 query templates out of which 27 were not compatible with the sqlite dialect and were discarded. The remainder were binned according to their mean latency when measured on a AWS m5.2xlarge instance. The chosen query types and their ids are listed in Table 4

### A.3 Baselines from prior work

Here we describe the specific implementation of prior work baselines used in Section 7.

- 1) Ernest [58]: Ernest uses a featurized linear model to estimate the time taken to run a job. We use this estimate to approximate the resource demand to meet the job’s SLO. On each round, we use the estimated demand as inputs to NJC to compute the allocations.
- 2) Quasar [15]: Quasar uses collaborative filtering to estimate a job’s resource demand, which we use as inputs to NJC to compute the allocations. We do not incorporate mechanisms for vertical scaling and workload co-location described in [15] to be consistent across all methods.

Job and SLO Type	Job Name	SLO	Utility Function
Database Serving (Latency)	db01	0.9	linear
	db02	0.9	linear
	db03	0.95	sqrt
	db11	0.9	linear
	db12	0.9	quadratic
	db13	0.95	quadratic
	db14	0.95	linear
	db15	0.95	quadratic
	db16	0.99	quadratic
Prediction Serving (Latency)	prs1	0.9	linear
	prs2	0.9	sqrt
	prs3	0.95	sqrt
ML Training (Throughput)	mlt1	400	sqrt
	mlt2	400	sqrt
	mlt3	450	linear
	mlt4	450	linear
	mlt5	500	quadratic
	mlt6	500	quadratic
	mlt7	500	quadratic

Table 3: SLO and utility functions used for jobs in experiments in §7.1. For Latency based SLOs, the SLO implies the fraction of queries that completed under 2 seconds. For Throughput based SLOs, the SLO is the desired query rate, measured in queries per second.

Query Bin	TPC-DS Query Ids	Mean Execution Time (s)
db0	93, 91, 92, 45, 85, 15, 32	0.28
db1	90, 84, 8, 55, 96, 81, 79	0.67

Table 4: Details of the bins created from TPC-DS queries. Each user’s workload is generated using these bins. Execution time is profiled on a SQLite3 database running on AWS m5.2xlarge instance with one allocated CPU core.

- 3) Minerva [45]: Minerva sets the allocation for job  $j$  at each step to be proportional to  $a_j/u_j$  where  $a_j$  and  $u_j$  are the allocation and utility at the previous round.
- 4) Parties [10]: Parties upsizes the allocation for a job if it violates or is close to violating the SLO, downsizes the allocation if the job comfortably satisfies the SLO, and otherwise does nothing. If the SLOs of all jobs cannot be met, it evicts the job from the server. As eviction is not an option in our setting we use the Parties logic to compute the demands which are then fed to NJC to obtain the allocations. For upsizing, we increase the demand by 20 CPUs and for downsizing, we decrease it by 5. These parameters were tuned so that the policy did reasonably well on all three metrics.
- 5) MIAD (Multiplicative-Increase/Additive-Decrease) [11]: This is inspired by TCP congestion control. If a user’s job violates the SLO, we increase its demand by  $1.5 \times$  the current allocation, and if it satisfies the SLO, we set the demand to be one minus the current allocation. We then invoke NJC to compute the allocation for the next round. These parameters were tuned so that the policy did reasonably well on all three metrics.

## A.4 Evolutionary Algorithm

We describe the evolutionary algorithm used in all of our experiments, i.e. to optimize the profiled information for the oracular welfare policies, to optimize the upper confidence bounds for the learning policies in §4.1.2 and §4.2, and the evolutionary algorithm baselines in §7.1 and §7.2. The input to the algorithm is a data source which the algorithm can query using an allocation and obtain a feedback signal. This data source can either be a cheap analytically computable function available in memory, as is the case for the oracles and learning policies, or an expensive experiment, as is the case when used as a baseline to directly

optimize for performance. The algorithm maintains a hash table mapping allocations to mean observed signal values. When it receives feedback for an allocation, it updates the mean value if the allocation has already been tried, or it creates a new entry and stores the feedback.

Our evolutionary algorithm proceeds as follows. It has an initialization phase of 10 rounds. In the first 2 rounds, it always queries a resource-fair allocation. In the remaining 8 rounds, it queries a random allocation  $a$  such that  $\sum_{j=1}^n a_j = R$ . On each subsequent round, it chooses a random allocation in the above manner with probability 0.1. With probability 0.9, it samples one of the existing allocations in the hash table based on the mean feedback value, performs a mutation operation, and queries the new allocation obtained via the mutation. We now describe these two steps.

- *Sampling*: Let  $\{(a_i, y_i)\}_i$  be the (allocation, mean feedback) pairs in the hash table. Let  $m, s$  denote the mean and standard deviation of the  $\{y_i\}$  values. We sample  $a_i$  with probability proportional to  $\exp((y_i - m)/s)$ .
- *Mutation*: The mutation operation is composed of a sequence of steps to modify a given allocation  $a$ . At each step, we randomly sample one job  $j$  which has an allocation of at least 2 CPUs; we then sample any other job  $k \neq j$ ; we then decrease  $j$ 's allocation by 1 and increase  $k$ 's allocation by 1. The number of steps is chosen uniformly at random between 1 and 20.

## A.5 Other experimental details

**Synthetic environment for robustness microbenchmark:** For the microbenchmark in Fig. 13(left), we use 5 users whose load is obtained by the same twitter trace from the experiments, and whose synthetic performance function is given by  $p_j(a, \ell) = 1/(1 + e^{-(a/\ell - b_j)})$ , where  $a$  is the allocation and  $\ell$  is the load. For the 5 users, we set  $b_j \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$ . We set the SLO to be 0.95 for all users (note that  $0 \leq p_j \leq 1$ ). As the stochastic observation, we sample a Gaussian with standard deviation 0.2.

# Karma: Resource Allocation for Dynamic Demands

## Abstract

We consider the problem of fair resource allocation in a system where user demands are dynamic, that is, where user demands vary over time. Our key observation is that the classical max-min fairness algorithm for resource allocation provides many desirable properties (*e.g.*, Pareto efficiency, strategy-proofness, and fairness), but only under the strong assumption of user demands being static over time. For the realistic case of dynamic user demands, the max-min fairness algorithm loses one or more of these properties.

We present Karma, a new resource allocation mechanism for dynamic user demands. The key technical contribution in Karma is a credit-based resource allocation algorithm: in each quantum, users donate their unused resources and are assigned credits when other users borrow these resources; Karma carefully orchestrates the exchange of credits across users (based on their instantaneous demands, donated resources and borrowed resources), and performs prioritized resource allocation based on users' credits. We theoretically establish Karma guarantees related to Pareto efficiency, strategy-proofness, and fairness for dynamic user demands. Empirical evaluations over production workloads show that these properties translate well into practice: Karma is able to reduce disparity in performance across users to a bare minimum while maintaining Pareto-optimal system-wide performance.

## 1 Introduction

Resource allocation is a fundamental problem in computer systems, spanning private and public clouds, computer networks, hypervisors, etc. There is a large and active body of research on designing resource allocation mechanisms that achieve Pareto efficiency (high resource utilization) and strategy-proofness (selfish users should not be able to benefit by lying about their demands) while ensuring that resources are allocated fairly among users, *e.g.*, [30,32,39,57,59,66,67].

For a system containing a single resource, the two most popular allocation mechanisms are strict partitioning [9,72] and max-min fairness [30,32,36,40,49,50,57,59,66].

The former allocates the resource equally across all users (“fair share”), independent of their demands; this guarantees strategy-proofness and fairness, but not Pareto efficiency since resources can be underutilized when one or more users have demands lower than the fair share. Max-min fairness alleviates limitations of strict partitioning by taking user demands into account: it maximizes the minimum allocation across users while ensuring that each user’s allocation is no more than their demand. A classical result shows that resource allocation based on max-min fairness guarantees each of the three desirable properties—Pareto efficiency, strategy-proofness, and fairness. These powerful properties have, over decades, motivated efforts in both systems and theory communities on generalizations of max-min fairness for allocating multiple resources [30–32], for incorporating application performance goals and deadlines [31,39,46,47], and for new models of resource allocation [17,22,25,33,59,66], to name a few.

This paper explores a complementary problem—resource allocation of a single elastic resource in a system where user demands are dynamic, that is, vary over time. Dynamic user demands are the norm in most real-world deployments [12,16,41,45,60,63,70,72,79]; for instance, analysis of production workloads in §2 reveals that user demands vary by as much as  $17\times$  within minutes, with majority of users having demands with standard deviation  $0.5 - 43\times$  of the average over time. We show in §2 that, for systems with such dynamic user demands, resource allocation based on the max-min fairness algorithm fails to guarantee one or more of its properties: (1) if the allocation is done based on demands at  $t=0$ , Pareto efficiency and strategy-proofness are no longer guaranteed; and, (2) if the allocation is done periodically, *long-term* fairness is no longer guaranteed—for  $n$  users with the same average demand, the max-min fairness algorithm may allocate some user as much as  $\Omega(n)$  more resources than other users over time.

We present Karma, a new resource allocation mechanism for dynamic user demands. The key technical contribution of Karma is a credit-based resource allocation algorithm: in each quantum, users receive credits when they donate a part of their fair share of resources (*e.g.*, if their demand

is less than their fair share); users can use these credits to borrow resources in any future quantum when their demand is higher than their fair share. When the supply of resources from donors is equal to the demand from borrowers, it is easy to exchange resources and credits among users. The key algorithmic challenge that Karma resolves is when supply is not equal to demand—in such scenarios, Karma carefully orchestrates resources and credits between donors and borrowers: donors are prioritized so as to keep credits across users as balanced as possible, and borrowers are prioritized so as to keep the resource allocation as fair as possible.

We theoretically establish Karma guarantees for dynamic user demands. Karma guarantees Pareto efficiency at all times: in each quantum, it allocates resources such that it is not possible to increase the allocation of a user without decreasing the allocation of at least another user. For strategy-proofness, Karma guarantees that a selfish user cannot increase their aggregate resource allocation by *over*-reporting their demands in any quantum. In addition, we show a new surprising phenomenon (that may primarily be of theoretical interest): if a user had perfect knowledge about the future demands of all other users, the user can increase its own aggregate allocation by a small constant factor by *under*-reporting its demand in some quanta; however, for  $n$  users, imprecision in this future knowledge could lead to the user losing  $\Omega(n)$  factor of their aggregate resource allocation by under-reporting their demand in any quantum. Put together, these results enable Karma to provide powerful guarantees related to strategy-proofness. Finally, for fairness, we prove that given a set of (past) allocations, Karma guarantees an optimally-fair resource allocation. We also establish that Karma guarantees similar properties even when multiple selfish users can collude, and even when different users have different fair shares.

We have realized Karma on top of Jiffy [41], an open-sourced multi-tenant elastic memory system; an end-to-end implementation of Karma is available at <https://github.com/resource-disaggregation/karma>. Evaluation of Karma over production workloads demonstrates that Karma’s theoretical guarantees translate well into practice: it matches the max-min fairness algorithm in terms of resource utilization, while significantly improving the long-term fairness of resources allocated across users. Karma’s fairer resource allocation directly translates to application-level performance; for instance, over evaluated workloads, Karma keeps the *average* performance (across users) the same as the max-min fairness algorithm, while reducing performance *disparity* across users by as much as  $\sim 2.4\times$ . Karma also incentivizes users to share resources: our evaluation shows that (1) Karma-conformant users achieve much more desirable allocation and performance compared to users who prefer a dedicated fair share of resources; and, (2) if users were to turn Karma-conformant, they can improve their performance by better matching their allocations with their demands over time.

## 2 Motivation

We begin by outlining our motivating use cases, followed by an in-depth discussion on the limitations of the classic max-min fairness algorithm for dynamic user demands.

**Motivating use cases.** Fair resource allocation is an important problem in private clouds where resources are shared by multiple users or teams within the same organization [12, 16, 17, 30–33, 36, 39, 40, 45, 46, 59, 60, 66, 70, 72, 79, 80]; our primary use cases are from such private clouds. Karma may also be useful for emerging use cases from multi-tenant public clouds where spare resources may be allocated to tenants while providing performance isolation [8, 14, 38, 41, 57, 63, 64, 66]. We discuss motivating scenarios in both contexts below.

One scenario is shared analytics clusters. For instance, companies like Microsoft, Google, and Alibaba employ schedulers [32, 35, 39, 69, 70, 80] that allocate resources across multiple internal teams that run long-running jobs (*e.g.*, for data analytics [23, 81]) on a shared set of resources. Consider memory as a shared resource; in many of these frameworks, main memory is used to cache frequently accessed data from slower persistent storage and to store intermediate data generated during job execution. Indeed, increasing the allocated memory improves job performance; however, since memory is limited and is shared across multiple teams, ensuring resource allocation fairness is also a key requirement. Moreover, since these jobs are usually long-running, their performance depends on long-term memory allocations, rather than instantaneous allocations [16, 32, 45].

Another use case is shared caches: many companies (*e.g.* Facebook [9, 12, 52] and Twitter [79]) operate clusters of in-memory key-value caches, such as memcached or Redis, serving a wide array of internal applications. In this use case, the memory demand of each application may be computed as the amount of memory that would be required to fit hot objects within the cache [18, 19, 52, 79]. In such settings, efficient and fair sharing of caches is of utmost importance [9, 19, 52, 72]: to maintain service level agreements, it is important to have consistently good performance over long periods of time, rather than excellent performance at some times and very poor performance at other times (see [9, 19, 52, 72] for more discussion on the importance of long-term performance).

Third, fair resource allocation while ensuring high utilization is also a goal in inter-datacenter bandwidth allocation [36, 40, 49]. Existing traffic engineering solutions used in production environments perform periodic max-min fair resource allocation to account for dynamic user demands [36, 40, 49]. Our work demonstrates that periodically performing max-min fair resource allocation over such dynamic demands leads to unfair resource allocation across users.

Finally, an interesting use case in the public cloud context is that of burstable VMs [2, 4] that use virtual currency to enable resource allocation over dynamic user demands. These VMs share resources with VMs from other users and are charged

Figure 1: **Analysis of Google and Snowflake workloads suggests that a large fraction of users have dynamic demands (left) that can change dramatically over short timescales (center, right)** (Left) CDFs, across users, of the ratio of standard deviation and mean of each user’s demand. (Center) For a randomly sampled user in the Snowflake trace, the variation in the user’s CPU and memory demands (normalized by minimum demand) over a 15 minute period. (Right) For a randomly sampled user in the Google trace, the variation in the user’s CPU and memory demands (normalized by minimum demand) over a 2 hour period.

on an instance-specific baseline. When resource utilization is below the baseline, users accumulate virtual currency that they can later use to gain resources beyond the baseline during periods of high demand. Given that Burstable VMs are primarily useful for dynamic user demands, they will likely need resource allocation mechanisms that guarantee high utilization, strategy-proofness, and fair resource allocation.

**Dynamic user demands.** Increasingly many applications running data analytics or key-value caches operate on data collected from social media, application and network logs, mobile systems, etc. A unique characteristic of these data is that they are less controllable by the organization because they are generated by entities outside of the organization. As a result, applications can observe highly time-varying dynamic resource demands [12, 16, 41, 45, 60, 63, 70, 72, 79].

To build a deeper understanding of variation in user demands over time, we analyze two publicly-available production workloads: (1) Google [60] resource usage information across 8 clusters (1000–2000 users per cluster) over a 30 day period; and, (2) Snowflake [72], a cloud-based database query engine that provides resource usage statistics for over 2000 users over a 14 day period. To characterize user demand variability over time, we compute—for each user—the ratio of the standard deviation and mean of their demands over the entire period. Figure 1 (left) shows that 40–70% of all users in both Google and Snowflake workloads have a standard deviation in CPU and memory demands at least  $0.5\times$  their mean, indicating high variability in demands for most users. Furthermore, the standard deviation in demands of as many as 20% of the users can be as high as their mean demand, with some users having extremely high variance in demands (standard deviations up to 12–43 $\times$  the mean). Similar observations have been made for time-varying user demands in inter-datacenter networks; for instance,

production studies [5] show that, on average, user demands vary by 35% within 5-minute intervals, with some demands varying by as much as 45% within a short period of time.

Figure 1 (center) shows the CPU and memory demands for a randomly-sampled user from the Snowflake trace over a 15 minute window (we show only one user and only 15 minute window for clarity; analyzing a sample of 100 users, we find 87% of the users to have similar demand patterns). The figure shows that user demands can change dramatically over tens of seconds, by as much as  $6\times$  and  $2\times$  for compute and memory, respectively. Similarly, we see significant variation in demands even for a random user from the Google trace (shown in Figure 1 (right)).

**Max-min fairness guarantees fail for dynamic user demands.** The classical max-min fairness algorithm for resource allocation provides many desirable properties, *e.g.*, Pareto efficiency, strategy-proofness, and fairness. However, buried under the proofs is the assumption that user demands are static over time, an assumption that does not hold in practice (as demonstrated in Figure 1). For the realistic case of dynamic user demands, max-min fairness can be applied in two ways, each of which leads to violating one or more of its properties. We will demonstrate this using the example in Figure 2; here, time is divided into five quanta and three users have demands varying across quanta.

First, one can naïvely perform max-min fair allocation just once based on user demands at quantum  $t = 0$ . This results in max-min fairness losing both Pareto efficiency and strategy-proofness. In the example of Figure 2, since allocations will only be done based on the demands specified by the users at  $t = 0$ , if users were to specify their true demands, user C will obtain an allocation of 1 unit leading to a total useful allocation of 3 units over the entire duration (as shown in Figure 2 (middle, top)); if user C were to lie

Figure 2: **Classical max-min fairness guarantees break for dynamic user demands.** Here, 6 units of a resource are shared by 3 users (fair share of 2). Discussion in §2.

and over-report their demand at  $t = 0$  as 2 units, then they can achieve a more desirable total useful allocation of 5 units (Figure 2 (middle, bottom)). This breaks strategy-proofness. In addition, max-min fairness is also not Pareto efficient: for many quanta, resources allocated to users will be underutilized as is evident in Figure 2 (middle).

A better way to apply max-min fairness for dynamic user demands is to periodically reallocate resources based on users’ instantaneous demands (e.g., every quantum of time periods, as in several operating systems and hypervisors [3, 73]). This trivially guarantees Pareto efficiency and strategy-proofness but results in extremely unfair allocation across users. Figure 2 (right, top) shows an example where max-min fairness can result in  $2\times$  disparity between resources allocated to users over the 5 quanta—user A receives a total allocation of 10 slices, while user C receives a total allocation of only 5 slices, despite them having the same average demand; this example can be easily extended to demonstrate that max-min fairness can, for  $n$  users, result in resource allocations where some user gets a factor of  $\Omega(n)$  larger amount of resources than other users (proof in [71]). Such disparity in resource allocations also leads to disparity in application-level performance across users since, as discussed above in use cases, many applications require consistently good performance over long periods of time, rather than excellent performance at some times and very poor performance at other times [22, 28, 32, 68]. We will demonstrate, in the evaluation section, that users experience significant disparity in application-level performance due to such disparate resource allocations.

For the rest of the paper, we focus on long-term fairness; informally, an allocation is considered fair if all users have the same aggregate resource allocation over time. Our goal is to design a resource allocation mechanism that, for dynamic user demands, guarantees Pareto efficiency, strategy-proofness, and fairness.

### 3 Karma

Karma is a resource allocation mechanism for dynamic user demands. Karma uses *credits* (§3.1, §3.2)—users receive credits when they donate a part of their fair share of resources (e.g., when their demand is less than their fair share), and can use these credits to borrow resources beyond their fair share during periods of high demand. Karma carefully orchestrates the exchange of resources and credits between donors and borrowers: donors are prioritized in a manner that ensures credit distribution across users remains as balanced as possible, and borrowers are prioritized in a manner that keeps the resource allocation as fair as possible. We will prove theoretically in §3.3 that, while simple in hindsight, this allocation mechanism simultaneously achieves Pareto efficiency, strategy-proofness, and fairness for dynamic user demands.

#### 3.1 Preliminaries

We consider the following setup for the problem: we have  $n$  users sharing a single resource (CPU, memory, GPUs, etc.); each user has a fair share of  $f$  resource units (each unit is referred to as a *slice*), and thus the pool has  $n \times f$  slices of the resource (as we discuss in §3.4, all our results hold for users having different fair shares). Time is divided into quanta, users demand a certain number of resource slices every quantum, and Karma performs resource (re)allocation at the beginning of each quantum. While user demands during each quantum can be arbitrary, unsatisfied demands in one quantum do not carry over to the next. Similar to prior work [30, 57, 59, 66], we assume that users are not adversarial (that is, do not lie about their demands simply to hurt others’ allocations), but are otherwise selfish and strategic (willing to misreport their demands to maximize their allocations).

#### 3.2 Karma design

Let  $0 \leq \alpha \leq 1$  be a parameter. Karma guarantees that each user is allocated an  $\alpha$  fraction of its fair share ( $= \alpha \cdot f$ ) in each quantum; we refer to this as the guaranteed share. Karma maintains a pool of resource slices—karmaPool—that, at any point in time, contains two types of slices:

- **Shared slices** are the slices in the resource pool that are not guaranteed to any user. It is easy to see that the number of shared slices in the system is  $n \cdot f - n \cdot \alpha \cdot f = n \cdot (1 - \alpha) \cdot f$ .
- **Donated slices**, that are donated by users whose demands are smaller than their guaranteed share.

We use these two sets of slices in the following manner. In any given quantum, if a user has demand less than its guaranteed share, then the user is said to be “donating” as many slices as the difference between the user’s guaranteed share and demand in that quantum. A user that has demand larger than its guaranteed share is said to be “borrowing” slices beyond its guaranteed share, which the system can potentially supply using either shared slices or donated slices.

### 3.2.1 Karma credits

Karma allocates resources not just based on users' instantaneous demands, but also based on their past allocations. To maintain past user allocation information, Karma uses credits.

Users earn credits in three ways. First, each user is bootstrapped with a fixed number of initial credits upon joining the system (we discuss the precise number once we have enough context, in §3.4); second, each user is allocated  $(1 - \alpha) \cdot f$  free credits every quantum as compensation for contributing  $(1 - \alpha)$  fraction of its fair share to shared slices. Finally, users earn one credit when some other user borrows one of their *donated* slices (one credit per quantum per slice).

Unlike earning credits, there is only one way for any user to lose credits: for every slice borrowed from the karmaPool (donated or shared), the user loses one credit.

### 3.2.2 Prioritized resource allocation

We now describe Karma's resource allocation algorithm, that orchestrates resources and credits across users (Algorithm 1). To make the discussion succinct, we refer to the sum of user demands beyond their guaranteed share as "borrower demand"; that is, to compute borrower demand for any given quantum, we take all users with demand greater than their guaranteed share and sum up the difference between their demand (in that quantum) and  $\alpha \cdot f$ . In quanta when borrower demand is equal to the supply (number of slices in karmaPool), Karma's decision-making is trivial: simply allocate all slices in karmaPool to the borrowers, and update credits for all users as described in the previous subsection. The key algorithmic challenge that Karma resolves is when the supply is either more or less than the borrower demand. We describe Karma allocation mechanism for such scenarios next and then provide an illustrative example.

**Orchestrating resources and credits when supply > borrower demand.** When supply is greater than borrower demand, there are enough slices in karmaPool to satisfy the demands of all borrowers. In such a case, Karma prioritizes the allocation of donated slices over shared slices (so that donors get credits), and across multiple donated slices, prioritizes the allocation of a slice from the donor that has the smallest number of credits—this allows "poorer" donors to earn more credits, and moves the system towards a more balanced distribution of credits across users. Intuitively, credits capture the allocation obtained by a user until the last quantum—users who obtained lower allocations in the past will have a higher than average (across users) number of credits, while those who received a surplus of allocations will have a below-average number of credits. Hence, balancing the number of credits across users over time allows Karma to move towards a more equitable set of total allocations across users. Once all donated slices are allocated, Karma allocates shared slices to satisfy the remaining borrower demands.

---

#### Algorithm 1: Karma resource allocation algorithm.

---

`demand[u]`: demand of user `u` in the current quantum  
`credits[u]`: credits of user `u` in the current quantum  
`alloc[u]`: allocation of user `u` in the current quantum  
`f`: fair share  
 `$\alpha$` : guaranteed fraction of fair share

Every quantum do:

```
1: shared_slices  $\leftarrow n \cdot (1 - \alpha) \cdot f$ 
2: For each user u,
3:   increment credits[u] by  $(1 - \alpha) \cdot f$ 
4:   donated_slices[u] =  $\max(0, \alpha \cdot f - \text{demand}[u])$ 
5:   alloc[u] =  $\min(\text{demand}[u], \alpha \cdot f)$ 
6: donors  $\leftarrow$  all users u with donated_slices[u] > 0
7: borrowers  $\leftarrow$  all users u with
8:   alloc[u] < demand[u] & credits[u] > 0
9: while borrowers  $\neq \emptyset$  and
10:    $(\sum_u \text{donated\_slices}[u] > 0 \text{ or } \text{shared\_slices} > 0)$ 
11: do
12:   b*  $\leftarrow$  borrower with maximum credits
13:   if donors  $\neq \emptyset$  then
14:     d*  $\leftarrow$  donor with minimum credits
15:     Increment credits[d*] by 1
16:     Decrement donated_slices[u] by 1
17:     Update the set of donors (line 6)
18:   else
19:     Decrement shared_slices by 1
20:   Increment alloc[b*] by 1
21:   Decrement credits[b*] by 1
22:   Update the set of borrowers (line 7)
```

---

**Orchestrating resources and credits when supply < borrower demand.** When supply is less than demand, karmaPool does not have enough slices to satisfy all borrower demands. In such a scenario, Karma prioritizes allocating slices to users with the maximum number of credits. This strategy essentially favors users that had fewer allocations in the past (and thus, a larger number of credits), hence moving the system towards a more balanced allocation of resources across users, promoting fairness. At the same time, reducing the credits for the users with the most credits also moves the system to a more balanced distribution of credits across users.

**Illustrative example.** We now illustrate through a concrete example. The running example in Figure 3 shows the execution of Karma's algorithm for the example from Figure 2 for  $\alpha = 0.5$ : that is three users A, B, and C, each with a fair share 2 slices ( $f = 2$ ), and a guaranteed share of 1 slice. Recall that, since  $(1 - \alpha) \cdot f = 1$ , each user receives 1 credit every quantum, and suppose all users are bootstrapped with 6 initial credits.

In the first quantum, C's demand is equal to the guaranteed share, while A and B request 2 and 1 slices beyond the guaranteed share, respectively. Since supply (= 3 shared slices in karmaPool) is equal to borrower demand, Karma uses the shared slices to allocate slices beyond the guaranteed share for

Figure 3: **Karma resource allocation for the running example of Figure 2:** Recall that there are 6 resource slices, 3 users each with average demand and fair share equal to 2. We show the case of the guaranteed share being 1 ( $\alpha=0.5$ ), with 6 bootstrapping (initial) credits for each user. Note that each user receives 1 free credit every quantum. Karma achieves significantly improved fair allocation than max-min fairness—it allocates each user an equal allocation of 8 resource slices over time.

A and B and satisfies their demands. This results in a final allocation of 3 slices for A, 2 slices for B, and 1 slice for C. A loses 2 credits, and B loses 1 credits, and no one gains any credits.

In the second quantum, A demands 3 slices, while B and C donate 1 slice each. The total supply ( $=5$ , with 2 donated slices and 3 shared slices) exceeds the borrower demand. A is allocated 3 slices and it loses 3 credits (since its allocation is 2 slices above its guaranteed share). B and C receive 1 credit each since their donated slices are used. Similarly, in the third quantum, B demands 3 slices, while A and C donate 1 slice each. Since total supply exceeds borrower demand, B receives the 3 slices it asked for, and loses 2 credits; A and C gain 1 credit each.

The fourth quantum is important: here, demand exceeds supply, and there are no donated slices. Now, unlike classic max-min fairness, Karma will prioritize the allocation of resources based on the credits of each tenant. Since at the start of this quantum, C has 11 credits, while A and B have only 6 and 7 credits respectively, C will be able to get 3 extra slices from the pool of shared slices by using 3 credits and achieve an allocation of 4. A and B will get their guaranteed allocation of 1 and do not gain or lose any credits.

In the fifth quantum, once again, demand exceeds supply. C has 9 credits, B has 8 credits, and A has 7 credits. Karma first prioritizes allocating to C giving it 1 extra slice, at which point both C and B have equal credits (8). Next, they both get 1 extra slice each, at which point the supply is exhausted. The final resulting allocation is 1 slice for A, 2 slices for B, and 3 slices for C.

In the end, A, B, and C end up with the exact same total allocation (8 slices) and number of credits (unlike max-min fairness where user allocations had a disparity of  $2\times$ ).

### 3.3 Karma Properties & Guarantees

In this section, we present a theoretical analysis of Karma. Recall from §3.1 that, similar to all prior works, users are considered selfish and strategic (that is, are willing to misreport their demands to maximize their allocations), but not adversarial (that is, do not lie about their demands simply

to hurt others' allocations). For the purpose of our theoretical analysis, we assume that Karma is initialized with a large enough number of initial credits so that users do not run out of credits during the execution of the algorithm (we discuss how to achieve this in practice in § 3.4). All our results hold for  $\alpha = 0$ ; extending our results to  $\alpha > 0$  is an interesting open question. Finally, while we provide inline intuition for each of our results, full proofs are presented in [71].

We define Pareto efficiency on a per-quantum basis. An allocation is said to be Pareto efficient if it is not possible to increase the allocation of a user without decreasing the allocation of at least one other user by a similar total amount during that quantum. Note that, Pareto efficiency on a per-quantum basis implies Pareto efficiency over time.

**Theorem 1.** *Karma is Pareto efficient.*

Karma's Pareto efficiency follows trivially from the observation that similar to max-min fairness, Karma allocation satisfies the two properties: (1) no user is allocated more resources than its demand, and (2) either all resources are allocated or all demands are satisfied.

For strategy-proofness, we make two important notes. First, if one assumes that the system has a priori knowledge of all future user demands, the resource allocation problem can be solved trivially using dynamic programming; however, for many use cases, it is hard to have a priori knowledge of all future user demands. This leads to our second note: Karma is solving an “online” problem (that is, it does not assume a priori knowledge of future user demands), and thus, we prove online strategy-proofness [7] defined as follows: assume that all users are honest during quanta 0 to  $q - 1$ ; then, a mechanism is said to be online strategy-proof if, for any quantum  $q$ , a user cannot increase its allocation during quantum  $q$  by lying about its demand during quantum  $q$ .

**Theorem 2.** *Karma is online strategy-proof.*

To prove Theorem 2, we actually prove a stronger result stated below. Karma's online strategy-proofness trivially follows from this.

Figure 4: The phenomenon of users (left) gaining a small factor of improvement in their allocations by specifying demands less than their real demands, by exploiting knowledge of all future demands of all users; (right) any imprecision in the knowledge of future demands of all users could result in a significant reduction in useful allocations of the lying user. The resource pool has 8 slices, and 4 users with fair share of 2 and guaranteed share of 0 ( $\alpha=0$ ).

**Lemma 1.** *A user cannot increase its useful resource allocation by specifying a demand higher than its real demand in any quantum.*

The proof for the lemma is a bit involved, but intuitively, it shows the following. The immediate effect of a user specifying a demand higher than its actual demand is that if the user is allocated more resources than its actual demand, these extra resources do not contribute to its utility, but do put the user into a disadvantageous position: not only can this user lose credits (either because it's asking for resources beyond its guaranteed share, or because it could have gained credits if this extra resource could have been allocated to some borrower), but also because other users get fewer resources; this makes other users be favored by the allocation algorithm in the future while making the lying user less favored. Thus, the user cannot increase its long-term “useful” allocation by specifying a demand higher than the real demand in any quantum. Specifically, it is possible that when a user over-reports its demand during quantum  $q'$ , the user receives an increased instantaneous allocation during some future quantum  $q > q'$ ; however, we are able to show that, in this case, the user will also receive reduced instantaneous allocation(s) during other quantum(s) in between  $q'$  and  $q$ , leading to either a lower or equal total allocation over the period between  $q'$  and  $q$ . The hardness in the proof stems from carefully analyzing such cascade effects: a small change in users' resource allocation in any quantum can result in complex changes in future allocations that may lead to higher instantaneous but equal or lower total allocations in future quanta. Once we prove this lemma, the proof for Karma's online strategy-proofness follows immediately.

While analyzing Karma properties, we encountered a new, surprising, phenomenon that may be of further theoretical interest: we show that a user that *knows all future demands of all other users* can report a demand that is lower than its actual demand in the current quantum to increase its allocation in future quanta by a small constant factor. However, any imprecision in the knowledge of all future demands of all other users could result in the user losing a factor of  $\Omega(n)$  of its total allocation.

**Lemma 2.** *A user cannot increase its total useful allocation by a factor more than  $1.5 \times$  by specifying a demand less than its real demand in any quantum. Gaining this useful allocation requires the user to know the future demands of all users. If the user does not have a precise knowledge of all future demands of all users, it can lose its useful allocation by a factor of  $\frac{n+2}{2}$  (for  $n \geq 3$ ) by specifying a demand less than its real demand.*

We provide intuition for this phenomenon using an example (Figure 4). In the left figure, user A is able to gain 1 extra slice in its overall allocation by under-reporting its demand (reporting 0 instead of 8) in the first quantum. By under-reporting, its allocation in the first quantum reduces, enabling it to get more resources during the second quantum when it competes with user C. In the third quantum, it is able to recover the resources it lost in the first quantum from user B, resulting in an overall gain. To see the flip-side, if the demands of other users had been as shown in Figure 4 (right), then user A sees a  $3 \times$  degradation in overall allocation.

To prove the first part of the Lemma 2, we consider an arbitrary user Alice and an arbitrary time period, and compare two scenarios—one where Alice is truthful (hereby called the truthful scenario) and one where Alice is deviating by under-reporting her demand during some quantum (hereby called the deviating scenario).

Our key insight for the proof is that bounding the increase in total allocation of *all users* is easier than reasoning about the increase in total allocation of an individual user (Alice) since even a small change in Alice's demand during one quantum can result in cascading effects on the total allocation of other users as well. To that end, we prove the following claim: the total amount of resources all the users have earned in excess in the deviating scenario compared to the truthful one can be at most as large as Alice's total allocation in the truthful scenario. We prove this claim based on the following observation: whenever Alice under-reports her demand she is effectively “donating” the allocation she would have gotten in the truthful scenario to the other users whose allocations in the deviating scenario increase. Since Karma is Pareto efficient, the total

gain in allocation across users during this quantum is limited by the amount donated by Alice which is in turn bound by Alice’s own allocation during this quantum in the truthful scenario. By applying this reasoning iteratively across all quanta<sup>1</sup>, we can show that the total increase in allocation across all users cannot exceed the total allocation of Alice in the truthful scenario. This already implies a  $2\times$  upper bound on the maximum increase in total allocation that Alice can achieve.

To tighten the upper bound, we prove a second claim: if Alice receives higher total allocation in the deviating scenario compared to the truthful scenario, then there must exist some other user Bob who gained an even larger increase in total allocation than Alice. Putting together the above two claims allows us to establish the desired upper bound. Based on the first claim, the total gain in allocation across all users cannot exceed Alice’s total allocation in the truthful scenario. This implies that the sum of total gains across Alice and Bob cannot exceed Alice’s total allocation in the truthful scenario. Since Bob’s gain is at least as large as Alice’s gain (based on the second claim), this implies that Alice’s gain is at most half the total allocation of Alice in the truthful scenario—a gain of at most  $1.5\times$ , thus proving the first part of Lemma 2.

The second part of the lemma is proven by first creating a set of demands where a user can under-report its demand during quantum  $q$  to earn increased total allocation by some quantum  $q' > q$ . Then we create a set of demands that are identical up to quantum  $q$  but vastly different from quanta  $q+1$  to  $q'$ . If the user (in the hope of facing the first set of demands) under-reports its demand on quantum  $q$  but ends up facing the second set of demands then this results in vastly different allocations by quantum  $q'$ . By correctly picking the two sets of demands we get the desired bounds.

In [71], we prove an even stronger result that extends Karma properties from Theorem 1, Theorem 2, Lemma 1 and Lemma 2 to the case of multiple colluding users:

**Theorem 3.** *No group of colluding users can increase their allocation by specifying a demand higher than their real demand. Additionally, for any group of colluding users, under-reporting demands cannot lead to more than a  $2\times$  improvement in their useful resource allocation. Finally, even if users form coalitions, Karma is Pareto efficient and online strategy-proof.*

Recall that Karma focuses on long-term fairness without a priori knowledge of future user demands. To that end, the following theorem summarizes Karma’s fairness guarantees:

**Theorem 4.** *For any quantum  $q$ , given fixed user allocations from quantum 0 to quantum  $q - 1$ , and user demands at quantum  $q$ , Karma maximizes the minimum total allocation from quantum 0 to quantum  $q$  across users.*

<sup>1</sup>It turns out that Alice under-reporting in a given quantum cannot cause cascading increases in total allocation across users in future quanta if Alice does not under-report in future quanta. This is because Karma prioritizes allocation to users with high credits (or equivalently low total allocations).

The proof for the above theorem follows from the prioritized resource allocation mechanism of Karma. Intuitively, given allocations from quantum 0 to  $q - 1$ , the user with the least total allocation up to quantum  $q - 1$  will have the largest number of credits. In quantum  $q$ , Karma will prioritize the allocation of resources to this user (until it is no longer the one with the minimum total allocation, after which it will prioritize the next user with the minimum total allocation, and so on), thus maximizing the minimum total allocation from quantum 0 to  $q$  across users—this is the best one can do in quantum  $q$  given past allocations.

### 3.4 Discussion

Finally, we briefly discuss some additional aspects of Karma design not included in the previous subsections.

**Bootstrapping Karma with initial credits.** Recall that, to bootstrap users, Karma allocates each user an initial number of credits. The precise number of initial credits has little impact on Karma’s behavior; after all, credits in Karma essentially capture a relative ordering between users, rather than having any absolute meaning. The only importance of the number of credits is to ensure that no user runs out of credits at any quantum (which, in turn, could lead to violation of Karma’s Pareto efficiency guarantees): even if spare resources are available, a user with high demand may not be able to borrow resources beyond the guaranteed share (line 7 of Algorithm 1) due to running out of credits. Thus, Karma sets the number of initial credits to a large numerical value to ensure that no user ever runs out of credits<sup>2</sup>,

**User churn.** Fairness is relatively ill-defined when users can join and leave the system on a short-term basis (*e.g.*, when a user runs a short query with large parallelism, and then leaves the cluster). Also, recall from our motivating scenarios, fair resource allocation in private clouds is usually performed for long-running services. However, Karma still handles user churn since, in many realistic scenarios, the set of all users of the system may not be known upfront during system initialization. For users that join and leave over longer timescales, Karma handles user churn with a simple mechanism: its credits. When a new user joins, either the resource pool size remains fixed and the fair share of all users is reduced proportionally or the resource pool size increases and the fair share of users remains the same. The credits of the existing  $n - 1$  users do not change, and the new user is bootstrapped with initial credits equal to the current average number of credits across the existing  $n - 1$  users. Intuitively, users who have donated more resources than they have borrowed will have above-average credits, and those who have borrowed

<sup>2</sup>For example, in a system with 100 users with fair share of 100 slices, setting initial credits to say  $10^{13}$  will ensure that even a worst-case user with highest possible demand (10000 slices) during all quanta cannot run out of credits for  $\sim 31$  years, which is good enough for all practical purposes.

more than they have donated will have below-average credits. As such, initializing the new user with the average number of credits (heuristically) puts the new user on equal footing with an existing user that has borrowed and donated equal amounts of resources over time. When a user leaves the system, the fair share of the remaining users is increased proportionally (or resource pool size reduces while maintaining the same fair share), and there is no change in their credits.

**Users with different fair shares.** We have presented Karma’s algorithm for the case of users having the same fair share merely for simplicity: all our results extend to the case of users having different fair shares. To generalize the algorithm to users with different fair shares, users with larger weights are charged fewer credits to borrow resources beyond their guaranteed share when compared to users with smaller weights. Intuitively, this enables users with larger weights to obtain more resources than users with smaller weights for the same number of credits. We achieve this by updating Line 20 of Algorithm 1 to decrement credits by  $\frac{1}{n \cdot w_i}$  instead of 1, where  $w_i$  is the normalized weight of the corresponding user, and  $n$  is the number of users. For users with different fair shares, this generalization leads to the same properties and guarantees as discussed in §3.3 (the only difference, is that the upper bound factor in Lemma 2 changes from  $1.5\times$  to  $2\times$ ). A full description of the weighted version of the algorithm along with proofs of guarantees can be found in [71].

**System parameters, and interpretation for  $\alpha$ .** Karma has only one parameter:  $\alpha$ ; one can think of resource slice size and quantum duration as parameters, but these are irrelevant to Karma’s guarantees: they hold for any slice size and quantum duration, as long as demands change at coarse timescales than the quantum duration. The  $\alpha$  parameter in Karma provides a tradeoff between instantaneous and long-term fairness. Providers can choose any  $\alpha$  depending on the desired properties. Intuitively, an  $\alpha$  smaller than 1 leads to a larger portion of shared slices, giving Karma’s algorithm more flexibility in adjusting allocations to achieve better long-term fairness.

## 4 Karma Implementation Details

We have implemented Karma on top of Jiffy [41], an open-sourced elastic far memory system. Jiffy has a standard distributed data store architecture (Figure 5(a)): resources are partitioned into fixed-sized slices (blocks of memory) across a number of resource servers (memory servers), identified by their unique sliceIDs (referred to as blockIDs in Jiffy). A logically centralized controller tracks the available and allocated slices across the various resource servers and stores a mapping that translates sliceIDs to the corresponding resource server. We have implemented Karma as a new resource allocation algorithm at the Jiffy controller<sup>3</sup>.

<sup>3</sup>Karma can thus directly piggyback on Jiffy’s existing mechanisms for controller fault tolerance [41, Section 4] to persist its state across failures.

Users interact with the system through a client library that provides APIs for requesting resource allocation and accessing allocated resource slices. Users express their demands to the controller through resource requests which specify the number of slices required. The controller periodically performs resource allocation using the Karma algorithm and provides users with the sliceIDs of the resource slices that are allocated to them. Users can then directly access these slices from the resource servers through read or write API calls without requiring controller interposition. In the rest of this section, we discuss the key data structures and mechanisms required to integrate Karma with Jiffy.

Karma employs three key data structures to efficiently implement the policies and mechanisms outlined in §3: karmaPool, a credit map, and a rate map.

**karmaPool.** Recall from §3.2 that the karmaPool tracks the pool of donated slices and shared slices, and needs to be updated when resource allocations change. Also, the resource allocation algorithm should be able to efficiently select donated slices from a particular user while satisfying borrower demands (§3.2.2). To this end, the karmaPool is implemented as a hash map, mapping userIDs to the list of sliceIDs corresponding to slices donated by them. The list of sliceIDs corresponding to shared slices is stored in a separate entry of the same hash map. When resource allocations change, the corresponding sliceIDs are added to or removed from the corresponding lists. As such, karmaPool supports all updates in  $O(1)$  time.

**Credit Tracking.** Karma employs two data structures for tracking and allocating credits across various users: a rate map and a credit map. The rate map maps each user to the *rate* at which it earns or spends its credits every quantum, that is, the difference between the user’s guaranteed share and the number of its allocated slices in that quantum. The rate is positive when the user is earning (that is, has donated slices) and negative when it is spending credits (that is, has borrowed slices), respectively. The credit map, on the other hand, maps each user to a counter corresponding to its current credits.

Separating the rate map and credit map facilitates efficient credit tracking at each quantum: Karma simply iterates through the rate map entries, and updates the credit counters in the credit map based on the corresponding user credit rates. Since the rate map only contains entries for users with non-zero rates, Karma can efficiently update credits for only the relevant users. At the same time, Employing a hash-map for each of them permits  $O(1)$  updates to the user credit rate or number of credits while performing resource allocation.

**Borrowing and donating slices.** Karma realizes its credit-based prioritized allocation algorithm (§3.2) using two modules at the controller. First is a *slice allocator* that maintains the karmaPool to track and update slice allocations across users, and, second a *credit tracker* that maintains the current number of credits for any user (via Credit Map) and

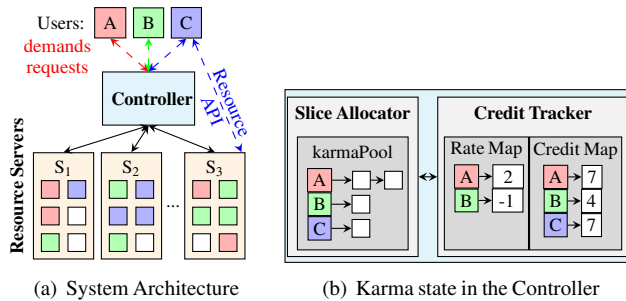

Figure 5: **Karma Design.** See §4 for details.

how it should be updated (via Rate Map). Figure 5(b) shows these modules along with the data structures they manage.

The slice allocator intercepts resource requests from users, periodically executes the Karma resource allocation algorithm (Algorithm 1) to compute allocations based on the user demands, and updates slices in the karmaPool accordingly. It interacts with the credit tracker to query and update user credits. A naïve implementation of Algorithm 1 runs in  $O(n \cdot f \cdot \log n)$  time, where  $n$  is the number of users, and  $f$  is the fair share<sup>4</sup>. Instead of computing allocations one slice at a time, we use an optimized implementation that carefully computes them in a batched fashion (full details are provided in [71]). This enables the slice allocator to support resource allocation at fine-grained timescales.

**Consistent hand-off of resources.** Since users are allowed to directly access slices from resource servers, we need to ensure consistent hand-off of slices from one user to another when slices are reallocated. For example, say user  $U_1$  has a slice during a given quantum, and in the next quantum, this slice is allocated to user  $U_2$ . We need to ensure that (1)  $U_1$ 's data is flushed to persistent storage before  $U_2$  overwrites it (2)  $U_1$  should not be able to read/write to the slice after  $U_2$  has accessed it (for example, there could be in-flight read/write requests to the slice which were initiated before  $U_1$  gets to know it's allocation changed).

Karma ensures the above by maintaining a monotonically increasing sequence number and current userID for each slice, at both the controller (within the karmaPool) and the resource servers (as slice metadata). On slice allocation, its userID is updated and its sequence number is incremented at the controller, and the sequence number is returned to the user. Subsequent user reads and writes to the slice specify this userID and sequence number. A slice read succeeds only if the accompanying sequence number is the same as the current slice sequence number, while a slice write succeeds only if the accompanying sequence number is the same or greater than the current sequence number. If a write necessitates an overwrite of the current slice content and metadata, the

<sup>4</sup>The loop in Line 10 of Algorithm 1 takes  $O(n \cdot f)$  iterations and each iteration would take  $O(\log n)$  time to find the donor/borrower with the minimum/maximum credits (if we were to maintain min/max heaps for the donor and borrower sets).

old slice content is transparently flushed persistent storage (e.g., S3) before the overwrite. In our example above,  $U_2$ 's first access to the slice after re-allocation will trigger a flush of  $U_1$ 's data to S3 and update the slice sequence number. Following this  $U_1$ 's accesses to this slice will fail since the current sequence number of the slices is higher.  $U_1$  can then read/write this data from persistent storage. Implementing consistent resource hand-off in Jiffy required minor changes to the controller (to track sequence numbers per slice), memory servers (to perform sequence number checking), and the client library (to tag requests with sequence numbers).

## 5 Evaluation

We have already established Karma properties theoretically in §3. In this section, we evaluate how Karma's properties translate to application-layer benefits over an Amazon EC2 testbed with real-world workloads. Our evaluation demonstrates that:

- Karma reduces the performance disparity between different users by  $\sim 2.4\times$  relative to classic max-min fairness, without compromising on system-wide utilization or average performance (§5.1);
- Karma incentivizes users to share resources, quantifying Karma's online strategy-proofness property (§5.2);

We primarily focus on the shared cache use case from §2 for the following reason. While datasets for the shared data analytics clusters use case are publicly available (e.g., Google and Snowflake datasets), they do not provide user queries that may impact our final conclusions. For the shared cache use case, we do have all the information we need: these datasets provide information on the working set size of each user over time, which can be fed into an end-to-end multi-tenant in-memory cache system running on Amazon EC2. We, thus, focus on this use case.

**Experimental setup.** Our experimental setup consists of a distributed elastic in-memory cache shared across multiple users backed by a remote persistent storage system. For the cache, we use Jiffy [41], augmented with our implementation of Karma (§4) and other evaluated schemes. If the evaluated scheme does not allocate sufficient slices to a user on Jiffy to fit its entire working set, the remaining data is accessed from remote persistent storage. When slices are reallocated between users across quanta, the corresponding data is moved between Jiffy and persistent storage through the consistent hand-off mechanism described in §4. We deployed our setup on Amazon EC2 using c5n.9xlarge instances (36 vCPUs, 96GB DRAM, 50Gbps network bandwidth). We host the Jiffy controller and resource servers across 7 instances and use 25 instances for the users/clients that issue queries to Jiffy. We use Amazon S3 as the persistent storage system.

**Workload.** We use the publicly available Snowflake dataset [72] that provides dynamic user demands in terms of memory usage for each customer from Snowflake's

Figure 6: **Understanding Karma benefits.** (a) Karma enables a much tighter throughput distribution across users (colored arrows show the absolute gap between median and minimum throughput across users). (b, c) It also enables a tighter distribution of average and tail latencies across users (again, colored arrows show the absolute gap between median and maximum latency across users). (d) Karma achieves much lower throughput disparity—ratio of median to minimum values of throughput across users—than classic max-min fairness. (e) It also significantly reduces the gap between the users with minimum and maximum overall allocations, (f) while achieving similar system-wide performance as max-min fairness.

production cluster. We use these demands as the dynamic working set size for individual users. For each user, we issue data access queries using the standard YCSB-A workload [20] (50% read, 50% write) with uniform random access distribution, with queries during each quantum being sampled (according to the YCSB parameters) within the instantaneous working set size of that user. If a query references data that is currently cached in Jiffy, then it is serviced directly from the corresponding resource server; otherwise, it is serviced from the persistent storage.

**Default parameters.** Unless specified otherwise, we randomly choose 100 users (out of  $\sim 2000$  users) over a randomly-chosen 15 minute time window (out of a 14-day period) in the Snowflake workload. To test for extreme scenarios, we set the length of each quantum to be one second (that is, a total of 900 quanta). The fair share of each user is 10 slices, and the total memory capacity of the system is set to the number of users times the fair share (1000 slices). Each slice is 128MB in size, while each query corresponds to a read or write to a 1KB chunk of data (the default size in the YCSB workload).

**Compared schemes.** We compare Karma to strict partitioning and max-min fairness, since they correspond to the two most popular fair allocation schemes, and represent extremes in resource allocation and performance. When evaluating Karma,

we set the number of initial credits to a large value<sup>5</sup>. The fraction of fair share that is guaranteed ( $\alpha$ ) is 0.5 by default.

**Metrics.** We evaluate system-wide resource utilization, along with both per-user and system-wide performance—key metrics for any resource allocation mechanism. For performance, we measure both throughput and latency (average and 99.9th percentile tail). We define performance *disparity* for an allocation scheme as the ratio of median to minimum performance (that is, throughput or latency) observed across various users. For any given user, we define *welfare* over time  $t$  as  $\frac{\sum_t \text{allocations}}{\sum_t \text{demands}}$ , that is, the fraction of its total demands satisfied by the allocation scheme. We define *fairness* as  $\frac{\min_{\text{users}} \text{welfare}}{\max_{\text{users}} \text{welfare}}$  (higher is better, 1 is optimal), as a measure of welfare disparity between users.

## 5.1 Understanding Karma Benefits

We now evaluate Karma’s benefits in terms of reducing disparity across users’ application-level performance as well as resource allocation.

**Karma reduces performance disparity between users.** Figure 6(a) shows the throughput distribution across users for our compared schemes; the y-axis is presented in log-scale to

<sup>5</sup>As discussed in §3.4, the precise value is unimportant. Here, we set it to 900,000, so that even if a user was allocated the full system capacity for the entire duration ( $1000 \times 900$ ) it would not run out of credits.

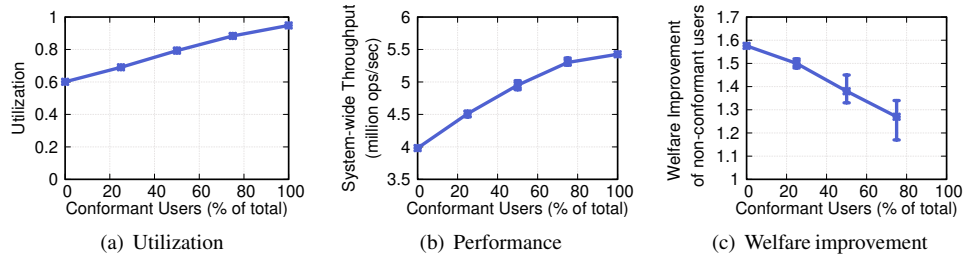

Figure 7: **Karma incentivizes resource sharing.** All metrics are computed as averages (with error bars) for three random selections of users being non-conformant. See §5.2 for details.

focus on the users at the tail of the distribution, which observe the most performance disparity. Since Karma strives to balance fairness over time, it significantly narrows the throughput distribution across users compared to the two baselines: the ratio between the maximum and minimum throughput across all users is  $7.8\times$  with strict partitioning and  $4.3\times$  with max-min fairness, but only  $1.8\times$  for Karma. As Figure 6(d) shows, Karma lowers the throughput disparity across users by  $2.4\times$  compared to max-min fairness. Karma also reduces average latency disparity (Figure 6(b)) by  $2.4\times$  and 99.9th percentile latency disparity (Figure 6(c)) by  $1.2\times$  compared to max-min fairness by enabling a tighter distribution for both latencies.

Equitability in performance across users for a scheme is closely tied to how fairly resources are allocated across users. Specifically, because of the large gap between elastic memory (Jiffy) and S3 latencies ( $50\text{--}100\times$ ), accesses to slices in S3 result in significantly lower throughput than accesses to slices in elastic memory. As a result, users’ average throughput ends up being roughly proportional to their total allocation of slices in elastic memory over time. Similarly, since a larger total allocation results in a smaller fraction of requests going to S3, average and tail latencies also reduce.

**Karma reduces disparity in allocations.** We now quantify disparities in overall allocations obtained by users across our compared schemes via our fairness metric in Figure 6(e). Due to dynamic demands, strict partitioning exhibits very poor fairness, since users with very bursty demands end up getting much lower total allocations than users who have steady demands<sup>6</sup>. While, max-min fairness observes better fairness compared to strict partitioning, the best-off user still receives  $4\times$  higher allocation than the worst-off user, resulting in poor absolute fairness. Karma achieves significantly better fairness with the best-off user receiving only  $1.5\times$  higher allocation than the worst-off user. It is able to achieve this by prioritizing the allocation of resources beyond the fair share to users with more credits (§3.2.2).

**Karma achieves Pareto efficiency and high system-wide performance.** Karma achieves the same overall resource

<sup>6</sup>Note that only *useful* allocations are considered—strict partitioning guarantees a fixed allocation at all times, but resources may remain unused when demand is low.

utilization as max-min fairness ( $\sim 95\%$ ). This is because Karma is Pareto efficient (§3.3) similar to max-min fairness and thus achieves near-optimal utilization. We find that the optimal utilization is  $< 100\%$  since some quanta observe total user demands less than system capacity.

Max-min fairness observes  $1.4\times$  higher system-wide throughput (that is, throughput aggregated across all users) than strict partitioning (Figure 6(f)) since it permits allocations beyond the fair share, allowing more requests to be served on faster elastic memory. Karma observes system-wide performance similar to max-min fairness for similar reasons; the slight variations are attributed to variance in S3 latencies.

## 5.2 Karma Incentives

We now empirically demonstrate that Karma incentivizes users to donate resources instead of hoarding them, to improve their own as well as overall system welfare. To this end, we vary the fraction of users using Karma that are *conformant* or *non-conformant*. A conformant user is truthful about its demands and donates its resources when its demand is less than its fair share. A non-conformant user, on the other hand, always asks for the maximum of its demand or its fair share (that is, it over-reports its demand during some quanta).

**Resource utilization and system-wide performance improve with more conformant users.** Figure 7(a) and Figure 7(b) show that Karma’s system-wide utilization and performance improve as the fraction of conformant users increases. This is because as more users donate resources when they do not need them, other users can use these resources, improving overall utilization and performance. When none of the users are conformant, since no one ever donates any resources, Karma essentially reduces to strict partitioning, hence achieving low overall utilization and performance. When all users are conformant, Karma achieves optimal utilization and performance, similar to classic max-min fairness.

**Becoming conformant improves user welfare.** Figure 7(c) shows the average welfare gain non-conformant users would achieve if they were to become conformant. When non-conformant users become conformant, it leads to significant ( $1.17\text{--}1.6\times$ ) welfare gains for them, empirically

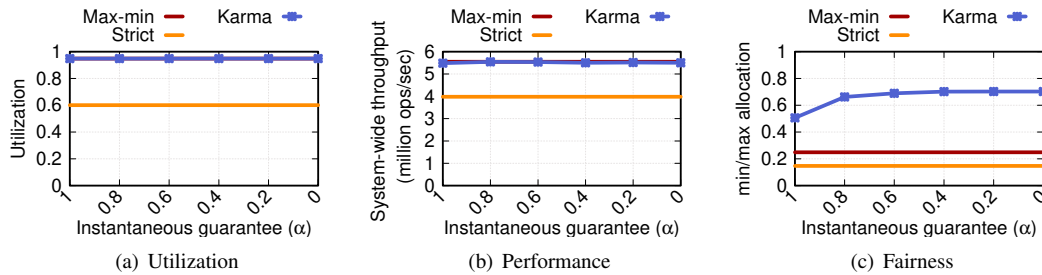

Figure 8: **Sensitivity analysis with varying instantaneous guarantee ( $\alpha$ )** (a, b) Karma matches the resource utilization and system-wide performance of max-min fairness independent of  $\alpha$  (c) Smaller values of  $\alpha$  result in improved long-term fairness.

validating Karma’s property that users have nothing to gain by over-reporting their demand (§3.3). Note that the gain varies with the number of conformant users in the system—the gains from non-conformant users becoming conformant are higher when the percentage of conformant users is low. As expected, the gains show diminishing returns as more users in the system become conformant as overall utilization is already high.

### 5.3 Karma Sensitivity Analysis

We now show sensitivity analysis with the only parameter in the Karma algorithm—the instantaneous guarantee ( $\alpha$ ). Figure 8 shows the resource utilization, system-wide performance, and fairness with  $\alpha$  varying between 0 and 1. Karma continues to match the resource utilization and system-wide performance of max-min fairness independent of  $\alpha$  (Figure 8(a) and Figure 8(b)). Varying  $\alpha$  has an impact on the long-term fairness achieved by Karma (Figure 8(c)), with smaller values of  $\alpha$  resulting in improved fairness, thus validating our discussion in §3.4. Even for  $\alpha = 1$ , Karma is able to achieve significantly better fairness compared to max-min fairness. This is because, while it allocates resources up to the fair share identically to max-min fairness, it prioritizes allocation beyond the fair share based on credits.

## 6 Related Work

There is a large and active body of work on resource allocation and scheduling, exploring various models and settings; it would be a futile attempt to compare Karma with each individual work. We do not know of any other resource allocation mechanism that guarantees Pareto efficiency, strategy-proofness, and fairness similar to Karma for the case of dynamic user demands; nevertheless, we discuss below the most closely related works.

**Max-min fairness variants in cloud resource allocation and cluster scheduling.** Many works study variants of max-min fairness for cloud resource allocation and cluster scheduling [8, 10, 17, 30–33, 44, 46, 57–59, 64, 66, 77], including recent work on ML job scheduling [15, 34, 47, 50, 55]. We make three important notes here. First, while dominant resource fairness

(DRF) [30] has generalized max-min fairness to multiple resources, it makes the same assumptions as max-min fairness: user demands being static over time; our goals are different: we have identified and resolved the problems with max-min fairness for the case of a single resource but over dynamic user demands. It is an interesting open problem to generalize Karma for the case of multiple resources.

Second, cluster scheduling has been studied under several metrics beyond fair resource allocation (*e.g.*, job completion time, data locality, priorities, etc.). Themis [47] considers long-term fairness but defines a new ML workload-specific notion of fairness, and is therefore not directly comparable to Karma. Our goals are most aligned with those works that study fair allocation under strategic users while guaranteeing Pareto efficiency. To that end, the closest to Karma is CARBYNE [32]. However, CARBYNE not only assumes non-strategic users but also, for the single-resource case (the focus of this paper), CARBYNE converges to max-min fairness. As discussed earlier, generalizing Karma to multiple resources remains an open problem; a solution for that problem must be compared against CARBYNE.

Finally, fairness in application-perceived performance is only indirectly related to fairness in resource allocation: other factors like software systems (*e.g.*, hypervisors and storage systems) and resource preemption granularity can impact performance. Similar to other mechanisms [9, 10, 16, 30–33, 39, 45, 46, 59, 60, 66, 67, 72, 77, 80], Karma’s properties are independent of these system-level factors; while our evaluation shows that Karma properties translate to application-level benefits, absolute numbers depend on the underlying system implementation.

**Allocation of time-shared resources.** Generalized Processor Sharing (GPS) [54] is an idealized algorithm for sharing a network link which assumes that traffic is infinitesimally divisible (fluid model). For equal-sized packets and equal flow weights, GPS reduces to Uniform Processor Sharing [54, Section 2], which is equivalent to max-min fairness. GPS guarantees fairness over arbitrary time intervals only under the assumption that flows are *continuously backlogged* [54, Section 2]. This assumption implies that

flows always have demand greater than their fair share, making it trivial to guarantee a max-min fair share of the network bandwidth over arbitrary time intervals. Classical fair-queueing algorithms [11, 24, 48, 65, 83] in computer networks approximate GPS with the constraint of packet-by-packet scheduling. Under this constraint, varying-sized packets and different flow weights make it hard to realize fairness efficiently; thus, the technical question that these algorithms solve is to achieve fairness approximately equal to GPS with minimal complexity. Karma focuses on a different problem—we show that GPS guarantees (equivalent to max-min fairness) are not sufficient when demands are dynamic and present new mechanisms to achieve fairness while maintaining other properties for such dynamic demands.

Stride [74] scheduling essentially approximates GPS in the context of CPU scheduling [74, Section 7], and thus the above discussion applies to it as well. DRF-Q [29] generalizes DRF to support both space and time-shared resources, but is explicitly designed to be memoryless similar to max-min fairness, and therefore suffers from similar issues for long-term fairness. Least Attained Service (LAS) [13, 43, 53] is a classical job scheduling algorithm that has been applied to packet scheduling [13], GPU cluster scheduling [34], and memory controller scheduling [42]. For  $\alpha = 0$ , Karma behaves similarly to LAS, and for  $\alpha > 0$ , Karma generalizes LAS with instantaneous guarantees. Moreover, our results from §3.3 establish strategy-proofness properties of LAS for dynamic user demands, which may be of independent interest.

**Theory works.** Several recent papers in the theory community study the problem of resource allocation for dynamic user demands. Freeman et al. [26] and Hossain et al. [37] consider dynamic demands under a different setting, where users can benefit when they are allocated resources above their demand; under this setting, they focus on instantaneous fairness (which is non-trivial since users can be allocated resources beyond their demand). Karma instead focuses on long-term fairness under the traditional model, where users do not benefit from resources beyond their demands. Sadok et al. [62] present minor improvements over max-min fairness for dynamic demands. Their mechanism allocates resources in a strategy-proof manner according to max-min fairness while marginally penalizing users with larger past allocations using a parameter  $\delta \in [0, 1)$ . For both  $\delta = 0$  and  $\delta \rightarrow 1$ , the penalty goes to 0 for every past allocation, and the mechanism becomes identical to max-min fairness; for other values of  $\delta$ , the penalty is at most a  $\delta(1 - \delta) \leq 1/4$  fraction of past allocation surplus, and it reduces exponentially with time (users who were allocated large amounts of resources further in the past receive an even smaller penalty). Thus, for all values of  $\delta$ , and in particular, for  $\delta = 0$  and  $\delta \rightarrow 1$ , their mechanism suffers from the same problems as max-min fairness. Aleksandrov et al. [7] and Zeng et al. [82] consider dynamic demands, but in a significantly different setting than ours where resources arrive over time.

**Pricing- and credit-based resource allocation.** Another stream of work related to Karma is pricing-based and bidding-based mechanisms for resource allocation, *e.g.*, spot instance marketplace and virtual machine auctions [1, 6, 27, 76, 84, 85]. While interesting, this line of work does not focus on fair resource allocation and is not applicable to use cases that Karma targets. XChange [75] proposes a market-based approach to fair resource allocation in multi-core architectures but focuses on instantaneous fairness rather than long-term fairness, unlike Karma. It assigns a “budget” of virtual currency to each user which can be used to bid for resources. This budget is however reset during every time quantum, and therefore information about past allocations is not carried over.

Credits are used in many other game theoretic contexts [25, 51, 61], *e.g.*, in peer-to-peer and cooperative caching settings to incentivize good behavior among participants with static demands [21, 56, 78]. However, we are not aware of any credit-based mechanisms that deal with resource allocation in the context of dynamic user demands.

## 7 Conclusion

This paper builds upon the observation that the classical max-min fairness algorithm for resource allocation loses one or more of its desirable properties—Pareto efficiency, strategy-proofness, and/or fairness—for the realistic case of dynamic user demands. We present Karma, a new resource allocation mechanism for dynamic user demands, and theoretically establish Karma guarantees related to Pareto efficiency, strategy-proofness, and fairness for dynamic user demands. Experimental evaluation of a realization of Karma in a multi-tenant elastic memory system demonstrates that Karma’s theoretical properties translate well into practice: it reduces application-level performance disparity by as much as  $2.4\times$  when compared to max-min fairness while maintaining high resource utilization and system-wide performance.

Karma opens several exciting avenues for future research. These include (but are not limited to) extending Karma theoretical analysis for  $\alpha > 0$ , generalizing Karma to allocate multiple resource types (similar to DRF), extending Karma to handle all-or-nothing or gang-scheduling constraints which are prevalent in the context of GPU resource allocation [15, 47], and applying Karma to other use cases such as inter-datacenter network bandwidth allocation and resource allocation for burstable VMs in the cloud.

## Abstract

Model parallelism is conventionally viewed as a method to scale a single large deep learning model beyond the memory limits of a single device. In this paper, we demonstrate that model parallelism can be additionally used for the statistical multiplexing of multiple devices when serving multiple models, even when a single model can fit into a single device. Our work reveals a fundamental trade-off between the overhead introduced by model parallelism and the opportunity to exploit statistical multiplexing to reduce serving latency in the presence of bursty workloads. We explore the new trade-off space and present a novel serving system, AlpaServe, that determines an efficient strategy for placing and parallelizing collections of large deep learning models across a distributed cluster. Evaluation results on production workloads show that AlpaServe can process requests at up to 10× higher rates or 6× more burstiness while staying within latency constraints for more than 99% of requests.

## 1 Introduction

Advances in self-supervised learning have enabled exponential scaling in model sizes. For example, large pretrained models like BERT [14] and GPT-3 [5] have unlocked a plethora of new machine learning (ML) applications from Copilot [18] to copy.ai [7] and ChatGPT [35].

Serving these very large models is challenging because of their high computational and memory requirements. For example, GPT-3 requires 325 GB of memory to store its parameters as well as a requisite amount of computation to run inference. To serve this model, one would need at least 5 of Nvidia’s newest Hopper 80 GB GPUs just to hold the weights and potentially many more to run in real-time. Worse yet, the explosive growth of model sizes continues unabated [6, 17]. Techniques like model compression and pruning are not sufficient in face of the exponential growth in model sizes and often come at the expense of reduced model quality [15].

\*Equal contribution.

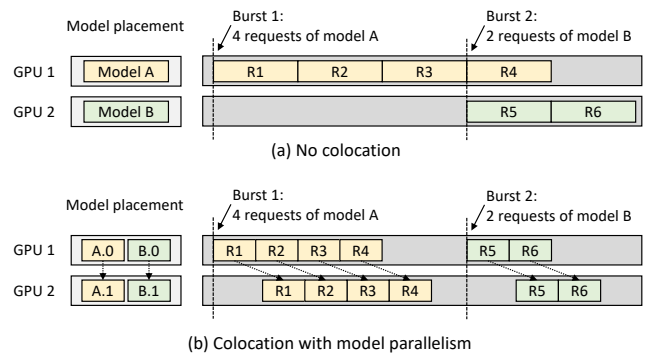

Figure 1: Two placement strategies for serving two models on two GPUs. In each subfigure, the left part shows the model placements and the right part shows the timeline for handling bursty requests. At the time of "Burst 1", 4 requests of model A come at the same time. Collocation with model parallelism can reduce the average completion time of bursty requests.

Provisioning sufficient resources to serve these models can be arduous as request rates are bursty. For example, using common workload traces, we observe frequent spikes in demand of up to 50× the average [54]. Meeting the service level objective (SLO) of latency usually means provisioning for these peak loads, which can be very expensive; additional devices allocated for this purpose would remain underutilized most of the time. Making matters worse, it is increasingly common to serve multiple models and multiple variations of the same large model in situations like A/B testing or serving fine-tuned models for specific domains (§2).

This paper studies how to efficiently serve multiple large models concurrently. Specifically, we explore the underappreciated benefits of model parallelism in online model serving, even for smaller models that can fit on a single device. Model parallelism refers to partitioning and executing a model on distributed devices (§2.1). The benefits of model parallelism have been well studied [23, 27, 31, 56] in the *throughput-oriented* training setting. However, its effects for model serving under *latency-sensitive* settings remains largely untapped.

We observe that there are fundamental transition points in

the model serving design space that challenge prior assumptions about serving, even for models that fit on a single device. For example, consider the scenario with two models and two GPUs, each of which has sufficient memory to hold one complete model. As shown in Fig. 1(a), the natural approach assumed by almost all existing serving systems [9, 33, 34] is to allocate one dedicated GPU for one model. This approach appears rational because partitioning the model across GPUs would incur communication overheads that would likely increase the prediction latency. However, we find that inducing additional model parallelism (to the point where per-example execution time actually *increases*) enables a wider range of placement strategies, e.g., model co-location, which can improve the statistical multiplexing of the system under bursty workloads. In Fig. 1(a), assuming the execution time of a model is  $y$ , the average end-to-end latency of request 1 through 4 is  $(1y + 2y + 3y + 4y)/4 = 2.5y$ . In Fig. 1(b), assuming a 10% model-parallel overhead, the average latency of request 1 through 4 is reduced to  $(1.1y + 1.6y + 2.1y + 2.6y)/4 = 1.85y$ . Co-location with model parallelism can utilize more devices to handle bursty requests and reduces the average completion time, despite its overheads (§3.1). Even if we batch the requests, the case still holds (§6.5).

Unfortunately, the decision of how to optimally split and place a collection of models is complex. Although leveraging model parallelism as above has its benefits, it still adds overheads that may negate those benefits for less bursty workloads. For example, we find that a particularly influential axis on the efficacy of model parallelism is per-GPU memory capacity (§3.2), although other factors (e.g., the arrival pattern, SLO) can also have a significant effect. Further, besides the inter-op model parallelism presented in Fig. 1, another kind of model parallelism, intra-op parallelism, presents its own distinct tradeoffs (§3.3). Ultimately, different styles of parallelism and their tradeoffs create a complex, multi-dimensional, and multi-objective design space that existing systems largely ignore and/or fail to navigate. However, not leveraging model parallelism in the serving setting is typically not an option for large models, and not addressing this trade-off space directly results in significant increases in cost and serving latency.

To that end, we present AlpaServe<sup>2</sup>, a system that automatically and efficiently explores the tradeoffs among different parallelization and placement strategies for model serving. AlpaServe takes a cluster resource specification, a set of models, and a periodic workload profile; it then partitions and places the models and schedules the requests to optimize SLO attainment (i.e., the percentage of requests served within SLO). To assist the design of AlpaServe, we first introduce a taxonomy and quantify the tradeoffs between different parallelization strategies in model serving (§3). We then present key algorithms to navigate the tradeoff space (§4). We design an iterative simulator-guided model placement algorithm

to optimize the collocation of models and a group partition algorithm to search for the best way to partition the cluster into disjoint model-parallel groups. In addition, we extend the existing auto-parallelization algorithms for training to make them more suitable for inference.

We evaluate AlpaServe with production workloads on a 64-GPU cluster (§6). Evaluation results show that, when optimizing one metric at a time, AlpaServe can choose to increase the request processing rate by  $10\times$ , achieve  $2.5\times$  lower latency deadlines, or tolerate  $6\times$  burstier traffic compared to previous state-of-the-art serving systems.

In summary, we make the following contributions:

- A detailed analysis of the tradeoff space of different model parallel strategies for efficient model serving.
- Novel model placement algorithms to incorporate model parallelism in a serving system.
- A comprehensive evaluation of AlpaServe with both synthetic and production workloads.

## 2 Background

Over the past few years, increasingly capable models have been developed for everything from recommendations to text generation. As a result, serving predictions from these models has become an essential workload in modern cloud systems. The structure of these workloads often follows a simple request-response paradigm. Developers upload a pre-trained model and its weights ahead of time; at runtime, clients (either users or other applications) submit requests for that model to a serving system, which will queue the requests, dispatch them to available GPUs/TPUs, and return the results.

The requirements of these model-serving systems can be stringent. To satisfy user demand, systems often must adhere to aggressive SLO on latency. At the same time, serving systems that must run continuously need to minimize their operational costs associated with expensive accelerators. Minimizing serving costs can be challenging because dynamically scaling compute resources would be too slow on the critical path of each prediction request: it can take multiple seconds just to swap a large model into accelerator memory [37]. Furthermore, there is significant and unpredictable burstiness in the arrival process of user requests. To meet tight SLO, contemporary serving systems are forced to over-provision compute resources, resulting in low cluster utilization [48].

Another pattern that emerges in serving large models is the use of multiple instances of the same or similar model architectures. This is commonly seen in the practice of pretraining on large unlabeled data and fine-tuning for various downstream tasks [14], which can significantly boost accuracy but results in multiple instances of the same model architecture. For example, Hugging Face serves more than 9,000 versions of fine-tuned BERT [24]. They either share a portion of the parameters or do not share any parameters at all for better accuracy. Prior works have [44, 57] exploited the property of shared parameters, but we do not consider the shared parame-

<sup>2</sup><https://github.com/alpa-projects/mms>

ters in this paper because AlpaServe targets general settings and full-weight tuning is still a major use case.

## 2.1 Model Parallelism in Model Serving

Distributed parallel model execution is necessary when attempting to satisfy the serving performance requirements or support large models that do not fit in the memory of a single device. At a high level, distributed execution of deep learning models can be classified into two categories: intra-operator parallelism and inter-operator parallelism [56].

**Intra-operator parallelism.** DL models are composed of a series of operators over multidimensional tensors, e.g., matrix multiplication over input and weight tensors. Intra-operator parallelism is when a single operator is partitioned across multiple devices, with each device executing a portion of the computation in parallel [43, 45, 50]. Depending on the specific partitioning strategy and its relationship to prior and subsequent operators in the model, partitioning can require communication among participating GPUs to split the input and then merge the output.

The benefit of intra-operator parallelism for single-request execution is twofold. First, it can expand the total amount of computation available to the target model, reducing its end-to-end latency. In a similar fashion, it can expand the total memory available to the model for storing its inputs, weights, and intermediate values. The cost is the aforementioned communication overhead.

**Inter-operator parallelism.** The other type of parallelism available to DL models is inter-operator parallelism, which assigns different operators of the model’s execution graph to execute on distributed devices in a pipeline fashion (a.k.a. pipeline parallelism) [23, 28, 30]. Here, devices communicate only between pipeline stages, typically using point-to-point communication between device pairs.

Unlike intra-operator parallelism, pipeline parallelism does not reduce the execution time of a single request. In fact, it typically increases the execution time due to modest amounts of communication latency between pipeline stages, although the total amount of transferred data is often lower than it is in intra-operator parallelism. Instead, the primary use of inter-operator parallelism in traditional serving systems is to allow the model to exceed the memory limitation of a single GPU.

## 3 Motivation and Tradeoff Analysis

As mentioned, both types of model parallelism reduce per-device memory usage by partitioning a model on multiple devices. A key motivation for this work is that we can use this property to fit more models on one device, enabling better statistical multiplexing of the devices when handling bursty requests. We explore this idea through a series of empirical examinations and theoretical analysis, starting with an illustrative example (§3.1), followed by an empirical analysis of when model parallelism is beneficial (§3.2), the overhead of

model parallelism (§3.3), and a queueing theory-based analysis (§3.4). All the experiments in this section are performed on an AWS EC2 p3.16xlarge instance with 8 NVIDIA 16GB V100 GPUs.

### 3.1 Case Study: A Two-model Example

We start with an illustrative experiment to show how model parallelism can benefit the serving of multiple models. We use two GPUs to serve two Transformer models with 6.7 billion parameters each (13.4 GB to store its FP16 weights). Because each GPU has 16 GB of memory, it can fit one and only one model. A single request takes around 0.4 s to process on one GPU.

We compare the following model placements, corresponding to the strategies in Fig. 1. The first is *simple placement*, where we place one model on each GPU due to the memory constraint. The second is *model-parallel placement*, where we use inter-op parallelism to partition each model to a 2-stage pipeline and let each GPU execute half of each model.

We evaluate the two placements when the requests to each model follow an independent Poisson process with an arrival rate of 1.5 request/s. Fig. 2a shows the cumulative distribution function (CDF) and average of request latency (which includes the GPU execution time and queuing delay). Model-parallel placement reduces the average latency of the simple placement from 0.70s to 0.55s, a  $1.3\times$  speedup. The speedup comes from the better burst tolerance: when a burst arrives that exceeds the capability of a single GPU, simple placement must begin queuing requests. However, as long as the other model does not receive many requests, the model parallel placement can use both GPUs to serve the requests for the popular model via statistical multiplexing of the GPUs.

This effect becomes more pronounced with higher burstiness, which we can demonstrate using a Gamma request arrival process with the same average request rate as above but a higher coefficient of variance (CV) of 3. As shown in Fig. 2b, the speedup on mean latency is now increased to  $1.9\times$ . Fig. 2d shows a representative trace of the corresponding total cluster utilization over time. Note that for each request burst, model-parallel placement can use the whole cluster and only take half of the time to process, while simple placement can only use half of the cluster.

In addition, we also evaluate the case where one model receives more requests than another. In Fig. 2c, we use Poisson arrival but let 20% of the requests ask for model 1 and 80% ask for model 2. Although replication performs slightly better for model 1 requests, it is drastically worse on model 2 requests compared to the model-parallel placement. For model-parallel placement, because both GPUs are shared across two models, the requests to both models follow the same latency distribution. Overall, model-parallel placement reduces the mean latency by  $6.6\times$ .

Figure 2: Latency CDF and cluster utilization in the 2-model example.

Figure 3: Replication and model parallel placement illustration with different memory budgets, where the memory budgets are set to be multiples of a single model’s size.

Figure 4: Serving performance with changing per-GPU memory budgets. Model parallelism is beneficial for limited memory budget. The dashed vertical line is the real per-GPU memory bound of a 16GB V100. The value is around 13GB due to the need to store activations and other runtime context.

### 3.2 When is Model Parallelism Beneficial

To further explore the nuances of model parallelism in serving, we increase the size of the deployment to 8 GPUs and 8 Transformer models with 2.6B parameters each. As a base setting, we set the requests to each model as a Gamma process with an average rate of 20 request/s and CV of 3; we then vary a range of factors to see their effects. Note that some of the settings we evaluate are impossible on real hardware (e.g., exceeding the memory capacity of a single device) so we leverage the simulator introduced in §5. The fidelity of the simulator is very high as verified in §6.1.

The model in this case is smaller (5.2GB), so one GPU can also store multiple models without model parallelism. We compare two placement methods: (1) *Replication*. In this setting, we replicate the models to different devices until each device cannot hold any extra models. Because all the models receive equal amounts of loads on average, we replicate each model the same number of times (Fig. 3a). (2) *Model Parallelism*.

Figure 5: Serving performance with changing arrival rates. Model parallelism is beneficial for smaller rates.

Figure 6: Serving performance with changing CVs. Model parallelism is beneficial for larger CVs.

*lism*. Here we use inter-operator parallelism and uniformly assign the Transformer layers to different GPUs.

**Device memory.** We evaluate the mean and the tail latency of the two placement methods under different device memory capacities. For replication, more GPU memory can fit more models onto a single GPU. For model parallelism, more GPU memory can also reduce the number of pipeline stages and reduce the overhead as in Fig. 3b. The resulting mean and P99 latency is shown in Fig. 4. With more memory, more models can fit into a single GPU, so the benefit of statistical multiplexing diminishes because replication can also effectively use multiple devices to serve the bursty requests to a single model. When the GPU memory capacity is large enough to hold all models, there is no gain from model parallelism.

**Request arrival.** We vary the parameters of the arrival process and compare the replication placement with the model-parallel placement with 8-stage pipeline parallelism. The mean and P99 latency results of changing arrival rate are shown in Fig. 5. When the arrival rate is low, model parallelism can greatly reduce the serving latency. However, when the arrival rate approaches the peak serving rate of the cluster, the benefit of model-parallel placement starts to diminish. Eventually, it starts to perform worse than replication. This is because when all models are equally saturated, the replication

Figure 7: SLO attainment with changing SLOs. Model parallelism is beneficial for smaller SLOs.

placement is able to achieve efficient cluster utilization and there is no benefit to the statistical multiplexing afforded by model parallelism. Instead, the overhead of model parallelism (§3.3) starts to become a significant factor.

The mean and P99 latency results of changing CV are in Fig. 6. With a higher CV, the requests become more bursty, and the benefit of model parallelism becomes more significant. As shown in the results, with a higher CV, model parallelism can greatly outperform the performance of replication.

**Service level objectives.** In prediction serving settings, it is common to have tight latency SLO and predictions made after these deadlines are often discarded [19]. For example, advertising systems may choose not to show an ad rather than delay rendering user content. In this case, the goal of the serving system is to optimize the percentage of requests that can be finished within the deadline, i.e., *SLO attainment*.

In this experiment, we measure how SLOs affect the performance of the placement methods. We compare the replication and the model-parallel placement with 8-stage pipeline parallelism. During execution, we drop the requests that will exceed the deadline even if we schedule it immediately. We scale the SLO to different multiplies of the single device execution latency (*SLO Scale* in Fig. 7a) and compare the SLO attainment of the two methods.

As in Fig. 7a, when SLO is tight ( $< 10\times$  model latency), model parallelism can greatly improve SLO attainment. However, when the SLO becomes looser, its SLO attainment plateaus but that of the replication placement keeps growing. This result shares the same core logic as previous experiments: When SLO becomes looser, more requests can stay in the waiting queue, and thus the effective burstiness of the requests decreases. When many requests are queued, the system is bounded by its total processing capability, which might be affected by the model parallelism overhead. In the real world, the SLO requirement is often less than  $5\times$  of the model execution latency [19], where model parallelism can improve SLO attainment.

**Summary:** Model parallelism benefits model serving through statistical multiplexing when the device memory is limited, the request rate is low, the request CV is high, or the SLO is tight.

(a) Inter-op parallelism. (b) Intra-op parallelism.

Figure 8: The overhead decomposition. The overhead of inter-op parallelism mainly comes from uneven partition while the overhead of intra-op parallelism comes from communication.

### 3.3 Overhead of Model Parallelism

In this section, we further investigate the overheads of different model parallel strategies and how they affect serving performance. Similar to the setup in Fig. 7a, we manually modify the overhead of model parallelism. Specifically, let the latency of a single model executing on the GPU be  $L$  and the number of pipeline stages be  $n$ . We set the total latency of pipeline execution to be  $\alpha L$  and the latency of each pipeline stage to be  $\alpha L/n$ , where  $\alpha$  is a parameter that controls the overhead. When  $\alpha = 1$ , model parallelism does not have any overhead and larger  $\alpha$  means higher overhead.

We show the results in Fig. 7b. If model parallelism does not have any overhead ( $\alpha = 1$ ), it can always outperform replication due to its ability to multiplex the devices. When the overhead becomes larger and the SLO is low, model parallelism still outperforms replication. However, with a larger SLO, the effective burstiness is reduced and the performance is dominated by the overhead.

Given that the overhead can greatly affect serving performance, we perform a detailed study of the multiple sources of model-parallel overhead in Fig. 8. For inter-op parallelism, when partitioning a single model into multiple stages, different stages need to communicate the intermediate tensors, and we denote this overhead as the *communication overhead*. In addition, the pipeline execution will be bottlenecked by the execution time of the slowest stage, making the effective latency to be the number of pipeline stages times the latency of the slowest stage [23]. We denote this as the *uneven partition overhead*. As in Fig. 8a, for inter-op parallelism, most overhead comes from the latency imbalance among different pipeline stages, instead of the communication between stages. While our previous discussion mainly focuses on inter-op parallelism, the other type of model parallelism, intra-op parallelism, has very different performance characteristics. Its overhead is merely brought by the collective communication across multiple devices [31], which cannot be overlapped with the neural network computation due to data dependency. From Fig. 8b, we can see that the communication overhead of intra-op parallelism is much higher than inter-op parallelism.

Finally, we compare the latency, throughput, and memory consumption of different model-parallel placements and the

Figure 9: The latency, throughput and memory usage vs. #GPUs for inter-op parallelism, intra-op parallelism, and replication. In subfigure (c), the lines for inter-op and intra-op parallelism overlap.

replication placement in Fig. 9. Because of the sequential dependence between the different stages, inter-op parallelism cannot reduce the execution latency of a single input data. Instead, the latency is slightly higher due to the communication between the stages. On the other hand, intra-op parallelism can largely reduce the latency via the parallel execution of different GPUs (Fig. 9a). However, because inter-op parallelism can pipeline the execution of different stages and only communicate a relatively small amount of data, it attains higher throughput compared to intra-op parallelism (Fig. 9b). Because both parallel methods split the model weight tensors across different GPUs, the total memory usage stays constant with increasing numbers of GPUs (Fig. 9c). This makes the statistical multiplexing of different GPUs across multiple models possible.

In the end, the tradeoff between parallelization strategies and their interplay with cluster resources, arrival patterns, and serving objectives forms an intricate design space.

### 3.4 Queuing Theory Analysis

In this section, we use queuing theory to mathematically verify the conclusions in §3.2 and §3.3. Specifically, we analyze the case where the inputs follow the Poisson arrival process. Since the execution time of a deep learning inference task is highly predictable [19], we assume the request serving time is deterministic. For the single device case, suppose the request rate to a model is  $\lambda_0$  and the single device latency is  $D$  with the utilization  $\lambda_0 D < 1$ , then the average number of requests  $L_Q$  and the average latency  $W$  in this M/D/1 queue [46] are:

$$L_Q = \frac{\lambda_0 D}{2(1 - \lambda_0 D)}, \quad W = D + L_Q D = D + \frac{\lambda_0 D^2}{2(1 - \lambda_0 D)}.$$

Now consider the example in §3.1. Let  $p\lambda, (1-p)\lambda$  be the average request rates for the two models respectively, where  $p \in [0, 1]$  controls the percentage of requests for both models. Then for the simple placement, the average latency can be derived as the average latency of two independent queues:

$$W_{simple} = D + \frac{p^2 \lambda D^2}{2(1 - p\lambda D)} + \frac{(1-p)^2 \lambda D^2}{2(1 - (1-p)\lambda D)}.$$

Figure 10: Maximal communication overhead  $\alpha$  and uneven partition overhead  $\beta$  satisfy  $W_{pipeline} \leq W_{simple}$  as a function of total utilization  $\lambda D$ .

Note that  $W_{simple}$  reaches minimum when  $p = 1/2$ . Intuitively, when  $p$  is not exactly half, one model receives more requests than the other. This larger portion of requests have a longer queuing delay, which leads to the higher overall mean latency.

For the model-parallel case, the requests to both models merged to a single Poisson Process with rate  $\lambda$ . For pipeline parallelism, suppose the latency for a single input to be  $D_s$  and the maximum stage latency to be  $D_m$ , then the average latency would be

$$W_{pipeline} = D_s + \frac{\lambda D_m^2}{2(1 - \lambda D_m)}.$$

Suppose there is no model-parallel overhead, then  $D_s = 2D_m = D$ . Let's first consider the case where  $p = 1/2$  (Fig. 2a). We have

$$W_{simple} = D + \frac{\lambda D^2}{4 - 2\lambda D}, \quad W_{pipeline} = D + \frac{\lambda D^2}{8 - 4\lambda D}.$$

In this case, the waiting time for model-parallel execution is half of the simple placement waiting time, as shown in the vertical lines in Fig. 2a. When the  $p$  is not 1/2,  $W_{simple}$  will increase while  $W_{pipeline}$  will stay the same, so the gap between  $W_{simple}$  and  $W_{pipeline}$  will be even larger, as in Fig. 2c.

Next, we consider the case where model parallelism incurs overhead. We measure the two types of overheads in §3.3 separately: With the overhead from communication,  $D_s = 2D_m = \alpha D$ , where  $\alpha \geq 1$  is the overhead factor. With the overhead from uneven stages, we suppose  $D_s = D$  still holds, but  $D_m = \beta D/2$  where  $\beta \geq 1$  is the overhead factor. To keep  $W_{pipeline} \leq W_{simple}$ , we can get the maximal  $\alpha$  and

Figure 11: AlpaServe Runtime System Architecture

$\beta$  as a function of the total utilization  $\lambda D$  separately and we visualize the function in Fig. 10. When the utilization is high, the benefit of statistical multiplexing diminishes, and thus the overhead needs to be low, as in §3.2. On the other hand, when the utilization is very low, most requests will not be queued, and thus the communication overhead  $\alpha$  needs to be low to keep the processing latency to be low. Note that the maximal overhead here is based on a uniform Poisson arrival distribution. A more bursty or more non-uniform arrival distribution will make the simple placement performs worse and make the model-parallelism placement outperforms the simple replication placement with even higher overhead.

## 4 Method

From §3, we can see that there are several key challenges to effectively utilize model parallelism for deep learning serving:

- Derive efficient model parallel strategies for inference to reduce the overhead of model parallelism. Specifically, find a partitioning strategy that minimizes the stage imbalance for inter-operator parallelism.
- Determine model-parallel placements according to the arrival pattern to maximize SLO attainment.

We built *AlpaServe* to specifically tackle these challenges. The runtime architecture of AlpaServe is shown in Fig. 11. AlpaServe utilizes a centralized controller to dispatch requests to different groups.<sup>3</sup> Each group hosts several model replicas on a shared model-parallel runtime. This section describes the architecture of AlpaServe and the key algorithms for efficiently leveraging model parallelism in a model serving system.

### 4.1 Automatic Parallelization for Inference

Since different parallelization configurations have different latency and throughput trade-offs, we need to enumerate multiple possible configurations for every single model and let the placement algorithm choose the best combination for all models in the whole cluster. Therefore, given a model, AlpaServe first runs an auto-parallelization compiler with various constraints to generate a list of possible configurations. We build several extensions on top of an existing auto parallelization training system, Alpa [56], to make it suitable for generating serving parallelization strategies. Alpa includes two passes

<sup>3</sup>For a larger service, AlpaServe can be extended as a hierarchical deployment with each controller only managing a subset of devices as in [52].

for generating efficient model parallel partitions: inter-op pass and intra-op pass. The inter-op pass uses a dynamic programming (DP) algorithm to figure out the optimal inter-op parallel plan, and it calls the intra-op pass for each potential pipeline stage, which is formulated as an integer linear programming (ILP) problem, to profile its latency with the optimal intra-op parallel plan. In AlpaServe, we keep the two compilation passes, but extends both passes for serving.

The inter-op pass in Alpa optimizes the overall pipeline execution latency, which includes the time of forward and backward propagation and weight synchronization. However, in serving workloads, only forward propagation is being executed and there is no need for weight synchronization. Therefore, we reformulate the dynamic programming in AlpaServe to merely focus on minimizing the maximal stage latency. Specifically, denote  $F(s, k)$  to be the maximum latency when slicing layers 1 to  $k$  into  $s$  stages. We can derive  $F$  as

$$F(s, k) = \min_{1 \leq i \leq k} \{\max\{F(s-1, i-1), \text{latency}(i, k)\}\},$$

where  $\text{latency}(i, k)$  denotes the latency of a stage composes of layer  $i$  to  $k$ . In Alpa, the  $\text{latency}$  function of all possible  $O(K^2)$  combinations is being profiled by the intra-op pass because of the complicated dependency between forward and backward passes. In AlpaServe, because the pipeline stages only perform forward propagation and only communicate intermediate results once between layer boundaries, we can accelerate the profiling by only profiling  $K$  layers and letting  $\text{latency}(i, k)$  to be the sum of the latencies for layer  $i$  to  $k$ . This acceleration enables us to efficiently enumerate different inter- and intra-op device partition setups and generate a list of parallel strategies for the placement algorithm in §4.2.

For the intra-op pass, we extend the ILP in Alpa to drop all configurations that use data parallelism. For serving workloads, because there is no need for weight synchronization, data parallelism can be achieved by the replication placement. We leave the decision of whether to replicate a model to the placement algorithm in §4.2.

### 4.2 Placement Algorithm

Given a set of models and a fixed cluster, AlpaServe partitions the cluster into several groups of devices. Each group of devices selects a subset of models to serve using a shared model-parallel configuration. Different groups can hold the same model as replicas. The requests for a model are dispatched to the groups with the requested model replica. We call a specific cluster group partition, model selection, and parallel configuration as a *placement*. Our goal is to find a placement that maximizes the SLO attainment.

However, finding the optimal placement is a difficult combinatorial optimization problem. The overall placement configuration space grows exponentially with the number of devices and the number of models. To make things worse, the objective “SLO attainment” has no simple analytical formula for

---

**Algorithm 1** Simulator-Guided Greedy Model Selection.

beam_sels ← {∅}
while true do
  new_sels ← ∅
  for sel ∈ beam_sels do
    for (m, (g, p)) ∈ M × (G, P) do
      // Parallelize the model as in §4.1.
      m_parallelized ← parallelize(m, g, p)
      sel' ← sel.add_model_to_group(m_parallelized, g)
      if sel' is in memory constraint then
        sel'.slo_attainment ← simulate(sel', W)
        new_sels.append(sel')
  if new_sels = ∅ then
    break
  beam_sels ← top-k_SLO_attainment(new_sels)
  sel* ← pick_highest_SLO_attainment(beam_sels)
  if sel*.slo_att > best_sel.slo_att then
    best_sel ← sel*
return best_sel
```

---

an arbitrary arrival distribution. Existing tools and approximations from queueing theory can only analyze simple cases in §3.4 and cannot model more complex situations [46]. Therefore, we resort to a simulator-guided greedy algorithm that calls a simulator to compute SLO attainment.

To compute the SLO attainment with a given set of requests and placement, in AlpaServe, we assume we know the arrival process in advance. Although short-term burstiness is impossible to predict, the arrival pattern over longer timescales (e.g., hours or days) is often predictable [48]. Given this predictability, AlpaServe either directly uses the history request traces or fits a distribution from the trace and resamples new traces from the distribution as the input workload to the simulator to compute the SLO attainment.

We design a two-level placement algorithm: Given a cluster group partition and a shared model-parallel configuration for each group, Algorithm 1 uses a simulator-guided greedy algorithm to decide which models to select for each group. Then, Algorithm 2 enumerates various potential cluster partitions and parallel configurations and compares the SLO attainment from Algorithm 1 to determine the optimal placement.

Given a cluster group partition with a fixed model-parallel configuration for each group, Algorithm 1 selects model replicas iteratively as a beam search algorithm: At each iteration, it enumerates all possible (model, group) pairs, parallelizes the model on the device group with the algorithms in §4.1, and checks whether the model can be put on the group under the memory constraint. For all valid selections, it runs the

          plmi* ← plm
    plm* ← concat(plm1*, ..., plmk*)
  if plm*.slo_att > best_plm.slo_att then
    best_plm ← plm*
return best_plm
```

---

simulator and computes SLO attainment. It then picks the top- $k$  solutions and enters the next iteration. The algorithm terminates when no more replicas can be put into any groups.

The complexity of Algorithm 1 is  $O(MGRS)$ , where  $M$  is the number of models,  $G$  is the number of groups,  $R$  is the number of replicas we can put according to the memory constraint,  $S$  is the number of requests in the workload (the simulation time is proportional to the number of the requests) and  $B$  is the beam size. It runs reasonably fast for our medium-scale cluster when the number of requests is small. When the number of requests is very large, we propose another heuristic to accelerate: Instead of using the simulator to evaluate all (model, group) pairs at each iteration, we can run the simulator only once and place a model with the most unserved requests in an available group with the lowest utilization. This reduces the time complexity to  $O((M + G)RS)$ . We find this heuristic gives solutions with SLO attainment higher than 98% of the SLO attainment get by the original algorithm in our benchmarks.

Algorithm 2 enumerates different group partitions and model-parallel configurations and picks the best one via multiple calls to Algorithm 1. When designing Algorithm 2, the first phenomenon we notice is that putting small and large models in the same group causes convoy effects, where the requests of small models have to wait for the requests of large models and miss the SLO. Therefore, in Algorithm 2, we first cluster models into model buckets. Each bucket contains a set of models with relatively similar sizes

and every model is assigned to one and only one bucket. Specifically, the function `get_potential_model_buckets` returns all the possible model bucket partitions that separate models whose latency difference is larger than a threshold into different disjoint buckets. We then enumerate all the potential ways to assign the devices to each bucket in `get_potential_device_buckets`.

Because different buckets include a disjoint set of models, we can then figure out the optimal placement for each bucket individually. For each bucket, we enumerate possible ways to partition the devices in the bucket into several groups in `get_potential_group_partitions` and enumerate the potential parallel configurations for each group with the method in `get_potential_parallel_configs`. We then call Algorithm 1 with `greedy_placement` to place models in the model bucket to the groups in the device bucket. We send the whole workload  $W$  to Algorithm 1, which ignores the requests that hit the models outside of the current bucket. Finally, a complete solution is got by concatenating the solutions for all buckets. The algorithm returns the best solution it finds during the enumerative search process.

Enumerating all possible choices can be slow, so we use the following heuristics to prune the search space. Intuitively, we want the different buckets to serve a similar number of requests per second. Therefore, we eliminate the bucket configurations with high discrepancies in the estimated number of requests it can serve per second for each bucket. Additionally, in `get_potential_group_partitions` and `get_potential_parallel_configs`, we assume all groups have the same size and the same parallel configurations except for the last group which is used when the number of devices is not divisible by the group size.

### 4.3 Runtime Scheduling

We use a simple policy to dispatch and schedule the requests at runtime. All requests are sent to a centralized controller. The controller dispatches each request to the group with the shortest queue length. Each group manages a first-come-first-serve queue. When a group receives a request, it checks whether it can serve the request under SLO and rejects the request if it cannot. This is possible because the execution time of a DNN model is very predictable and can be got in advance by profiling [19]. In most of our experiments, we do not include advanced runtime policies such as batching [19], swapping, and preemption [21]. These techniques are complementary to model parallelism. Nevertheless, we discuss how they fit into our system.

**Batching.** Batching multiple requests of the same model together can increase the GPU utilization and thus increase the throughput of a serving system. In our system, we do find batching is helpful, but the gain is limited. This is because we mainly target large models and a small batch size can already fully saturate the GPU, which is verified in §6.5. To isolate the benefits of model parallelism and make the results more

explainable, we decide to disable any batching in this paper except for the experiments in §6.5.

**Preemption.** The optimal scheduling decision often depends on future arrivals, and leveraging preemption can help correct previous suboptimal decisions. The first-come-first-serve policy may result in convoy effects when models with significantly different execution times are placed in the same group. We anticipate a least-slack-time-first policy with preemption can alleviate the problems [12].

**Swapping.** The loading overheads from the CPU or Disk to GPU memory are significant for large models, which is the target of this paper, so we do not implement swapping in AlpaServe. We assume all models are placed on the GPUs. This is often required due to tight SLOs and high rates, especially for large models. The placement of models in AlpaServe can be updated in the periodic re-placement (e.g., every 24 hours).

**Fault tolerance.** While the current design of AlpaServe does not have fault tolerance as a focus, we acknowledge several potential new challenges for fault tolerance: With model parallelism, the failure of a single GPU could cause the entire group to malfunction. Additionally, the use of a centralized controller presents a single point of failure.

## 5 Implementation

We implement a real system and a simulator for AlpaServe with about 4k lines of code in Python. The real system is implemented on top of an existing model-parallel training system, Alpa [56]. We extend its auto-parallelization algorithms for inference settings to get the model-parallel strategies. We then launch an Alpa runtime for each group and dispatch requests to these groups via a centralized controller.

The simulator is a continuous-time, discrete-event simulator [39]. The simulator maintains a global clock and simulates all requests and model executions on the cluster. Because the simulator only models discrete events, it is orders of magnitude faster than the real experiments. In our experiment, it takes less than 1 hour for a 24-hour trace. The fidelity of the simulator is very high because of the predictability of DNN model execution, which is verified in §6.1.

## 6 Evaluation

In this section, we evaluate AlpaServe’s serving ability under a variety of model and workload conditions. The evaluation is conducted on a range of model sizes, including those that do and do not fit into a single GPU, and we show that AlpaServe consistently outperforms strong baselines across all model sizes. In addition, we evaluate the robustness of AlpaServe against changing arrival patterns and do ablation studies of our proposed techniques. Evaluation results show that AlpaServe can greatly improve various performance metrics. Specifically, AlpaServe can choose to save up to  $2.3\times$  devices, handle  $10\times$  higher rates,  $6\times$  more burstiness, or  $2.5\times$  more stringent SLO, while meeting the latency SLOs for over 99% requests.

Name	Size	Latency (ms)	S1	S2	S3	S4
BERT-1.3B	2.4 GB	151	32	0	10	0
BERT-2.7B	5.4 GB	238	0	0	10	0
BERT-6.7B	13.4 GB	395	0	32	10	0
BERT-104B	208 GB	4600	0	0	0	4
MoE-1.3B	2.6 GB	150	0	0	10	0
MoE-2.4B	4.8 GB	171	0	0	10	0
MoE-5.3B	10.6 GB	234	0	0	10	0

Table 1: The first three columns list the sizes and inference latency of the models. The latency is measured for a single query with a sequence length of 2048 on a single GPU. BERT-104B’s latency is reported using a minimal degree of inter-op parallelism. The latter columns list the number of instances for each model in different model sets named as S1-S4.

## 6.1 Experiment Setup

**Cluster testbed.** We deploy AlpaServe on a cluster with 8 nodes and 64 GPUs. Each node is an AWS EC2 p3.16xlarge instance with 8 NVIDIA Tesla V100 (16GB) GPUs.

**Model setup.** Since Transformer [47] is the default backbone for large models, we choose two representative large Transformer model families: BERT [14] and GShard MoE [27] for evaluation.<sup>4</sup> In ML practice, the large model weights are usually pretrained and then finetuned into different versions for different tasks. Hence, for each model family, we select several most commonly used model sizes [5], and then create multiple model instances at each size for experimentation. Also, we design some model sets to test the serving systems under different model conditions; details about model sizes, their inference latency on testbed GPUs, and the number of model instances in each model set are provided in Tab. 1.

**Metrics.** We use *SLO attainment* as the major evaluation metric. Under a specific SLO attainment goal (say, 99%), we concern with another four measures: (1) the minimal number of devices the system needs, (2) the maximum average request rate, (3) the maximum traffic burstiness the system can support, and (4) the minimal SLO the system can handle. We are particularly interested in a SLO attainment of 99% (indicated by vertical lines in all curve plots), but will also vary each variable in (1) - (4) and observe how the SLO attainment changes.

**Simulator fidelity.** We want to study the system behavior under extensive models, workload, and resource settings, but some settings are just beyond the capacity of our testbed. Also, it is cost- and time-prohibitive to perform all experiments on the testbed for the days-long real traces. To mitigate the problem, we use the simulator introduced in §5 for the majority of our experiments, noticing that DNN model execution [19] has high predictability, even under parallel settings [27, 56].

<sup>4</sup>In this paper, we focus on non-autoregressive large models which perform inference with one forward pass, but note that the techniques proposed in this paper can be extended to auto-regressive models like GPT-3.

SLO Scale	Selective Replication		AlpaServe	
	Real System	Simulator	Real System	Simulator
0.5x	00.0%	00.0%	33.3%	33.3%
1x	00.0%	00.0%	53.5%	53.2%
1.5x	29.7%	30.2%	64.1%	64.7%
2x	36.9%	36.8%	79.0%	80.6%
3x	49.5%	48.5%	91.4%	92.1%
4x	58.6%	57.8%	96.4%	96.5%
5x	64.9%	64.0%	97.6%	97.9%
10x	83.1%	82.6%	100.0%	99.7%

Table 2: Comparison of the SLO attainment reported by the simulator and the real system under different SLO scales.

We study the fidelity of the simulator in Tab. 2. Given two model placement algorithms, we compare the SLO attainment reported by the simulator and by real runs on our testbed under different *SLO Scales*. The error is less than 2% in all cases, verifying the accuracy of our simulator. Additionally, we conduct experiments on cluster testbed for results in §6.3.

## 6.2 End-to-end Results with Real Workloads

In this section, we compare AlpaServe against baseline methods on publicly available real traces.

**Workloads.** There does not exist an open-source production ML inference trace to the best of our knowledge. Therefore, we use the following two production traces as a proxy: Microsoft Azure function trace 2019 (MAF1) [42] and 2021 (MAF2) [54]. They were originally collected from Azure serverless function invocations in two weeks, and have been repurposed for ML serving research [4, 25]. The two traces exhibit distinct traffic patterns. In MAF1, each function receives steady and dense incoming requests with gradually changing rates; in MAF2, the traffic is very *bursty* and is distributed across functions in a highly *skewed* way – some function receives orders of magnitude more requests than others. Note that most previous works [19] are evaluated on MAF1 only. Since there are more functions than models, following previous work [4, 25], given a model set from Tab. 1, we round-robin functions to models to generate traffic for each model.

**Setup.** SLO attainment depends on many factors. For each metric (1) - (4) mentioned in §6.1, we set a default value, e.g., the default SLO is set as tight as  $5 \times$  inference latency (SLO Scale=5). This forms a *default setting*, given which, we then vary one variable (while fixing others) at a time and observe how it affects the resulting SLO attainment. To change the two variables (3) and (4), which characterize traffic patterns, we follow Clockwork [19] and Inferline [8] and slice the original traces into time windows, and fit the arrivals in each time window with a Gamma Process parameterized by rate and coefficient of variance (CV). By scaling the rate and CV and resampling from the processes, we can control the rate and burstiness, respectively.

**Baselines.** We compare AlpaServe to two baseline methods:

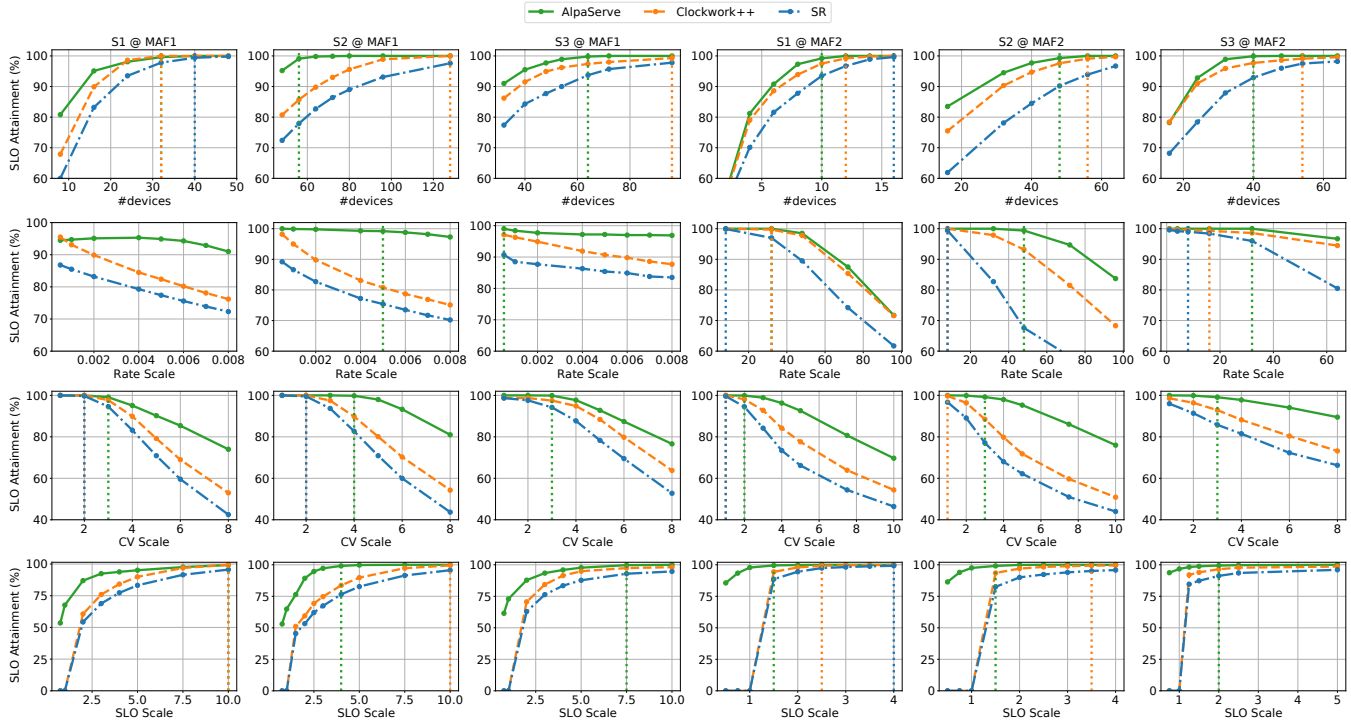

Figure 12: SLO attainment under various settings. In column S1@MAF1, we replay the MAF1 trace on the model set S1, and so on. In each row, we focus on one specific metric mentioned in §6.2 to see how its variation affects the performance of each serving system. If any, the dotted vertical line shows when the system can achieve 99% SLO attainment.

(1) *Selective Replication (SR)*: use AlpaServe’s placement algorithm without model parallelism, which mimics the policy of a wide range of existing serving systems [9, 44]; (2) *Clockwork++*: an improved version of the state-of-the-art model serving system Clockwork [19]. The original Clockwork continuously swaps models into and out of GPUs. This helps for very small models (e.g., w/ several million parameters) but incurs significant swapping overheads on larger models. For fair comparisons, we implement Clockwork++ in our simulator, which swaps models following Clockwork’s replacement strategy at the boundary of every two windows<sup>5</sup> of the trace using SR’s algorithm, but *assuming zero swapping overheads*. We believe it represents a hypothetical upper bound of Clockwork’s performance. Since all the baselines can only support models that can fit into one GPU memory,<sup>6</sup> we use model set S1, S2 and S3 from Tab. 1 in this experiment.

**SLO attainment vs. cluster size.** Fig. 12’s first row shows the SLO attainment with varying cluster sizes when serving a specific (model set, trace) pair. AlpaServe outperforms the two baselines at all times and uses far fewer devices to achieve 99% SLO attainment thanks to model parallelism. By splitting

<sup>5</sup>For MAF1, we follow Clockwork to set the window size as 60 seconds. For MAF2, we set it as 5.4K seconds.

<sup>6</sup>In our cluster testbed, the per-GPU memory is 16GB, but the actual available space for model weights is around 13GB due to the need to store activations and other runtime context.

one model replica onto  $N$  devices, AlpaServe can achieve similar throughput as if  $N$  replica were created for replication-only methods; but note AlpaServe uses only one replica of memory. Surprisingly, although we let Clockwork++ adjust to the traffic dynamically with zero overhead, AlpaServe still wins with a static placement; this is because model-parallel placement is by nature more robust to bursty traffic.

It is worth noting that replication-only methods can at most place 2 replicas of BERT-2.6B on a V100 (13GB memory budget), resulting in a substantial memory fraction, while model parallelism can avoid such memory fractions and enable more flexible placement of models.

**SLO attainment vs. rate.** Fig. 12’s 2nd row varies the rate of the workloads. For a stable trace like MAF1, AlpaServe can handle a much higher rate than baselines. While for a skewed and highly dynamic trace MAF2, whose traffic is dominated by a few models and changes rapidly, the replication-based methods have to allocate the majority of the GPUs to create many replicas for “hot” models to combat their bursty traffic; those GPUs, however, may go idle between bursts, even with frequent re-placement as in Clockwork++. In AlpaServe, each model needs fewer replicas to handle its peak traffic.

**SLO attainment vs. CV.** Fig. 12’s 3rd row varies the CV of the workloads. The traffic becomes more bursty with a higher CV, which aggravates the queuing effect of the system and increases the possibility of SLO violation. The traditional

solution to handle burstiness is by over-provision, wasting a lot of resources. AlpaServe reveals a hidden opportunity to handle this by model parallelism.

**SLO attainment vs. SLO.** Fig. 12’s 4th row shows the effect of different SLO. Previous work [19] which targets serving small models usually sets SLO to hundreds of milliseconds, even though the actual inference latency is less than 10 ms. Thanks to the intra-op parallelism, AlpaServe can maintain good performance under similar SLO when serving large models, whose inference latency can be over 100 ms. When SLO is tight, even less than the model inference time, AlpaServe favors intra-op parallelism to reduce the inference latency, which also reduces AlpaServe’s peak throughput due to the communication overhead but can make more requests to meet their SLO. When SLO becomes looser, AlpaServe will automatically switch to use more inter-op parallelism to get higher throughput.

### 6.3 Serving Very Large Models

Today’s large models may possess hundreds of billions of parameters [5, 31, 53]. To serve large models at this scale, the common practice in production is to choose the model parallelism strategy manually and use dedicated GPUs for each model [51]. To show AlpaServe has improved capability in serving very large models, we deploy model set S4 on our testbed, each requiring at least 16 GPUs to serve in terms of memory usage. As baselines, for each model, we enumerate all combinations of inter- and intra-op parallelisms on 16 GPUs. In contrast, AlpaServe searches for the optimal GPU group allocation and model placement according to the arrival traffic and tries to achieve statistical multiplexing.

**Offered load.** In the default setting, the traffic is generated via a Gamma Process with an average rate of 8 requests/s and CV of 4. We then split the requests to each model following a power law distribution with an exponent of 0.5 to simulate the real-world skewness.<sup>7</sup> Similar to §6.2, we vary one of the rate, CV, or SLO in the default setting to see how each factor contributes to the resulting performance. It is worth noting that all results presented in this section are obtained via real execution on the testbed cluster.

**SLO attainment.** Fig. 13 shows the SLO attainment of each system under various settings. Although enumerating parallelism strategies and selecting the best can improve performance, it still remains a substantial gap compared to AlpaServe. This means that the traditional way of using dedicated GPUs to serve large models is not ideal. We check the solution of AlpaServe and find it slices the cluster evenly into two groups, each with the (4, 8) inter-/intra-op parallel configuration, and groups the models in a way that balances the requests between two groups. This further proves that our motivation in §3.1 still holds for extremely large models. By

<sup>7</sup>Uniform split yielded similar results.

Figure 13: SLO attainment as we vary the rate, CV, and SLO scale. (8,2) means 8-way inter-op parallelism and in each pipeline stage using 2-way intra-op parallelism.

space-sharing the devices, AlpaServe can exploit new opportunities for statistical multiplexing, which is advantageous for bursty workloads but largely under-explored by prior work.

### 6.4 Robustness to Changing Traffic Patterns

Until now, AlpaServe’s good performance is based on the assumption we make in its placement algorithm that we know the arrival process in advance. In practice, the arrival process can be approximated using historical traces but the unavoidable real-world variance may make the prediction inaccurate. In this experiment, we study how AlpaServe performs if the traffic patterns change.

We reuse the same setting for S2@MAF1 in §6.2, but this time for AlpaServe and SR, we randomly slice two one-hour traces from MAF1, one is what their algorithms are assumed, while the other one is used as the actual arrival process. While for Clockwork++, we still run its algorithm directly on the actual arrival process to respect its online nature. Similarly, we vary different factors and compute the SLO attainment for each system. We repeat the experiments three times and show the average results in Fig. 14.

Unsurprisingly, SR’s performance drops significantly when traffic changes. By contrast, AlpaServe maintains good performance and still outperforms Clockwork++, an online adjustment algorithm, using a static placement generated from substantially different traffic patterns. This confirms that, in face of highly-dynamic traffic patterns, statistical multiplexing with model parallelism is a simple and better alternative than existing replication- or replacement-based algorithms.

### 6.5 Benefits of Dynamic Batching

Batching is a common optimization in other serving systems [19, 33, 34] and the choice of batch size is critical to the performance because it can increase GPU utilization and thus increase the system throughput. However, in large model scenarios, the benefit of batching is limited mainly due to two reasons. First, for large models, a small batch size will saturate the GPU, which means there is little gain to batching more requests. Second, the execution latency grows linearly with the batch size [44], so when the SLO is tight (say SLO Scale is less than 2), batching is simply not a choice.

To isolate the benefits of model parallelism and make the

Figure 14: The actual arrival traffic for AlpaServe and SR is different from what their algorithms are assumed, while Clockwork++ runs directly on the actual traffic.

Figure 15: SLO Attainment when batching is enabled.  $mb=2$  means the maximum batch size is 2.

results more explainable, we decide to disable any batching in other experiments but prove that the batching strategy is purely orthogonal to the scope of this paper in this subsection. To prove this, we implement a standard batching algorithm in AlpaServe and evaluate its performance.

**Batching strategy.** When a request arrives, it will get executed immediately if any device group is available. Otherwise, it will be put into a per-model requests queue for batching. When a device group becomes idle, it will choose a model which has a replica on it and batch as many requests as possible from the requests queue of the model while satisfying the SLO requirements.

**Setup.** As the model size increases, the potential benefit of batching decreases. Therefore, we choose to evaluate model set S1. We generate a synthetic Gamma Process traffic with an average rate of 4 requests/s and a CV of 4 for each model.

**SLO attainment.** Fig. 15 (left) shows the SLO attainment achieved by AlpaServe with different maximum batch size settings under various SLO scales. When the SLO requirement is tight, any batching will violate the SLO so there is no gain with batching enabled. Also, although we choose to serve the smallest model in Tab. 1, a small batch size like 2 combined with a long sequence length of 2048 already saturates the GPU, so a larger maximum batch size brings no performance improvement. Fig. 15 (right) compares the improvement for AlpaServe and Clockwork++ with our batching algorithm enabled.<sup>8</sup> When the SLO requirement becomes loose, both AlpaServe and Clockwork++ have better SLO attainment to

<sup>8</sup>SR is left out to make the figure clearer as it is worse than Clockwork++.

(a) Transformer 1.3B. (b) Transformer 2.6B.

Figure 16: Comparison of the model parallel overhead between manual partition (lighter color) and the partition found by the automatic algorithm (darker color).

some extent. Since AlpaServe’s performance is good even without batching and batched requests with different batch sizes will incur stage imbalance and pipeline bubble in inter-op parallel, the absolute improvement of Clockwork++ is slightly better.

## 6.6 Ablation Study

In this section, we study the effectiveness of our proposed auto-parallelization (§4.1) and placement algorithms (§4.2).

**Benefits of auto-parallelization.** We show that the auto-parallelization ability allows AlpaServe to not only generalize to arbitrary model architectures but even also reduce parallelism overheads – hence improved serving performance (see §3.3 for more discussion). To see that, typical manual model-parallel parallelization strategies offered in *de facto* systems [1, 31, 32] is to assign an equal number of (transformer) layers to each pipeline stage. These strategies often fail to create balanced workloads across distributed GPUs because contemporary large models have heterogeneous layers, such as embedding operations. The extensions introduced in §4.1 automatically partition the models at the computational graph level and generate nearly-balanced stages. Empirically, as shown in Fig. 16, for 8 pipeline stages, auto-parallelization reduces the total overhead by 32.9% and 46.7% for Transformer 1.3B and 2.6B respectively, which is necessary for achieving good serving performance when model parallelism is used for serving.

**Effectiveness of the placement algorithm.** We now test the

Figure 17: Ablation study of placement algorithms.

effectiveness of our placement algorithm on a synthetic workload. We serve the most challenging model set S3 (Tab. 1) on our testbed. The rate distribution of the models follows a power law distribution. The arrival pattern of each model is a Gamma process. Three variants of the placement algorithms are evaluated. *Round robin* means placing models in a round-robin fashion and using 4-stage pipelines for all groups. *Greedy placement* uses our greedy placement and 4-stage pipeline for all groups. *Greedy placement + Group partitioning* performs greedy placement plus group partitioning search. As shown in Fig. 17, both placement and group partitioning are necessary to achieve good SLO attainment. In the left subfigure, the group partitioning increases the rate by  $1.5\times$  compared to greedy placement without group partitioning over 99% SLO attainment, while round robin can never reach 99% SLO attainment. In the right subfigure, the group partitioning increases the traffic burstiness that can be handled to meet 99% SLO attainment by  $1.3\times$ .

## 7 Related Work

**Model serving systems.** There has been a proliferation of model serving systems recently. These range from general-purpose production-grade systems like TensorFlow Serving [34] and NVIDIA Triton [33], which are widely used but do not provide any support for automatic placement or latency constraints. They also include systems that are optimized for single-model serving [51] or serving of specific classes of models (e.g., transformers) [16, 51, 57]. AlphaServe targets a broader set of models and features than these systems.

For SLO-aware, distributed serving, most serving systems ignore placement-level interactions between models. Clockwork [19], for instance, primarily focuses on predictability; when scheduling, it greedily loads and executes models on available GPUs. Shepherd [52] utilizes preemption to correct sub-optimal scheduling decisions. For large models, loading model weights and preemption can easily overwhelm practical SLOs. Other systems like Clipper [9], Infaas [40], and DVABatch [10] also do not reason about the latencies of co-located models.

Nexus [44] is very related to our work in that it examines the placement of models; however, Nexus is an example of a system that takes the traditional replication approach described in §3 and, thus, misses a broad class of potential parallelization strategies that we explore in this paper.

**Inference optimizations for large models.** AlphaServe is complementary to another large body of work on optimizations for inference over large models. These include techniques like quantization [13], distillation [41], offloading [1], better operator parallelism [36], and CUDA kernel optimization [11, 26]. Some of these optimizations are intended to stem the tide of increasing model sizes; however, all of these gains are partial—the challenge of serving large models has continued to escalate rapidly despite these efforts.

**Model parallelism for training.** AlphaServe is largely orthogonal to the large body of work on model parallelism in training [23, 28, 31, 37, 56]. As described in §3, serving presents a unique set of constraints and opportunities not found in training workloads. Where these systems do intersect with AlphaServe, however, is in their methods for implementing model parallelism along various dimensions. In particular, AlphaServe builds on some of the parallelization techniques introduced in [56].

**Resource allocation and multiplexing.** The problem of how to multiplex limited resources to the incoming requests is one of the oldest topics in computer science and has been studied in different application domains [3, 29, 38]. Recent work on DL scheduling uses swapping [2], preemption [20], interleaving [55], and space-sharing [49] to realize fine-grained resource sharing. Rather, the contribution of this paper is a deep empirical analysis of the applications of these ideas to an emerging space: the serving of multiple large models.

## 8 Conclusion and Future Work

In this paper, we presented AlphaServe, a system for prediction servings of multiple large deep-learning models. The key innovation of AlphaServe is integrating model parallelism into multi-model serving. Because of the inherent overheads of model parallelism, such parallelism is traditionally applied conservatively—reserved for cases where models simply do not fit within a single GPU or execute within the required SLO. AlphaServe demonstrates that model parallelism is useful for many other scenarios, quantifies the tradeoffs, and presents techniques to automatically navigate that tradeoff space.

In the future, we will extend AlphaServe to more complicated scenarios, including serving multiple parameter-efficient adapted models (e.g., LoRA [22]), models with dependencies, and autoregressive models [5].

## Abstract

With the growing complexity of deep neural networks (DNNs), developing DNN programs with intricate control flow logic (e.g., loops, branches, and recursion) has become increasingly essential. However, executing such DNN programs efficiently on accelerators is challenging. Current DNN frameworks typically process control flow on the CPU, while offloading the remaining computations to accelerators like GPUs. This often introduces significant synchronization overhead between CPU and the accelerator, and prevents global optimization across control flow scopes.

To address this challenge, we propose COCKTAILER, a new DNN compiler that co-optimizes the execution of control flow and data flow on hardware accelerators. COCKTAILER provides the *uTask* abstraction to unify the representation of DNN models, including both control flow and data flow. This allows COCKTAILER to expose a holistic scheduling space for rescheduling control flow to the lower-level hardware parallelism of accelerators. COCKTAILER uses a heuristic policy to find efficient schedules and is able to automatically move control flow into kernels of accelerators, enabling optimization across control flow boundaries. Evaluations demonstrate that COCKTAILER can accelerate DNN models with control flow by up to 8.2× over the fastest one of the state-of-the-art DNN frameworks and compilers.

## 1 Introduction

In deep neural networks (DNNs), control flow plays a crucial role in accomplishing sophisticated tasks, akin to its usage in general programming languages. Examples of this include iterating over sequential data like text and time steps, activating different components of the model based on input-data-driven conditions, dynamically skipping some computation based on runtime decisions for efficient computation, and recursively

traversing tree-based data structures. A DNN program is typically divided into two parts: control flow and data flow. The data flow is typically represented as a graph of DNN operators, which can be efficiently executed on specialized accelerators such as GPUs. The control flow, on the other hand, is either implemented as a special operator [4] or by directly reusing the built-in statements of programming languages [36], and is typically executed on a CPU. Therefore, the control flow and data flow are executed alternatively in an entire DNN computation: the control flow determines which part of the data flow should be executed, and then the corresponding data flow is sent to accelerators for processing and the result is obtained, which is used to decide the next step of control flow.

However, the interleaved execution paradigm on both sides in existing DNN frameworks often introduces significant efficiency issues. First, the control flow and data flow require frequent synchronization between the CPU and accelerator (e.g., for checking conditions based on results), resulting in significant communication overhead (e.g., across PCIE) in the critical path. Second, the control flow in a DNN program often establishes explicit boundaries between data flow operators, which prevents their holistic optimization for maximum efficiency, such as fusing two operators across a loop scope. Lastly, the control flow implicitly serializes the execution of data flow operators that could potentially be executed in parallel. We have observed that these overheads are prevalent in existing DNN models and can often occupy as much as 72% of the total time in PyTorch. These efficiency issues not only introduce obstacles to dynamic model developments but also make many optimizations, e.g., dynamically skipping some computation, hard to achieve theoretical speedup.

Based on our observation of DNN workload patterns, the fundamental reason for the inefficiency is the *parallelism mismatch* between the control flow and data flow. In particular, control flow operations, such as loops, branches, and recursion, are single-thread semantic and execute in a strictly sequential order. However, the data flow operators are parallelizable, running on multiple parallel threads (e.g., GPU cores) and synchronizing periodically across different scopes

<sup>£</sup>Tsinghua University, BNRist

<sup>\*</sup>Work is done during the internship at Microsoft Research.

of threads (between operators or thread blocks). To control the execution flow of a parallel program, the mismatch between control flow and data flow forces existing practices to place the control flow either outside the DNN operators (e.g., in existing DNN frameworks) or inside an individual DNN operator, through implementing custom kernels in an ad-hoc way (e.g., Relu operator). This can be either inefficient or unscalable to support the increasing demands for control flow in DNN workloads.

In this paper, we present a new DNN compiler, COCKTAILER, that addresses the challenges of co-optimizing control flow and data flow in a single space. COCKTAILER is based on three key insights observed from studying DNN models and modern accelerators. First, the data flow in DNNs is inherently a multi-level parallel program, where individual operators are executed in different hardware parallelism, such as threads, thread blocks, or kernels in GPUs. Second, the control flow operations in DNNs are mostly applied at the operator level, where all lower-level parallelisms share the same control result. This implies that the control flow can be rescheduled to the low-level parallelism by replicating the control logic to all parallel tasks at different levels. Most importantly, modern hardware accelerators, such as GPUs, are designed to support the control logic in their low-level programming languages in each thread, which makes this rescheduling approach feasible in practice.

Based on these insights, COCKTAILER introduces the *uTask* abstraction as the primitive execution unit of a DNN program for both control flow and data flow. An operator in data flow can be naturally decomposed into different levels of granularity of *uTasks* aligned with its computation parallelism. For control flow, COCKTAILER introduces three types of special *uTasks*: loop *uTask*, branch *uTask*, and *uTask* reference, to represent the program with control flow as a special *uTask*. By unifying the DNN program into the *uTask* granularity, COCKTAILER creates a holistic space for co-scheduling control flow *uTasks* with compute *uTasks*, i.e., by assigning the control flow *uTask* to the most efficient parallel level with data dependencies resolved correctly. To facilitate this scheduling, COCKTAILER proposes a scheduling mechanism and a traverse-based bottom-up scheduling policy that incorporates all control flow optimizations such as function inline, loop unroll, and recursion unroll.

As a result, COCKTAILER is able to automatically move control flow operations, such as loops or branches, into accelerator side when applicable, enabling more optimization opportunities across the control flow boundary. COCKTAILER is built on top of general DNN tensor compilers by leveraging their kernel generation capabilities for *uTask*, allowing it to adapt to different accelerators such as CUDA GPUs and ROCm GPUs easily. COCKTAILER’s approach can be applied to both DNN frameworks that implement control flow as special operators or language-built-in statements, by only compiling the sub-programs that can be optimized by COCK-

Figure 1: Models with control flow

TAILER. Evaluation with 7 typical DNN models on CUDA GPUs and ROCm GPUs shows that COCKTAILER accelerates these models by up to  $8.2\times$  over the fastest one of state-of-the-art DNN frameworks and compilers. Furthermore, the evaluation shows that COCKTAILER not only reduces the overheads introduced by control flow but also enables scenarios like dynamically skipping some computation by achieving real speedup. The code has been open-sourced<sup>1</sup>.

## 2 Background and Motivation

DNNs have been successfully applied in many areas, such as computer vision, speech, and natural language. Meanwhile, the concept of control flow in programming languages is introduced to deep learning. The architecture of DNN models rapidly evolves from sequential feed-forward layers [15, 23, 38] to structures with complex control logic [16, 39–41, 46, 47], enabling dynamic computation and adaptability within the network architecture:

- **Dynamic computation.** Control flow enables constructing dynamic computation architectures, which can adapt their structure during runtime. For example, the loops are widely used to handle variable-length sequences (e.g., text, speech, time-series data) in RNNs [16, 40, 58] and Transformers [43].
- **Conditional computation.** Control flow enables the execution of specific parts of the model based on certain conditions [7, 24] like executing different parts of the model for images with different resolution.
- **Efficient computation.** Control flow can help reduce the computational resources required by DNN models by selectively executing parts of the model based on input data or intermediate results, e.g., the early-exiting mechanism [46, 47] that can skip some layers on easy input samples. Besides, control flow can be leveraged to adapt DNN models to different environments (e.g., different hardware accelerators) by trading off computation cost and model performance via control flow [26].

Dynamic computation for structural data is a common requirement in modern deep learning models. For instance, nearly 27% of the 52 models in PyTorch Hub (as of commit ID 1c747e2) contain structural data (e.g., sequence, tree). Furthermore, a survey on dynamic DNN models [13] indicates

<sup>1</sup>[https://github.com/microsoft/nnfusion/tree/cocktailer\\_artifact/artifacts](https://github.com/microsoft/nnfusion/tree/cocktailer_artifact/artifacts)

that conditional computation and efficient computation are promising research directions.

In programming languages, control flow constructs are typically categorized into the following types: sequence, branch, loop, and subroutine (function). Similarly, a majority of DNN models with complex control flow can be categorized into models with loops for temporal-wise dynamism (e.g., LSTM [16], NASRNN [58], Seq2seq [40]), models with branches to skip computation (e.g., BlockDrop [47], SkipNet [46]), and models with tree-based architecture via recursion (e.g., RAE [39], Tree-LSTM [41]). We discuss the three representative categories with their representative models, as shown in Figure 1.

- **Loop.** Seq2seq [40] can generate arbitrary-length sequences. It contains a while loop that continues to emit new tokens until an end-of-sequence (EOS) token.
- **Branch.** BlockDrop [47] is a convolution neural network that can drop some convolution layers. Each layer is implemented by an if statement with two branches for whether executing the branch or not.
- **Recursion.** RAE [39] computes the embedding of a parse tree by traversing the tree. It can be implemented by a depth-first search using recursion.

To support these emerging DNN models, there are two mainstream approaches. The first one, represented by TensorFlow of version 1.x [4], supports these complex model architectures by introducing a set of control flow operators [52] like `Enter` and `NextIteration`. Then, these control flow operators are executed in the framework runtime with the CPU threads. The second one, represented by PyTorch [36] and JAX [11], leverages the programming language to represent and execute the control flow. For example, in PyTorch, algorithm designers program control logic in Python, and these control flow statements are running in the Python runtime.

Both approaches schedule data flow operators onto the accelerators while maintaining control flow in the CPU side for execution. The reason is the *parallelism mismatch* between the control flow and the data flow. Specifically, different from data flow operators (e.g., matrix multiplication) that have internal data parallelism, control flow operations are represented as single-thread computation. Modern hardware accelerators have massive hierarchical parallel processing units. For example, GPUs contain many parallel streaming multiprocessors (SMs) and each SM has many parallel cores. This architecture aligns with data flow operators' parallelism, but it is hard to schedule the single-thread control flow to the massive hierarchical parallel processing units for execution. Therefore, current practices [4, 11, 36, 52] schedule control flow operations to the CPU side for execution. Such approaches introduce boundaries between DNN operators of different basic blocks, resulting in performance issues.

Figure 2 compares JAX's performance of executing the three models via dynamic control flow to executing the corresponding traced static graph that has removed all the control

Figure 3: Timeline of BlockDrop in JAX. The data copy from GPU to CPU (MemcpyD2H) causes synchronization.

flow computation and only remains data flow computation. Compared with the traced graph baseline, the control flow computation of JAX causes  $1.16\times$ ,  $1.54\times$ , and  $56.22\times$  slow-down in Seq2Seq, BlockDrop, and RAE, respectively. More results can be found in §5. The loop in Seq2seq and branches in BlockDrop use control flow operators. The recursion in RAE is executed in Python. Both approaches cannot match the performance of static traced graphs.

The performance issue comes from the following parts.

**(1) Boundary overheads.** Executing data flow operators on the accelerator and control flow operations on the CPU can incur synchronizations between the CPU and the accelerator. Take the BlockDrop model on a CPU-GPU system as an example, the DNN operators in the branch body are executed in the GPU side, while the branch operation is executed in the CPU side. The CPU stalls when waiting for the GPU to provide the data required for deciding the branch target, and then the GPU stalls to wait for the CPU to check the branch condition and send the following operations to the GPU. The boundary overheads mainly contain the communication between the CPU and the accelerator and the kernel launching. This boundary may also break the asynchronous execution in the accelerator side.

Figure 3 shows part of the timeline of JAX executing the BlockDrop model that the CPU-GPU synchronization not only has high synchronization overheads but also breaks the asynchronous execution and causes a long idle time without computation in the GPU side.

**(2) Boundary limits the optimization scope.** Executing control flow and data flow on separate sides divides the DNN program into sub-programs, each representing a static data flow that can be executed on the accelerator side. Many DNN optimizations (e.g., Rammer [28], kernel fusion [35, 56], etc.) are limited to only optimizing these sub-programs, resulting in sub-optimal performance. Consider a multi-layer LSTM model as an example: the DNN operators in LSTM cells across different layers can be scheduled for parallel execution. However, the loop control flow constrains the DNN optimizations within a cell, resulting in overlooking this parallelism.

**(3) Boundary prevents parallelism in DNN programs.** This boundary makes the DNN programs in different con-

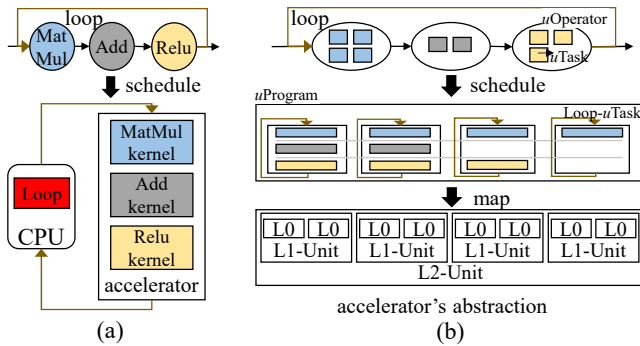

Figure 4: System overview of DNN computation in (a) existing DNN frameworks (e.g., JAX), and (b) COCKTAILER

control flow statements executed sequentially due to the synchronizations between the CPU and the accelerator, which may prevent possible inter-operator parallelism. Take the RAE model as an example, the recursion builds up a tree-based architecture where operators without dependencies can be executed concurrently. However, because the control flow can only be executed sequentially, operators of nodes without dependencies are executed sequentially.

**Observations and opportunities.** Given the fundamental limitations of current approaches described above, it is desirable to schedule the DNN programs including control flow and data flow in a single space (i.e., the accelerator side). However, it is challenging to achieve this because of the parallelism mismatch between control flow and data flow. Fortunately, control flow in DNN programs is applied across DNN operators, that is to say, the DNN operators’ computation under control flow shares the same control logic. On the other hand, most hardware accelerators (e.g., GPUs) have the ability to execute control flow instructions. If we represent control flow in a finer granularity that can be properly mapped to the parallel processing units for execution, we can schedule both data flow and control flow to the accelerator side.

### 3 COCKTAILER Design

The observation in §2 motivates COCKTAILER, a DNN compiler for co-optimizing control flow and data flow in a single space. Figure 4 shows the overview of COCKTAILER. First, COCKTAILER takes a DNN program with control flow and data flow as input, where each operator in the data flow is a *uOperator* that consists of independent and homogeneous *uTasks*. Each *uTask* can be scheduled to one compute unit of the accelerator. Second, instead of scheduling control flow on the CPU side and data flow on the accelerator side separately, COCKTAILER schedules control flow and data flow inside the program in a single space. COCKTAILER will generate the *uProgram* representation for the program, which contains multiple independent *uTasks* (e.g., the Loop-*uTasks* in Figure 4(b)) that can be scheduled to the parallel compute units in hardware accelerators for execution. Each *uTask* represents

both the control flow and data flow logic of one compute unit.

COCKTAILER abstracts an accelerator of massive parallelism as multiple levels of parallel processing units. In each level, there are parallel and homogeneous processing units, which construct a higher level of processing unit. This hardware abstraction naturally aligns with common hardware accelerators. Take the NVIDIA GPU as an example, there are multiple homogeneous streaming multiprocessors (SMs) in a GPU, where each SM consists of multiple homogeneous cores. Therefore, NVIDIA GPUs can be mapped as an architecture with 3 levels of parallel processing units in COCKTAILER’s hardware abstraction shown as Figure 4: L0 is the core (thread); L1 is the SM (thread block); L2 is the GPU device (kernel).

The example loop structure in Figure 4 is scheduled as a *uProgram* mapped on the 3-level accelerator. The *uProgram* consists of 4 loop-*uTasks* for 4 L1-Units respectively and each loop-*uTask* is mapped to a L1-Unit for execution. Both the data flow operators and the loop are scheduled into the loop-*uTasks*. Take the first loop-*uTask* as an example, it has a loop control flow and a list of *uTasks* for data flow operations containing 1 MatMul *uTask*, 1 Add *uTask*, and 1 ReLU *uTask*.

The concepts of *uTask*, *uOperator*, and *uProgram* are described in detail in §3.1. And the *uProgram* scheduling is illustrated in §3.2.

#### 3.1 *uTask*-based DNN Program

To co-schedule the control flow and the data flow of a DNN program to accelerators with massive parallel units, COCKTAILER defines the DNN program in fine grained with the concept of *unit-task* (*uTask*). Specifically, *uTask* is defined as the computation logic that can be scheduled to one of the multi-level processing units in hardware accelerators for execution. Note that the computation in a *uTask* can be a list of other *uTasks*, i.e., a nested *uTask*. *uProgram* represents the execution plan of the *uTask*-represented DNN program mapped to a level of parallel processing units on the hardware.

***uTask* and *uOperator* for data flow operators.** As Figure 5(a)(c) show, a data flow operator is represented as a group of independent and homogeneous *uTasks* where each *uTask* is the computation to be scheduled to one processing unit. Specifically, each *uTask* takes a slice of the input tensor via `get_input_data()` and executes the corresponding computation defined in `compute()`. Then, a *uOperator* is defined as the collection of all *uTasks* of the corresponding data flow operator. The *uTasks* of a *uOperator* are indexed by the logical `uTask_id` and called by `compute(uTask_id)`. The total *uTask* count in an *uOperator* is reported by `get_uTask_num()`. When all *uTasks* in an operator are executed, the execution of this operator is finished.

Data flow operators (e.g., matrix multiplication) are usually implemented as multiple independent and homogeneous tasks that are scheduled to the massive parallel units of accelerators

<pre>interface uTask {     void compute();     void get_input_data(); };</pre>	<pre>interface NestedUTask: uTask {     void compute();     void get_input_data();      vector&lt;uTask&gt; body_uTasks; };</pre>	<pre>interface uOperator {     void compute(uTask_id);     size_t get_uTask_num();      set&lt;uTask&gt; uTasks; };</pre>	<pre>interface uProgram {     void compute(uTask_id);     size_t get_uTask_num();     set&lt;uTask&gt; uTasks;     size_t unit_level; };</pre>
(a)	(b)	(c)	(d)

Figure 5: The definition of *uTask*, *uOperator* and *uProgram*

for execution. Each task consumes a slice of the input tensor, processes the corresponding computation over the input slice, and produces a slice of the output tensor. Take the NVIDIA GPU as an example, the kernel of an operator (e.g., matrix multiplication) is scheduled as multiple thread blocks and each of them is mapped to an SM for processing a tensor slice. Furthermore, a thread block is scheduled as multiple threads and mapped to cores for processing a tensor slice. Therefore, the concept of *uTask* is not only natural to represent the fine-grained computation of data flow operators, but also aligns with the hardware architecture of multi-level parallel processing units in accelerators.

***uTask* for control flow.** It is natural to represent data flow operators with *uTasks* due to the internal data parallelism that can be divided into parallel tasks. However, different from DNN operators, the control flow cannot be divided into such parallel tasks. To enable the scheduling of control flow on the parallel processing units, we need to bridge this gap of the mismatching between the control flow computation and the massive parallelism in the accelerator.

Control flow operation applies to a scope of DNN operators in DNN programs. When the DNN operators can be divided into independent and homogeneous *uTasks*, controlling the DNN operators is equal to applying control flow computation on each *uTask*. For example, assuming there is a loop structure that has a matrix multiplication operator in the loop body, compared with executing the loop over the operator, it is equally that let each unit of the hardware accelerator process the loop control flow over the *uTask* of the operator. If we apply such control flow on the scope of the fine-grained representation of these DNN operators, we can schedule such computation including the control flow to the parallel processing units of the hardware accelerators. That is to say, we can represent control flow in the *uTask* granularity by replicating the control flow computation to the multi-level parallel units that each unit executes the control flow independently and controls the *uTasks* scheduled on the unit.

According to the observation, COCKTAILER represents control flow operations as *NestedUTasks* defined in Figure 5(b), where the computation in the body is represented in the *body\_uTasks*. These *uTasks* have data dependencies and should be executed sequentially on one processing unit. Different from data flow operators that the *get\_input\_data()* extracts a slice of the input tensor, the input data of the *uTasks* in the *body\_uTasks* of control flow is related to the results of the control flow. For example, in the LSTM model, the

```
1 interface LoopUTask: NestedUTask {
2     void compute();
3     void get_input_data();
4     void control_flow();
5     vector<uTask> body_uTasks;
6 };
```

(a) Loop-*uTask*

```
1 interface BranchUTask: NestedUTask {
2     void compute();
3     void get_input_data();
4     void control_flow();
5     vector<uTask> then_uTasks;
6     vector<uTask> else_uTasks;
7 };
```

(b) Branch-*uTask*

Figure 6: Control flow *uTasks*

*uTasks* in the body of the loop control flow require different values of the loop counter in different loop steps. Therefore, the *get\_input\_data()* for control flow should prepare the input data with consideration of the results of control flow. Note that different control flow operations have different data access patterns in the *body\_uTasks*. We will discuss it in detail in the following.

According to Section 2, there are three types of control flow in DNN programs: loop, branch, and recursion. Therefore, COCKTAILER defines the concepts of loop-*uTask*, branch-*uTask*, and *uTask* reference correspondingly to represent the fine-grained *uTask* for control flow in DNN programs.

(1) *Loop-uTask*. Figure 6(a) shows the *uTask* definition for the loop control flow. COCKTAILER currently supports two types of loop control flow, i.e., for loop and while loop. The *control\_flow()* interface implements the for loop or the while loop condition. The body computation of a loop represented in *uTasks* is implemented in *body\_uTasks*. Note that the *body\_uTasks* is executed multiple times in a loop with different input data in each loop step. For example, in the LSTM model, the computation of a LSTM cell in each loop step requires the same model parameter tensors but different loop counter tensors and state tensors. The *get\_input\_data()* interface needs to prepare the corresponding tensors in each loop step.

(2) *Branch-uTask*. Figure 6(b) shows the *uTask* definition for the branch control flow. The *control\_flow()* interface implements the condition computation in the branch. The branch-*uTask* has *then\_uTasks* and *else\_uTasks* to indicate the computation of two branches represented in *uTasks*, respectively. The *get\_input\_data()* interface returns the required data for a branch indexed by the condition result.

(3) *Function*. A function can be natively represented

```

1 ScheduleOperator(op, D, unit_level, config);
2 ScheduleControlFlow(g, D, unit_level, config);
3 Config SetResource(D, unit_level, resource);

```

Figure 7: Scheduling interfaces

with `NestedUTasks` that each `uTask` represents the computation in the function body in the fine-grained `uTasks` in the `body_uTasks`. The `get_input_data()` interface prepares input data tensors and The `compute()` interface executes the `uTasks` in `body_uTasks` sequentially.

(4) *Recursion and uTask reference.* Functions can be represented with `uTasks`. However, recursion is a special case in functions that a function may call itself in the function body. That is to say, a `uTask` may have itself in its `body_uTasks`. To support recursion, COCKTAILER introduces `uTask` reference to reference a `uTask` definition. The `uTask` reference can be considered as a function call to a `uTask`. The difference between a reference and a `uTask` is that the reference is a declaration for a `uTask` while a `uTask` defines the computation in a function. When executing a reference, COCKTAILER will find its `uTask` definition and execute this `uTask`.

The `uTask` abstraction in COCKTAILER is a general abstraction to represent control flow. We show how to represent loop, branch, function and recursion with `uTask` as most of current DNN models only contain these structures. More types of control flow can be represented by inheriting the `NestedUTask`.

**uProgram** The generated execution plan of the whole input DNN program is represented by a `uProgram`. The `uProgram` contains independent `uTasks`, each of which is the compute logic scheduled to one processing unit of the `unit_level` of the accelerator. The `uTasks` can be executed by `compute`, and the total `uTask` count of the `uProgram` is reported by `get_utask_num`.

The `uTask` abstraction enables COCKTAILER to represent DNN programs with data flow operators and control flow in a fine granularity for accelerators with massive parallelism. This representation opens a new space for co-scheduling control flow and data flow.

### 3.2 uProgram Scheduling

The `uTask` representation for DNN programs opens a large scheduling space for co-optimizing control flow and data flow in a single space. Instead of the pre-defined schedule in existing frameworks that executes data flow on the accelerator side while executes control flow on the CPU side, COCKTAILER chooses to explore this scheduling space at compile-time. To achieve this, COCKTAILER separates the scheduling policy from its mechanism. On the mechanism side, COCKTAILER provides *scheduling interfaces* with *scheduling constraints*. On the policy side, COCKTAILER provides a *traverse-based scheduling policy*. Note that the scheduling is generally designed for operators of `uTask` representation and can be executed automatically.

**Scheduling interfaces.** COCKTAILER provides three interfaces `ScheduleOperator`, `ScheduleControlFlow` and `SetResource`, to facilitate the scheduling process, as shown in Figure 7. Specifically, `ScheduleOperator` schedules an operator `op`, which can be either a data flow `uOperator` or a solely-scheduled control flow operation, into the target `uProgram` with `unit_level` of the accelerator `D`. The `config` describes the current scheduling status including the target `uProgram` and is initialized by the `SetResource`. `ScheduleOperator` will set the target `uProgram` to `NULL` if it fails to schedule the `uOperator`. Similarly, `ScheduleControlFlow` schedules a control flow operation whose body has been scheduled to the required `unit_level` under the scheduling `config`, and returns `NULL` when failing to schedule this control flow. To ensure correctness, both schedule functions will add necessary `barriers` to enforce the desired `uTask` dependency. Moreover, as control flow should control the `uTasks` in the body, a scheduling constraint is shown below.

**Constraint 1** *The unit\_level of control flow should not be lower than the unit\_level of data flow in the body.*

COCKTAILER also has a profiler that measures the execution time for a `uProgram`. The profiled information could guide a policy on deciding whether to schedule a `uProgram` to the `unit_level` of the accelerator.

**Traverse-based bottom-up scheduling policy.** Algorithm 1 describes a traverse-based scheduling policy to show how to use the interfaces and the profiler to schedule control flow and data flow in a single space to the accelerator side. This policy takes a DNN program `g` represented as control flow operations and `uOperators` in data flow and the accelerator `D` as input and returns a list of scheduled `uPrograms` on this accelerator. The policy also accepts a `unit_level` parameter indicating the highest scheduled `unit_level` of the operators inside the graph `g` or `NULL` if the operators inside the graph are not scheduled yet, which is the initial case. If the input program has multiple operators, COCKTAILER will put these operators into a function operator before scheduling.

Initially, this policy schedules all the data flow `uOperators` to `uProgram` (line 4 and line 21-27). The policy continues by progressively trying to schedule more parts of the program to the same `uProgram` if the profiler suggests this schedule could reduce the overall execution time (line 5-27). Specifically, the policy will recursively traverse the program (line 7) until it only contains a `uOperator` (line 3-4) and schedule it to the `uProgram` via `ScheduleProgram` which achieves this via `ScheduleOperator`. During the traverse, if all the operations in the input program are scheduled to accelerator's units (line 21), the policy will try to schedule this program (i.e., the control flow) to the `uProgram` (line 21-27) via `ScheduleProgram`. `ScheduleProgram` implements scheduling an input program `g` to a `unit_level` of the accelerator `D`. Note that the input `g` is either a graph of operators

---

**Algorithm 1: Traverse-based Scheduling Policy**

---

**Data:**  $g$ : DNN program represented with  $uOperator$ ;  $D$ : accelerator  
**Result:**  $uProgram$

```

1 Function Schedule( $g, D, unit\_level = NULL$ ):
2    $ulevel = unit\_level, ulevel_{max} = D.unit\_levels.size() - 1, uProgs = []$ ;
3   if  $g \in D.Operators$  and  $ulevel$  is  $NULL$  then
4      $ulevel = 0$ ;
5   if  $ulevel$  is  $NULL$  then
6     for  $op \in g.TopoSort()$  do
7        $g_{op}, ulevel_{op} = Schedule(op, D, NULL)$ ;
8        $ulevel = \max(ulevel, ulevel_{op})$ ;
9        $uProgram_p = uProgs[-1]$ ;
10       $ulevel_m = \max(ulevel_{op}, uProgram_p.ulevel)$ ;
11      if  $ulevel_m < ulevel_{max}$  then
12         $g_{merge} = uProgram_p.g + g_{op}$ ;
13         $g_{merge}, ulevel_{merge} = Schedule(g_{merge}, D, ulevel_m)$ ;
14        if  $ulevel_{merge} < ulevel_{max}$  then
15           $uProgs[-1] = g_{merge}.uProgs[0]$ ;
16           $ulevel = \max(ulevel, ulevel_{merge})$ ;
17          continue;
18         $uProgs.append(g_{op}.uProgs)$ ;
19    else
20       $uProgs = g.uProgs$ 
21    if  $ulevel < ulevel_{max}$  then
22      for  $ulevel_{cur} \in range(ulevel, ulevel_{max})$  do
23         $uProgram_{cur} = ScheduleProgram(g, D, ulevel_{cur})$ ;
24        if  $uProgram_{cur}$  is not  $NULL$  then
25          if  $Latency(uProgram_{cur}) < Latency(uProgs)$  then
26             $uProgs = [uProgram_{cur}]$ ;
27             $ulevel = ulevel_{cur}$ ;
28       $g.uProgs = uProgs$ ;
29      return  $g, ulevel$ ;
30 Function ScheduleProgram( $g, D, unit\_level$ ):
31   //  $g$  is a graph of operators in  $uTask$  representation or a control
32   // flow operation that the body has been scheduled
33    $resource = GetResource(D, unit\_level)$ ; // calculate resource
34    $cfg = SetResource(D, unit\_level, resource)$ ;
35   if  $g \in D.ControlFlow$  then
36     return ScheduleControlFlow( $g, D, unit\_level, cfg$ );
37   else
38     for  $op \in g.TopoSort()$  do
39       ScheduleOperator( $op, D, unit\_level, cfg$ );
40     return  $cfg.uProg$ ;

```

---

in  $uTask$  representation (including  $uOperators$  and scheduled control flow) or a control flow whose body has been scheduled as  $uProgram$ . Therefore, *ScheduleProgram* calls *SetResource* to configure the scheduling and leverages the config to schedule the program with *ScheduleOperator* and *ScheduleControlFlow*. The  $unit\_level$  is maintained as Constraint 1 during scheduling.

Several optimizations can be employed to reduce the scheduling time. For conciseness, these optimizations are not explicitly shown in the pseudo code. For example, trials on different  $unit\_levels$  (line 22) can be performed in parallel.

**Scheduling optimizations** There are three optimization opportunities during the scheduling, depending on the inputs and the DNN programs.

*Function inline.* To remove function call overhead, COCKTAILER converts a function control flow without recursion to

Figure 8: Parallel execution of recursive calls

a sequence of computation. It removes the function control flow boundary and applies DNN optimizations to a larger program scope.

*Loop unroll.* COCKTAILER unrolls the loop control flow with some steps to explore more optimization opportunities. For example, unrolling the loops in a multi-layer RNN model can expose parallelism between RNN cells. Loop unrolling is applied during scheduling and is evaluated to decide whether to enable this unroll.

*Recursion unroll.* It is similar to loop unroll in that the recursion is also able to be unrolled to explicitly expose the recursion tree structure. COCKTAILER applies this optimization to DNN programs to unroll the recursion structure several times to expose more optimization opportunities. For example, the unrolled recursion tree can naturally expose parallelism between recursive calls, which can be leveraged for concurrent execution. Figure 8 shows an example of recursion unroll. By unrolling the recursive calls, computation without dependencies (e.g., nodes 2 and 3 in Figure 8) can be executed concurrently. Recursion unroll is applied during scheduling. The scheduler will evaluate the unrolled results to decide whether to enable this unroll and schedule the unrolled body to different computation units.

These optimizations are in *ScheduleControlFlow*. The scheduler will try to enable these optimizations and evaluate the performance with some sample data to decide whether to enable optimizations or not.

## 4 Implementation

COCKTAILER is implemented by about 10000 lines of code including Python and C++ on top of PyTorch [36] and Rammer [28]. COCKTAILER does not require any effort from model developers, who can still work on a native PyTorch program. COCKTAILER first exports the PyTorch program to an ONNX graph with built-in loop and branch operators and an extended invoke operator for representing recursion. With the converted ONNX graph, COCKTAILER automatically performs the scheduling of data flow and control flow, and applies control-flow-related optimizations described in §3. Then, COCKTAILER wraps the generated code as a customized PyTorch operator and replaces the PyTorch program with a call to this operator.

We implemented COCKTAILER for NVIDIA GPUs and AMD GPUs because they are the most popular accelerators

```

1 // y = matmul(x, w); out = tanh(y);
2 __device__ void UProg<NumUTask=2>(float* x,
  float* w => float* out | char* tmp,int id) {
3   if (id == 0) {
4     float *y = (float*)tmp;
5     MatmulUOp.compute(x, w => y, id=0);
6     MatmulUOp.compute(x, w => y, id=2);
7     Barrier(blocks={0,1});
8     TanhUOp.compute(y => out, id=0);
9   } else if (id == 1) {
10    float *y = (float*)tmp;
11    MatmulUOp.compute(x, w => y, id=1);
12    MatmulUOp.compute(x, w => y, id=3);
13    Barrier(blocks={0,1});
14    TanhUOp.compute(y => out, id=1);
15  }
16 }

```

Figure 9: Example of *uTask*

for DNNs. In the rest of this section, we describe the details about implementing COCKTAILER for NVIDIA CUDA GPUs, and briefly describe our implementation on AMD GPUs. COCKTAILER can be ported to other accelerators if they align with the hardware abstraction described in §3 and expose APIs to control the units (e.g., Graphcore IPU).

## 4.1 COCKTAILER on NVIDIA CUDA GPUs

As described in §3, an NVIDIA GPU can be abstracted as a 3-level hardware. COCKTAILER implements the ScheduleOperator interface on top of Rammer [28], AutoTVM [6], Ansor [53], Roller [57], and manually-implemented kernels. Specifically, COCKTAILER first obtains the source code of each dataflow operator on the given unit\_level by choosing from existing manual implementations of simple operators like element-wise ones or by tuning the operator with AutoTVM, Ansor, or Roller. COCKTAILER then leverages Rammer to convert the data flow operators' kernel source code to a *uOperator* with multiple *uTasks*. After that, COCKTAILER schedules the program and generates the kernel code for the control flow body.

### 4.1.1 Code Generation for Nested-*uTask*

**Overall structure** A list of *uOperators* inside a function will be scheduled to a *uProgram* with multiple Nested-*uTasks*. It will be converted to a function with pointers to the related tensors. Specifically, we use (A => B | C) to represent a function with tensor A as input, tensor B as output, and tensor C as a buffer saving intermediate results. The function also accepts a *uTask\_id* parameter for indexing the *uTasks* in the *uProgram*. Figure 9 provides an example Function-*uProgram* with a *matmul* *uOperator* implemented by 4 *uTasks* and a *tanh* *uOperator* implemented by 2 *uTasks*. This Function-*uProgram* contains 2 *uTasks*, each of which contains 2 *matmul* *uTasks* and 1 *tanh* *uTasks* in the *body\_uTasks* with proper barrier inserted (line 5-8, 11-14). The barrier can be implemented by using CUDA Cooperative Groups [1] or extending a lock-free GPU synchronization technique [48].

```

1 for i in range(10):
2   inpi = inp[i]
3   xi = matmul(inpi, wx)
4   h = tanh(xi + h)

```

(a) A simplified RNN model

```

1 __device__ void LoopUProg(float* inp, float* wx
  , float* h_in => float* h_out | float* tmp) {
2   float *inpi = tmp, *xi = tmp + 1024;
3   CopyUOp(h_in => h_out); Barrier();
4   for (int i = 0; i < 10; i++) {
5     GatherUOp(inp, &i => inpi); Barrier();
6     MatmulUOp(inpi, wx => xi); Barrier();
7     AddTanhUOp(xi, h_out => h_out); Barrier();
8   }
9 }

```

(b) Loop-*uTask* for the RNN model

Figure 10: Example of Loop-*uTask*

The Function-*uProgram* allocates the storage for Tensor *y* (line 4,10) and wraps the code with function name and signature (line 2). The `__device__` function qualifier is used so that this function can be called by other *uTasks*. We will omit the *uTask\_id* in the following sections and only show the generated code of one *uTask* inside the *uOperator* for brevity.

**Block alignment** One challenge of scheduling multiple DNN operators into a single GPU kernel comes from the variance of thread count inside each GPU block (*blockDim*). The *blockDim* of the kernel for a *uProgram* have to be set to the maximum *blockDim* of its *uOperators*, so that kernels with a large number of GPU blocks (*gridDim*) and small *blockDim* will execute inefficiently when they are scheduled into the same kernel of an operator with large *blockDim*. To address this problem, we re-implement the *uOperators* with configurable *blockDim* if possible (e.g., element-wise ones, reduction, and transpose). During schedule, COCKTAILER collects the fastest kernel of *uOperators* with predefined *blockDim* (e.g., *matmul* and convolution), and configure the *blockDim* of configurable *uOperators* to the maximum *blockDim* of the collected *uOperators*. If the *blockDim* of the collected *uOperators* varies greatly, COCKTAILER will leverage an extended Roller [57] to re-generate kernels with a fixed *blockDim*.

**Register pressure** The generated long-running GPU kernel may face register pressure. To alleviate this problem, COCKTAILER uses the profiling in §3.2 to detect performance drop due to register overuse and stop enlarging the current kernel. For control flow graph with no back edges, COCKTAILER can also utilize the branch recluster technique in §4.1.3 to both schedule the control flow to the accelerator side and reduce the kernel size.

### 4.1.2 Code Generation for Loop-*uTask*

**Overall structure** Figure 10(a) shows a simplified RNN model. It is scheduled to a Loop-*uProgram* with several Loop-*uTasks*. Each Loop-*uTask* in the *uProgram* contains *body\_uTasks* from three types of *uOperators*, i.e., gather,

```

1  if (cond) :
2    tmp1 = matmul(x, w1)
3    y = sigmoid(tmp1)
4    z = conv(y, w2)
5  else:
6    z = x + b

```

(a) A DNN model with branch

```

1  __device__ void BranchUProg(bool* cond, float*
   x, float* w1, float* w2, float* b, float*
   y_in => float* y_out, float* z_out | float*
   tmp) {
2  if (*cond) {
3    float *tmp1 = tmp;
4    MatmulUOp(x, w1 => tmp1); Barrier();
5    SigmoidUOp(tmp1 => y_out); Barrier();
6    ConvUOp(y_out, w2 => z_out);
7  } else {
8    AddUOp(x, b => z_out); // no Barrier
9    CopyUOp(y_in => y_out);
10 }
11 }

```

(b) Branch-*u*Task for the DNN model

Figure 11: Example of Branch-*u*Task

matmul, and fused add-tanh operations. This Loop-*u*Program takes three input tensors named *inp*, *wx*, *h* (*h<sub>in</sub>* in Figure 10(b)), and produces an updated tensor *h* (*h<sub>out</sub>* in Figure 10(b)). The generated code of each Loop-*u*Task contains a loop (line 4) and the *u*Tasks (line 5-7) separated by barriers for synchronization across GPU blocks.

**Memory management** Different from existing DNN frameworks that allocate tensors at runtime, COCKTAILER needs to statically allocate tensor memory to execute the control flow operations on GPUs. The variables in the loop body can be divided into four categories: (1) constants (*wx*, *inp*); (2) intermediate results (*inp<sub>i</sub>*, *xi*); (3) iteration count (*i*); (4) loop-carried dependencies (*h*). All these variables are represented by pointers to the corresponding pre-allocated tensors and can be obtained from *get\_input\_data*. Specifically, the pointer to the constants are the corresponding function inputs, the intermediate results are allocated from a *tmp* buffer (line 2 in Figure 10(b)), and the pointer to the iteration count is *&i*. The pointers to the loop-carried dependencies are a little complex because the variable exists in both input tensors and output tensors of the Loop-*u*Operator. First, some CopyUOperators are inserted to copy the input tensors (*h<sub>in</sub>*) to the corresponding output tensors (*h<sub>out</sub>*). Then, the *body\_uTasks* is generated via only visiting the output tensors. Additional CopyUOperators and dependencies between *u*Operators in the loop body are added to ensure the correctness of the overlapped input and output tensors.

### 4.1.3 Code Generation for Branch-*u*Task

**Overall structure** Figure 11(a) contains a DNN model with two branches, The then branch takes tensors *x*, *w1*, and *w2* as inputs and produces tensors *y* and *z*; The else branch takes tensors *x* and *b* as inputs and produces tensor *z*. The input of the generated Branch-*u*Program is the union of inputs of

(a) Single kernel

(b) Branch reclustering

Figure 12: Optimize Branch-*u*Program by branch reclustering

the two branches as well as the *cond* tensor. The output is the union of the outputs of the two branches. If an output only exists in one branch, CopyUOperators will be added to the other branch to move the corresponding old value to the output tensor (line 9 of Figure 11(b)). The intermediate results are saved in tensors allocated from the *tmp* buffer. As only one branch may be executed in each run, the intermediate results of the two branches can use the same memory space.

**Branch reclustering** Scheduling a whole ControlFlow-*u*Program to a single GPU kernel is not always the best choice because different operations prefer different GPU occupancy (number of threads concurrently executed on an SM). For example, *matmul* uses a large amount of shared memory and registers for saving the tiles, resulting in limited occupancy, while element-wise operations prefer large occupancy to improve memory bandwidth. COCKTAILER also tries to schedule a Branch-*u*Program to multiple Branch-*u*Programs with each Branch-*u*Program containing *u*Operators with similar preferred occupancy and keeps the execution of branch condition on the GPU. The example model in Figure 12 contains limited-occupancy-*u*Operators *matmul* and *conv* (in green) and large-occupancy-*u*Operators *sigmoid*, *add*, and *copy* (in blue). These *u*Operators are scheduled into three Branch-*u*Programs for limited occupancy, large occupancy, and limited occupancy, respectively. The two branches are co-scheduled so each GPU kernel can contain *u*Operators from both branches. This branch reclustering technique reduces the kernel size, thus can also alleviate register pressure of large GPU kernels.

### 4.1.4 Code Generation for *u*Task Reference

**Overall structure** *u*Task reference is a special case that calls a *u*Task defined in another *u*Program. It is designed for recursions where a function may call its callers like Figure 13(a). To support recursion, the function declarations of all *u*Programs whose *u*Tasks are referenced by *u*Task references are generated at the start of the code (line 1 of Figure 13(b)). Then, all *u*Programs generate their function definitions. The maximum stack depth of our recursion implementation cannot be increased at runtime, so users need to manually set a limit to the stack depth, or COCKTAILER will use all free memory to save the intermediate results in the call stack. The base

```

1 def Recursion(l, r, is_leaf, inp, w, root):
2   cond = is_leaf[root]
3   if cond:
4     output = inp[root]
5   else:
6     a = Recursion(l, r, is_leaf, inp, w, l[root])
7     b = Recursion(l, r, is_leaf, inp, w, r[root])
8     c = a + b
9     output = matmul(c, w)
10  return output

```

(a) A recursive model

```

1 __device__ void RecursionUProg(float* l, float*
  r, bool* is_leaf, float* inp, float* w, int*
  root => float* output | char* tmp);
2 __device__ void BranchUProg(float* cond, float*
  l, float* r, bool* is_leaf, float* inp,
  float* w, int* root => float* output | char*
  tmp) {
3   if (*cond) {
4     GatherUOp(inp, root => output);
5   } else {
6     float *a = tmp, *b = tmp+256, *c = tmp+512;
7     RecursionUProg(l, r, is_leaf, inp, w, l + (*
  root) => a | tmp + 768); Barrier();
8     RecursionUProg(l, r, is_leaf, inp, w, r + (*
  root) => b | tmp + 768); Barrier();
9     AddUOp(a, b => c); Barrier();
10    MatmulUOp(c, w => output);
11  }
12 }
13 __device__ void RecursionUProg(float* l, float*
  r, bool* is_leaf, float* inp, float* w, int*
  root => float* output | char* tmp) {
14  float *cond = tmp;
15  GatherUOp(is_leaf, root => cond); Barrier();
16  BranchUProg(cond, l, r, is_leaf, inp, w, root
  => output | tmp + 256);
17 }

```

(b) The generated code

Figure 13: Example of recursion with  $\mu$ Task reference

case check is kept in the function body as a branch operation.

**Simulation of GPU stack** Though NVIDIA GPUs have the built-in support of recursion, the stack is slow and with very limited supported depth. The reason is that GPU needs to save the registers of all threads during function calls. However, in a DNN program, we only need to save the pointers to tensors and the program counter of the current stack frame before performing a function call. Moreover, the same set of tensor pointers are shared by multiple  $\mu$ Tasks, and only a single copy needs to be saved. Therefore, we have the opportunity to reduce the size of saved information to both increase the stack depth and reduce the time for saving the stack frame.

To achieve this, COCKTAILER implements a stack in global memory to simulate the function call behavior. As it is dangerous to directly update the program counter, COCKTAILER choose to inline all  $\mu$ Programs to a single function and use “goto” together with “labels” inserted into the inlined function to simulate the update of the program counter. The labels are placed at the start of the function and at the end of each function call inside the function. Instead of maintaining program counters, the stack saves the label of each stack frame. Each stack frame only consumes tens of bytes of memory, so COCKTAILER can also save the stack in GPU shared memory

to avoid the memory fence and inter-block barrier for maintaining a synchronized stack across different  $\mu$ Tasks when possible.

## 4.2 COCKTAILER on AMD ROCm GPUs

AMD ROCm GPUs provide a HIP programming model [2], which is similar to CUDA and is compatible with most CUDA statements. Besides, AMD provides a hipify tool to convert a CUDA kernel to a HIP kernel. COCKTAILER first generates a CUDA kernel and then leverages the hipify tool to convert it to the HIP version. Some  $\mu$ Operators are re-implemented due to the difference between CUDA and ROCm architectures.

## 5 Evaluation

**Platform** Our evaluation is on two accelerators: (1) NVIDIA Tesla V100-PCIE-32GB GPU with 2 Intel Xeon 5218 CPUs. The compiler is CUDA 11.5. (2) AMD Instinct MI100 GPU with 2 Intel Xeon 6338 CPUs. The compiler is ROCM 4.3.

**Baselines** We compare COCKTAILER with representative state-of-the-art deep learning frameworks including the most popular imperative framework PyTorch [36] v1.11 for CUDA and v1.10 for ROCM with TorchScript [3] enabled, the representative DAG-based framework TensorFlow v1.15 [4], and JAX v0.3.20 [11] with just-in-time compilation (JIT) enabled. ROCM 5.3 is used in JAX due to compatibility problems. Note that the latest TensorFlow 2 is redesigned as an imperative framework like PyTorch and JAX, therefore we choose TensorFlow v1.15 to evaluate the DAG-based framework. We also create a baseline that accelerates each basic block of the DNN program with Rammer [28] and relies on PyTorch for executing the control flow operations (COCKTAILERBASE). COCKTAILERBASE uses the same kernel implementation of each operator and the same compilation passes excluding the control-flow-related ones as COCKTAILER.

**Benchmarks** Our evaluation includes a set of representative DNN models that covers typical architectures like CNN, RNN, and transformers, different application domains including CV, NLP, and speech, and different types of control flow operations including loops, branches, and recursions. LSTM [16] is a representative RNN model for NLP and speech, and has been manually optimized by both deep learning frameworks and libraries. We use the built-in LSTM operators when possible, which are linked to the manually optimized LSTM im-

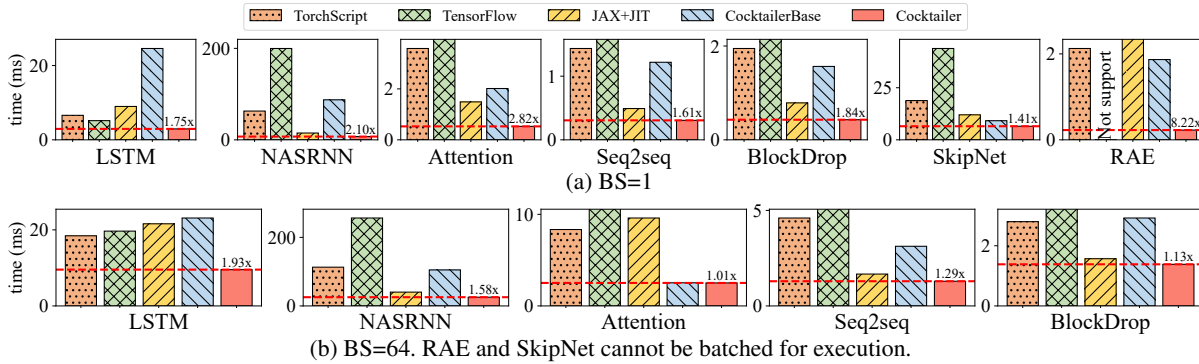

Figure 14: End-to-end DNN inference on NVIDIA V100 GPU

plementation in vendor libraries like cuDNN. NASRNN [58] is another RNN-based model created by network architecture search (NAS) that has not been manually optimized yet. Attention [43] is a widely used architecture in NLP and CV. We use an auto-regressive attention mechanism to continue sentences. The above three models contain loops with fixed iteration counts. Seq2seq [40] is a sequence-generation model that contains a while loop for continuously generating new tokens until an end-of-sequence (EOS) token is emitted or the maximum sequence length limit is reached. BlockDrop [47] and SkipNet [46] are two CNN-based CV models with branches for skipping some layers. Recursive Autoencoder (RAE) [39] is a well-known recursive model for NLP. The configuration of these models is listed in Table 1.

We set the batch size (BS) of the experiments to 1 and 64 to match the requirements for online inference and offline inference. The time is measured by averaging 100 tests after 100 warm-up runs. For models using real datasets, we randomly sample  $100 \times BS$  cases from the datasets.

## 5.1 End-to-end Evaluation on NVIDIA GPU

Figure 14 shows the inference performance of COCKTAILER by comparing with TorchScript, TensorFlow, and JAX with JIT enabled. All three frameworks support control flow operations by executing them on CPU. Overall, COCKTAILER outperforms the best baseline in each model by  $1.85\times$  in geometric mean (up to  $8.22\times$ ). Specifically, COCKTAILER outperforms TorchScript by  $3.98\times$  on average (up to  $9.35\times$ ), TensorFlow by  $18.45\times$  on average (up to  $196.85\times$ ), and JAX by  $3.05\times$  on average (up to  $327.62\times$ ). The time for compiling each model (except kernel tuning by AutoTVM and Anso) is several seconds to minutes.

**Models with loops** LSTM has been manually optimized by many frameworks and vendor libraries, and we use the fastest built-in implementation in the baselines. The core control flow operations of LSTM are two loops iterating over the input sequence and the layers respectively. TensorFlow and TorchScript use the manually-optimized LSTM in cuDNN library, while JAX loops over manually-optimized LSTM cell implementation. According to profiling, TensorFlow uses

the persistent-RNN [8] to optimize the loop over the input sequence, but it does not accelerate the loop iterating over the layers. TensorFlow with BS=64, TorchScript, and JAX only optimizes the operators in one LSTM cell, and does not perform joint optimizations on LSTM cells in different iterations. Different from these systems, COCKTAILER fully unrolls the static loop over layers and unrolls some steps of the loop over inputs, so that it can expose a large set of operators to the data flow optimization passes and benefit from the inter-operator schedule of Rammer. COCKTAILER outperforms all framework with handly-optimized implementations by  $1.75\times$  when BS=1 and  $1.93\times$  when BS=64.

The computation of NASRNN and Attention has not been manually optimized. These frameworks optimize the basic block using only passes for compiling static data flow, and execute the loop on CPU. COCKTAILER performs some loop optimizations and schedules the loop to thread block level. With such optimizations, COCKTAILER achieves  $2.10\times$  on NASRNN model and  $2.82\times$  speedup on Attention model over the fastest baseline when BS=1. However, COCKTAILER only achieves  $1.01\times$  speedup over COCKTAILERBASE on Attention BS=64 because control flow only take a small portion of execution time when the body computation is large enough.

Seq2seq is implemented with a while loop, and existing frameworks need to copy the decision from the accelerator to the CPU to decide whether to continue the loop. By executing the loop on GPU, COCKTAILER can both use fewer kernels and avoid such synchronization. The speedup over the fastest baseline is  $1.61\times$  and  $1.29\times$  when BS=1 and BS=64, respectively.

**Models with branches** BlockDrop and SkipNet drop some layers from ResNet with decisions generated at runtime. The baselines need to copy the decision from GPU to CPU to decide whether to launch the next layer. COCKTAILER avoids such synchronized copy by scheduling the branch to block level for BlockDrop BS=1, and using branch reclustering for BlockDrop BS=64 and SkipNet BS=1. COCKTAILER accelerates BlockDrop by  $1.84\times$  and  $1.13\times$  over the best baseline when BS=1 and BS=64, respectively, and accelerates SkipNet by  $1.41\times$ .

Figure 15: Control flow overhead of models with loops.

**Model with recursion** RAE is a recursive model. TensorFlow does not support recursion. PyTorch and JAX can only run this model in Python, resulting in poor performance. COCKTAILER schedules the recursion to block level with parallel execution and executes the recursive calls efficiently with the simulated stack, resulting in  $9.35\times$ ,  $327.62\times$ , and  $8.22\times$  speedup over PyTorch, JAX, and COCKTAILERBASE respectively.

**Discussion** Whether a model is control flow bound or data flow bound depends on the ratio of control flow computation and data flow computation. According to the evaluation among different models in Figure 14, it is clear that COCKTAILER can achieve higher speedup when model execution has more control flow computation, e.g., NASRNN, RAE. When the data flow occupies the most computation (e.g., Attention in BS=64), COCKTAILER can achieve similar performance with the fastest baseline.

## 5.2 Control Flow Overhead Analysis

In this section, we evaluate the performance degradation caused by control flow boundary in different systems when BS=1. The results are shown in Figure 15, 16, and 18. For each model, we choose an input with a typical execution trace of the dataset. We compare the real scenario that executes control flow at runtime to executing the traced computation graph with no control flow to evaluate the overhead. The traced graph baseline of COCKTAILER is compiled by Rammer with the same kernel implementations and compilation passes for data flow as COCKTAILER.

**Models with loops** Figure 15 shows the control flow overhead of models with loops. The input data of LSTM, NASRNN, and Attention is a sequence with length provided in Table 1, and the input to Seq2seq generates a 10-token-sequence which is near to the average sequence length of the dataset.

For LSTM model, Rammer can explore the parallelism of

Figure 16: Control flow overhead of models with branches. "No skip" refers to running all layers of the ResNet model.

cells in different steps if all steps are unrolled. The dynamic unrolling of COCKTAILER provides similar performance with Rammer, but can support dynamic step count. Other systems do not explore such parallelism and are slower than COCKTAILER. To expose the loop of TorchScript and TensorFlow, we do not use their cuDNN LSTM here.

For NASRNN, Attention, and Seq2seq models, COCKTAILER schedules the loop to thread block level with only one GPU kernel, and is faster than Rammer which uses a larger number of kernels. A similar phenomenon also appeared in the NASRNN model with JAX. JAX generates thousands of different kernels for execution the unrolled loop and is slower than looping over the NASRNN cell with 3 kernels for 1000 times. This indicates that an efficient implementation of control flow can sometimes be faster than running the unrolled data flow.

For Seq2seq model, TorchScript, TensorFlow, and JAX need to copy the decision back to CPU to decide whether to execute the next iteration of the while loop, causing a synchronization between CPU and GPU. Therefore, when control flow is used, the increase of execution time is larger than that of kernel time. COCKTAILER does not have such a problem because all control flow operations are executed on GPU.

**Models with branches** Figure 16 shows the control flow overhead of models with branches. The two models skip some layers from a ResNet model, and we add a "no skip" which is a normal ResNet without skipping layers. The ratios of executed layers are 7/15 for BlockDrop and 23/33 for SkipNet, which are similar to the average ratio of the models respectively.

Due to the synchronization between CPU and GPU, the control flow operations of the baselines increase the execution time by at least 34% over the traced version for BlockDrop, while COCKTAILER only increases the execution time by 11%. Therefore, though more than half of the layers are skipped, the performance improvement of layer skipping compared with the original ResNet model is only at most  $1.44\times$  in the baselines, while COCKTAILER achieves  $1.79\times$  speedup. In SkipNet, the network for making the skip decision is heavier and the ratio of executed layers is larger, so the traced graph may take longer execution time than the original ResNet model. The slow execution of control flow makes the performance of

Figure 17: Different ratio of executed layers

Figure 18: Control flow overhead of RAE with recursion.

this model even worse in baselines, while COCKTAILER can still provide reasonable performance.

Figure 17 shows the performance of BlockDrop and SkipNet at different ratios of executed layers. The results of JAX, the fastest baseline of the two models are also included. When the executed ratio is 0, the model executes all control flow operations but runs no layers, and COCKTAILER achieves  $3.00\times$  and  $2.68\times$  speedup over JAX on BlockDrop and SkipNet, respectively. This proves the low control flow overhead of COCKTAILER. In SkipNet, if the model is executed with JAX, the layer-skipping can improve the performance only when the ratio of executed layers is lower than 20%, while if executed with COCKTAILER, this ratio becomes about 65%.

**Model with recursion** Figure 18 shows the control flow overhead of the recursive RAE model. The input is a 65-node tree from the Stanford Sentiment Treebank dataset. PyTorch and JAX can only execute the recursion in Python and the time is much longer than executing the traced graph. Rammer processes nodes without dependencies in parallel with a static schedule that only works for this tree, while COCKTAILER executes the model by control flow operations on the GPU side and only increases the time by 11%.

**Discussion** Compared with the traced graph baseline which removes all the control flow operations in the models and can be considered as the optimal status, COCKTAILER achieves similar performance. Besides, the overall latency of COCKTAILER is similar to the kernel time, which indicates that COCKTAILER can minimize the overheads introduced by control flow. Furthermore, the evaluations on BlockDrop and SkipNet show that COCKTAILER also enables scenarios like efficient computation by achieving real speedup. We hope COCKTAILER can provide more flexibility for algorithm researchers to design DNN architectures with control flow.

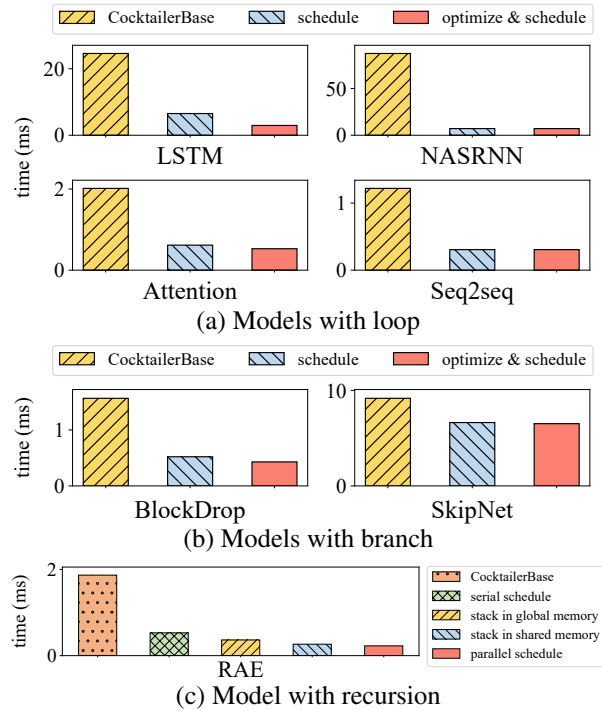

Figure 19: Breakdown of models with BS=1

### 5.3 Breakdown of Optimizations

Figure 19(a) provides the breakdown of optimizations applied on models with loops. On average, scheduling the loop to block level provides  $4.95\times$  speedup over COCKTAILERBASE that executes the loop in PyTorch runtime. And applying the optimizations in §3.2, especially the dynamic loop unrolling further improves the performance of LSTM by  $2.22\times$  and Attention by  $1.17\times$ . In LSTM, the loop is re-scheduled to kernel level after loop unrolling.

Figure 19(b) provides the breakdown for models with branches. The branches of the two models are executed on GPU, with branch reclustering used in SkipNet. The scheduling provides  $3.01\times$  and  $1.38\times$  speedup over COCKTAILERBASE on BlockDrop and SkipNet, and the optimizations further accelerate the two models by  $1.21\times$  and  $1.02\times$ .

Figure 19(c) shows the performance of the RAE model. Executing the recursion on GPU provides  $3.54\times$  speedup over COCKTAILERBASE. The simulation of stack using global memory and shared memory are  $1.45\times$  and  $1.99\times$  faster than using the built-in GPU stack. And the parallel scheduling of  $\mu$ Programs further improves the performance by  $1.17\times$ .

### 5.4 End-to-end Evaluation on AMD GPU

Figure 20 compares TorchScript, TensorFlow, JAX with JIT enabled and COCKTAILER on AMD MI100 GPU with BS=1. COCKTAILER outperforms the three frameworks on all benchmarks by  $2.97\times$  over TorchScript on average (up to  $5.86\times$ ),  $21.28\times$  over TensorFlow on average (up to  $112.34\times$ ), and  $3.22\times$  over JAX on average (up to  $272.63\times$ ).

Figure 20: End-to-end DNN inference on AMD MI100 GPU with BS=1

## 6 Related Work

Supporting control flow in deep learning can be divided into two categories. The first one, represented by TensorFlow 1.x [4] and TorchScript [36], executes control flow operations in the framework runtime on CPU. Control flow is implemented as special operators (`NextIteration` for loops [52], `Switch` for branches [52], and `InvokeOp` for recursions [19]) or instructions in the runtime. The second one, represented by Chainer [42], PyTorch [36], and JAX [11], leverages the runtime of general-purpose language like Python to support the control flow operations. The control flow operations are expressed with Python statements and executed by the Python interpreter. AutoGraph [31], Janus [18], and Terra [22] show that the control flow operations expressed by general-purpose languages can sometimes be converted to the control flow operators in the framework runtime. Despite different ways of supporting control flow, the control flow operations in these works can only be executed by CPU.

Some special forms of control flow have been deeply optimized. VersaPipe [55] optimized pipelines for general GPU programs. Cortex [10] provides interfaces to describe recursion with data patterns (i.e., the recursion tree structure). It assumes that the jump direction of all control flow only depends on the input recursion tree structure, so it does not apply to control flow depending on dynamically computed data, e.g., the while loop with unknown iteration count in Seq2seq [40], and the branches whose direction is decided at runtime in BlockDrop [47] and SkipNet [46]. COCKTAILER does not assume the availability of such tree structures and works on these models.

Past works on batching (e.g., DyNet [33], Cavs [49], Tensorflow Fold [27], BatchMaker [12], Program-counter-autobatching [37], and ORCA [51]) enable the parallelization in different control flow operations by introducing a scheduler to batch the ready-to-execute operators, which is another applicable approach and is complementary to COCKTAILER. Specifically, COCKTAILER can compile subgraphs of a model, and then batching can be applied to these subgraphs. Applying batching on the more coarse-grained subgraph granularity can also reduce the scheduling cost in the batching scheduling.

There are many deep learning compilers for optimizing a computation graph without control flow, including TVM [6], TASO [20], Rammer [28], DNNFusion [35], PET [44], and AStitch [56]. These optimizations are compatible with COCKTAILER. COCKTAILER even enlarges their optimization scope because the boundary of control flow has been reduced. Com-

pilation optimizations like function inline [5], loop unroll [9] have been introduced in general-purpose language compilers on CPU programs and have been implemented in COCKTAILER. COCKTAILER further introduces the new *uTask* abstraction to represent both data flow and control flow operations, which aligns with the parallelism of hardware accelerators, enabling analyzing and optimizing both data flow and control flow computation over heterogeneous accelerators (i.e., GPU). To scale DNN models on distributed architectures, frameworks and compilers like Tofu [45], FlexFlow [21], GSPMD [50], PipeDream [32], Tutel [17], FasterMOE [14], FlexMoE [34], BaGuaLu [29], Alpa [54] and SuperScaler [25] parallelize the execution of deep learning models across multiple hardware devices, but only focus on models with static architectures or specific types of dynamic models (e.g., Mixture-of-Experts [30]). COCKTAILER exposes the parallelism of control flow operations, which can be leveraged to support dynamic models over distributed devices.

## 7 Conclusion

DNN frameworks and compilers suffer from performance issues when supporting sophisticated dynamic DNN models. The parallelism mismatch between control flow and data flow results in separate execution of DNNs on the CPU and accelerator, causing not only overheads but also missed optimization opportunities. COCKTAILER supports sophisticated DNN models by co-scheduling the execution of control flow and data flow that (1) provides the fine-grained *uTask* abstraction for control flow and data flow in DNN programs to open a holistic scheduling space on hardware accelerators; (2) designs the scheduling mechanism and a heuristic policy to exploit this scheduling space; (3) provides control flow optimizations in both scheduling and code generation. Evaluations demonstrate that COCKTAILER significantly outperforms state-of-the-arts on sophisticated DNN models. By enabling the co-optimizing of control flow and data flow in a single space, COCKTAILER positions itself as a new enhancement to the deep learning infrastructure.

## A Artifact Appendix

### Abstract

This artifact helps to reproduce the results of OSDI'23 paper: COCKTAILER: Analyzing and Optimizing Dynamic Control Flow in Deep Learning.

### Usage

The input of COCKTAILER is a PyTorch program. COCKTAILER exports the PyTorch program to ONNX format with ONNX loop and branch operators as well as an extended invoke operator for recursion. Then COCKTAILER generates the code with optimizations described in the paper and wraps the code to a PyTorch custom operator for execution.

### Scope

The artifact can be used to reproduce the experiments of the paper, including the end-to-end comparison (Figure 14 and 20), control flow overhead analysis (Figure 2, 15, 16, and 18), performance of different ratio of executed layers (Figure 17), and breakdown of optimizations (Figure 19).

### Contents

This artifact includes the code of COCKTAILER, input data of experiments, a guide for setting up the environment of the experiments, and scripts for running the experiments. It helps to reproduce the following Figures:

- Figure 2: Control flow overhead in JAX
- Figure 14: End-to-end DNN inference on NVIDIA V100 GPU
- Figure 15: Control flow overhead of models with loops
- Figure 16: Control flow overhead of models with branches
- Figure 17: Different ratio of executed layers
- Figure 18: Control flow overhead of RAE with recursion
- Figure 19: Breakdown of models with BS=1
- Figure 20: End-to-end DNN inference on AMD MI100 GPU with BS=1

### Hosting

The main contents of COCKTAILER are hosted at [https://github.com/microsoft/nfusion/tree/cocktailer\\_artifact/artifacts](https://github.com/microsoft/nfusion/tree/cocktailer_artifact/artifacts), branch `cocktailer_artifact`.

## Requirements

This artifact needs two machines:

- a machine with 8 NVIDIA V100 GPUs, with NVIDIA driver properly installed. Users can either follow the installation guide to setup the software environment or install the NVIDIA Container Toolkit to reproduce the results within the docker provided by the artifact.
- a machine with 1 AMD MI100 GPU, with ROCm driver and docker properly installed. Users can then reproduce the results within the dockers provided by the artifact.

# WELDER: Scheduling Deep Learning Memory Access via *Tile-graph*

## Abstract

With the growing demand for processing higher fidelity data and the use of faster computing cores in newer hardware accelerators, modern deep neural networks (DNNs) are becoming increasingly memory intensive. A disparity between underutilized computing cores and saturated memory bandwidth has been observed in various popular DNN models. This inefficiency is caused by both the conventional treatment of DNNs as compute-intensive workloads and the lack of holistic memory access optimization in DNN models.

In this paper, we introduce WELDER, a deep learning compiler that optimizes the execution efficiency from a holistic memory access perspective. The core of WELDER is *tile-graph*, an abstraction that facilitates fine-grained data management at tile level. By leveraging the observation of optimization independence across memory layers, WELDER is able to decompose the whole combinatorial DNN optimization space into several independent ones and effectively trade off between intra- and inter-operator data reuse using a tile traffic-based cost model. This allows WELDER to unify previous ad-hoc memory optimizations into a single space, generate efficient execution plans with 89 more optimization patterns, and outperform state-of-the-art solutions significantly. WELDER is also able to handle DNN models with arbitrarily large input by combining the existing accelerator memory and host memory as a whole system.

## 1 Introduction

Deep neural networks (DNNs) have been used in a wide range of tasks like vision and language analysis and synthesis. Conventional wisdom treats DNNs as compute-intensive workloads. A DNN model is often defined as a dataflow graph (DFG), where each node represents a compute-intensive operator (e.g., matrix multiplication). These operators are offloaded to modern accelerators with massive parallel computing cores, such as GPUs and TPUs [23], to speed up com-

putation. To utilize accelerators efficiently, DNN frameworks and compilers explore various optimization techniques, such as code specialization [15, 50, 52] and operator fusion [15, 31].

Although these computation centric optimizations are shown effective for classic DNN models, we observe that modern DNNs are becoming increasingly memory intensive. Our profiling on a range of state-of-the-art DNN models reveals that the bottleneck of the end-to-end DNN computation is mostly on GPU memory. The memory bandwidth utilization can be as high as 96.7% while the average utilization of computing cores is only 51.6% (§2). Moreover, we observe the disparity between the underutilized cores and the saturated memory bandwidth could become even larger with the evolution of both hardware and DNN models. Modern models are processing higher fidelity data, e.g., larger images, longer sentences, high-definition graphics, which consume more memory bandwidth in the computation. Furthermore, the faster computing cores (e.g., TensorCore [6]) impose an even greater pressure on memory.

Optimizing memory intensive DNN workloads is challenging as it requires improving the sophisticated data access and reuse patterns across multiple memory layers (e.g., GPU DRAM and shared memory). From the memory perspective, DNN computation comprises of a repetitive process for each operator to 1) load input tensors across memory hierarchy, 2) compute at the cores, and 3) store the resulting tensors across memory hierarchy. To derive a good data access pattern, it requires a careful calculation of the size of tile, a partition of a tensor, along each tile dimension. Such a tiling strategy is already difficult to obtain in existing practice [5, 50, 52]. As a further complication, due to the different algorithmic semantics, each operator may require a different data access patterns. Such diversity across operators makes *inter-operator* data reuse especially challenging, and often infeasible. If the derived tile shape of an operator at a certain memory layer does not match that of a downstream operator, it is difficult to reuse the tile at that layer. Consequently, existing approaches either focus on intra-operator optimization and leave all inter-operator intermediate tensors in the lowest memory layer

\*Work is done during the internship at Microsoft Research.

(e.g., GPU memory), or rely on rule-based operator fusions to alleviate the inter-operator memory overhead. These rules are only applicable for specific operator combinations (e.g., register fusion for element-wise operators [10, 13, 15], shared memory fusion for a limited set of operator types [51]) and can be suboptimal when having different input sizes or running on different hardware configurations.

In this paper, we introduce WELDER, a deep learning compiler that holistically optimizes memory access for end-to-end DNN models consisting of general operators. The design of WELDER is based on three key observations. First, to resolve potential tile shape conflicts between two adjacent operators, we observe that their aligned tile shape can be automatically inferred by propagating an output tile shape from back to front, given that the computing logic in each operator can be accurately preserved (e.g., through the tensor expression). Second, to decide which tile shape will lead to better performance, by enforcing the computation pattern to be aligned with hardware feature (e.g., TensorCore), we can just minimize the data traffic across all memory layers. Given the operators with aligned tile configuration, we notice that their data traffic can be easily modeled based on their input/output tile sizes and the input/output tensor shapes. Finally, when considering the whole memory hierarchy, we observe that the optimization of memory traffic is inherently independent across memory layers, i.e., *inter-layer independence*. Particularly, the above traffic model is determined only by the tile configuration at the memory layer of interest. These observations allow us to optimize the whole space with an effective process: starting from aligning two adjacent operators at independent memory layers, deciding their optimal tiling size at the right memory layer guided by traffic costs, and expanding the optimization to include further operators.

WELDER incorporates these insights into a new DNN compiler design. First, to facilitate fine-grained data management, WELDER proposes *tile-graph*, a tile-level data-flow graph to model DNN computation. Each node in the graph processes one data tile of a tensor at a time. To map DNN computation to a multi-layered memory hierarchy, WELDER allows the control of each node’s data tile size and the desired memory layer to reuse the data tile between two nodes. Specifically, WELDER provides a `SetConnect` interface to set the data reuse layer for each edge and a `Propagate` interface to infer the tile configurations within a group of connected nodes. Second, to efficiently optimize the tile level data-flow scheduling holistically, WELDER exploits the *inter-layer independence* properties in the data-flow computation to decouple the optimization space into multiple sub-spaces. Based on this, WELDER proposes a two-layered scheduling policy that enumerates different memory connection options for each edge and decides on an efficient tile configuration for each sub-space guided by the traffic cost model. Finally, the optimized execution plan is mapped to executable code for a specific hardware accelerator through four abstracted com-

puting interfaces defined in the hardware layer: `Allocate`, `LoadTiles`, `ComputeTile`, and `StoreTiles`.

With the tile level holistic data-flow scheduling, WELDER is the first to unify all common operator fusions (e.g., register-based element-wise fusion, shared-memory fusion, etc.) into a single framework. This generality allows WELDER to find 89 uncommon operator fusion patterns automatically that are mostly unexplored by existing rule-based approaches (§5.2). Interestingly, our approach can easily support new requirements for handling DNN models with arbitrarily large input (e.g., high-resolution images), where even a single operator may be too large to fit in the GPU memory. Specifically, by extending the current memory hierarchy with additional layers (e.g., host memory), WELDER can generate an optimized execution plan across the combined hierarchy of host and device memory.

We have implemented WELDER on top of TVM [15], Rammer [31] and Roller [52]. Our evaluation is conducted on 10 state-of-the-art DNN models covering both classic and recent model structures for various tasks including vision, NLP, 3D-graphics, etc. The evaluation results show that WELDER significantly outperforms the state-of-the-art DNN framework and compilers like PyTorch, ONNXRuntime, and Anso on both NVIDIA and AMD GPUs, with up to  $21.4\times$ ,  $8.7\times$ ,  $2.8\times$  speedups, respectively. WELDER’s automatic optimization even outperforms TensorRT [7] and Faster Transformer [2], which are a highly optimized handcrafted DNN inference library and a model-specific implementation from NVIDIA, with up to  $3.0\times$  and  $1.7\times$  speedups. Furthermore, when running these models on hardware with faster computing cores such as TensorCore, we observe a larger improvement in performance, highlighting the importance of memory optimization for future AI accelerators.

## 2 Motivation

**Modern DNNs are memory-bounded.** Figure 1 presents the average GPU utilization, including both computational FLOPS and global memory throughput, for a representative DNN benchmark running with ONNXRuntime [8]. As shown, the average computation utilization is only 51.6% while memory utilization is 96.7%. When examining the model types, we find that ResNet and BERT, which are dominated by convolution and matrix multiplication operators and can achieve relatively high computation utilization (e.g., >80%), are two representative classical models. However, the remaining models, which are popular models proposed in recent years, exhibit low computation efficiency due to introducing more memory-intensive patterns beyond compute-intensive operators. Additionally, we observe that the new DNN models often have a higher ratio of memory store traffic to load traffic compared to classical models. The primary reason is these models tend to process high-fidelity data and generate large activations across layers. However, current systems such

Figure 1: Computation FLOPS and memory bandwidth utilization for different models on NVIDIA V100 GPU.

Figure 2: Latency numbers of unfused, fused, and each individual kernels of Matmul and Softmax.

as ONNXRuntime have limited optimizations for reducing inter-operator traffic. This indicates that these models will frequently exchange large intermediate data across operators through global memory. The results highlight the need for optimizing memory access efficiency across operators.

### Conflicted intra- and inter-operator data reuse patterns.

Optimizing intra-operator and inter-operator data reuse simultaneously is challenging. An operator is often implemented as nested multi-level loops over all tensor dimensions. Within the operator, the data reuse across multiple memory layers are often implicitly optimized using sophisticated loop tiling techniques [5, 50, 52]. We consider a typical pattern of two consecutive operators, i.e., Matmul and Softmax. When the two operators are optimized independently, their optimal tile sizes in shared memory are different, e.g.,  $[32 \times 64]$  for Matmul and  $[4 \times 128]$  for Softmax. As a result, Softmax is unable to reuse the intermediate data from Matmul in shared memory, leading to a total latency of 0.36ms, as shown in Figure 2. However, if we force them to take into account both intra- and inter-operator data reuse, the fused operator latency can be reduced to 0.29ms, achieving a 1.26x speedup. Upon examining their aligned tile size (i.e.,  $[16 \times 128]$ ), we observe that both operators sacrifice their own efficiency (e.g., with 15% and 4% performance degradation when running separately, due to suboptimal data tile for intra-operator data reuse) in favor of overall efficiency. This demonstrates the need for an efficient data reuse solution across intra-operator and inter-operator to optimize memory access holistically.

**Key observations.** Through a further analysis on the example in Figure 2, we have identified three key observations. First, an aligned tile configuration across operators can be deduced based on a chain of shape inference starting from an output tile shape. For example, if we want to compute a  $[4 \times 128]$  output tile of Softmax, based on its computing logic (e.g., tensor expression), we can deduce that its dependent

input tile shape is also  $[4 \times 128]$ . Then, by using  $[4 \times 128]$  as the output tile of Matmul, we can further deduce that input tile shapes of Matmul will be  $[4 \times k]$  and  $[k \times 128]$ , where  $k$  is an reduction size that can be set as any number not exceeding the reduction dimension size of the Matmul. In this way, the two operators can be fused by reusing the intermediate data tile ( $[4 \times 128]$ ) in shared memory.

Second, given the aligned tile configuration and the original tensor shapes, the total memory traffic can be easily derived analytically. In this example, the Matmul takes input tensors A in shape  $[98304 \times 64]$  and B in  $[64 \times 128]$  respectively, and an output tensor C in  $[98304 \times 128]$ . The Softmax then takes C as input and produces an output tensor D in the same shape. Input tensors A, B, and the output tensor D are in global memory. Given these shapes, we can first calculate the memory traffic when computing a single output tile (i.e.,  $[4 \times 128]$ ) of tensor D. To do so, it will first load a tile of shape  $[4 \times k]$  from tensor A and a  $[k \times 128]$  tile from tensor B for Matmul, and then the intermediate tile  $[4 \times 128]$  will be consumed by Softmax in shared memory, and write a tile of shape  $[4 \times 128]$  to tensor D, where the  $k$  can be replaced as 64 given the input tensor shape of  $[98304 \times 64]$ . Thus, the total traffic incurred in global memory for an individual output tile is 35KB  $((4 \times 64 + 64 \times 128 + 4 \times 128) \times 4 \text{Bytes}(\text{FP32}))$ , where the traffic of the intermediate tile  $[4 \times 128]$  is saved due to data reuse in shared memory. To compute the full output tensor D, a total of 24,576 such computations are required (i.e.,  $(98304 \times 128) / (4 \times 128)$ ), resulting in a total global memory traffic of 840MB (i.e.,  $24,576 \times 35\text{KB}$ ). Interestingly, changing the output tile to  $[16 \times 128]$  will reduce the total traffic to only 264MB, following the same calculation.

Finally, our traffic-cost calculation is only determined by the tile configuration at the memory layer of interest, e.g., the output tile shapes of  $[4 \times 128]$  or  $[16 \times 128]$  in shared memory, once the tensor shapes are specified. This allows us to choose the tile size for each layer independently in order to optimize the traffic cost from the lower memory layers.

These observations together provide us an effective way to optimize memory access holistically, i.e., aligning a group of adjacent operators through an output tile shape, deciding on the best tile shape based on memory traffic, and optimizing for each memory layer independently. In this way, WELDER is able to change the original coarse-grained inter-operator dependency into a more fine-grained tile-level dependency, which essentially removes some false barriers between operators and enables more concurrency.

## 3 WELDER Design

The observations in §2 motivate WELDER, a deep learning compiler that aims to improve the performance of modern DNNs in a holistic memory access scheduling space. Figure 3 shows the system overview. WELDER takes a full DNN model as input and converts it into a data-flow graph of tile-based

Figure 3: System overview of WELDER.

computing tasks (i.e., *operator-tiles*), which is called *tile-graph* (§3.1). A tile-graph provides fine-grained control over data tile configurations and memory placement. Given a tile-graph, WELDER resolves the intra-operator and inter-operator data-reuse conflicts through a "first-connect-then-schedule" approach: it first assumes two adjacent operators can reuse data tile at a certain memory layer (i.e., connect), and then derives the best common tile shape to see if the total memory traffic can be reduced. To facilitate this goal, WELDER provides two tile-graph scheduling interfaces: *SetConnect* and *Propagate* (for the chain of shape inference). Based on this, we propose a two-step scheduling algorithm, i.e., *graph connecting* and *sub-graph scheduling*, to recursively decide an efficient tile-graph execution plan for multiple memory layers, known as a *hierarchical tile-graph* (§3.2). Finally, this plan is then mapped to an executable code for a specific hardware accelerator using four abstracted computing interfaces defined in the hardware layer, i.e., *Allocate*, *LoadTiles*, *ComputeTile*, and *StoreTiles* (§3.3). The memory specification of the abstracted accelerator is used by the tile-graph scheduling layer to guide the optimization process.

### 3.1 Operator-tile and Tile-graph

WELDER defines DNN computation in a fined-grained task granularity named *operator-tile*. A DNN operator, such as convolution, can be implemented as multiple homogeneous operator-tiles, which are executed either in a streaming or parallel manner to compute all the data tiles in the output tensors [31]. Each operator-tile takes as input a data tile sliced from the input tensors and computes a data tile in the output tensors, with the computing logic described by an index-based tensor expression [15]. Figure 4(a) and (b) shows examples of operator-tiles for Conv and MaxPool, where the Conv operator computes a  $[1 \times 1 \times C]$  data tile by taking a  $[3 \times 3 \times C]$  data tile as input, and the MaxPool operator takes an input tile of  $[2 \times 2 \times F]$  and computes an output tile of  $[1 \times 1 \times F]$ .

To improve the utilization of hierarchical memory re-

Figure 4: Illustration of two operator-tiles: (a) Conv and (b) MaxPool; and (c) connecting them into a tile-graph (the weight tensor of Conv is omitted for simplicity).

sources, such as the shared memory, WELDER allows two adjacent operator-tiles to be "connected" through a common intermediate data tile, also known as a *reuse-tile*. This allows the second operator-tile to consume the data produced by the first operator-tile directly, without the need to materialize it into a full intermediate tensor. Figure 4(c) illustrates an example of this connection between two operator-tiles for Conv and MaxPool, using a  $[2 \times 2 \times F]$  reuse-tile. Multiple operator-tiles can be connected along each adjacent edge to form a data flow graph of operator-tiles, known as a *tile-graph*.

**Tile propagation.** Once connected, most tiles in a tile-graph are correlated, which can be automatically inferred by propagating an output tile shape to the entire graph. This is achieved by using a chain of shape inferences from the output nodes to the inputs. For each operator-tile, the dependent region of the input tensor can be accurately determined by analyzing its tensor expression and output tile size. In cases where the input region may contain irregular patterns such as sparse or noncontinuous access (e.g., *Gather* or *Convolution* with strides), our expression analysis provides a conservative upper bound as the input tile shape. If the tile-graph has multiple output nodes, their output shapes may also be correlated, as they may share a common ancestor node in the graph. In this case, after propagating the first output tile, we propagate separate shapes for the remaining output nodes, aligning them with the first one. If there is an inconsistent tile shape between the two propagations, we do not connect the latter output node to the current graph.

**Memory traffic and footprint.** After the tile propagation, the memory traffic and footprint of a tile-graph can be determined. First, the memory traffic for an individual tile-graph can be calculated by summing its input and output tile sizes. The total traffic is obtained through further multiplying this value by the number of tile-graphs needed to compute the full output tensor (e.g., through dividing the tensor size by the output tile size). Second, the minimum memory footprint for the tile-graph can be calculated using a memory allocation algorithm (e.g., *bestfit* [19]) by allocating all data tiles in a topological order. As a footprint optimization, input tiles that contain reduction axes can be further partitioned into smaller

Figure 5: Map three consecutive operators to a three-layer memory hierarchy (the weight of Conv is omitted).

ones, which can be loaded and consumed sequentially by accumulating their results to the output tile. Specifically, a particular policy can automatically try different tiling sizes along the reduction axes during the tile propagation.

### 3.2 Tile-graph Scheduling

To map a DNN model represented by an initial data flow graph to an accelerator, we can recursively partition each operator into multiple operator-tiles to fit within each memory layer, and connect operator-tiles at higher memory layers to exploit inter-operator data reuse. As a result, an entire DNN computation can be modeled as a data streaming pipeline over a two-dimensional space, with data tiles moving up and down the memory hierarchy vertically and being passed to successor operators at different layers horizontally.

Figure 5 illustrates an example of mapping three consecutive operators (Conv, ReLU, and MaxPool) to a three-layered memory hierarchy (e.g., from L2 to L0). The input tile of the Conv operator is repeatedly loaded from L2 to L1 and then L0 for computation. By connecting the Conv and ReLU operators at L0, the output of the Conv operator can be reused as the input for the ReLU operator, and the two operators form a tile-graph at L0. At the same time, they are consolidated into a virtual node (i.e., Conv+ReLU) in L1. The output of the ReLU is then continuously spilled into the data tile at L1 and reused as the input for the MaxPool, through further connection at L1. This allows all three operators to form a single tile-graph at the L1 layer, resulting in the virtual node Conv+ReLU+MaxPool in L2. After this recursive process, all operators are connected at the lowest layer as a single tile-graph.

**Decoupling optimization space.** Given the observation that DNN computation is mostly memory-bounded, our major optimization goal of the data streaming pipeline can be transformed to minimizing the memory traffic. This allows us to decompose the whole optimization space into several sub-spaces by leveraging the inherent independence of optimizing

```
void SetConnect(Edge *edge, MemLevel level);
TileConfig Propagate(TileGraph g,
                    Map<Axis, Dim> config);
size_t MemFootprint(TileGraph g);
size_t MemTraffic(TileGraph g);
```

Figure 6: The scheduling interface in WELDER

traffic across memory layers. Specifically, the total data traffic loaded from and stored to a lower memory layer for a given tile-graph can be estimated by just its output tile shape, i.e., used to deduce all the input and output tile shapes. Based on this property, different tile-graphs from the same or different memory layers can independently optimize their memory traffic by searching for the optimal tile shapes. For example, in Figure 5, the tile-graph of Conv and ReLU at L0 can be optimized independently of the L1 tile-graph (e.g., formed by the Conv+ReLU and MaxPool operators), which is referred to as *inter-layer independence*. This further implies that the optimal tile configurations of the sub-graphs Conv-ReLU and MaxPool at L0 are also independent, due to their independence with the tile-graphs at L1, to which we refer as *intra-layer independence*. In practice, the only constraint is that the tile size at the lower memory level must be larger than the tile size at the upper memory level. This is often the case, as the lower memory level typically has greater capacity than the upper memory level. With these properties, we can independently schedule each tile-graph given a graph connection plan.

**Scheduling interface.** WELDER provides two scheduling interfaces to control graph connecting and sub-graph tiling, as shown in Figure 6. First, the graph connecting is implemented using the SetConnect interface, which assigns a memory level for an edge in the tile-graph (the lowest level by default). After connecting, the tile shapes in the graph is inferred through the Propagate interface, by specifying the dimensional sizes of the output tiles and the optional reduction axes in input tiles. For example, in Figure 5, we can use the SetConnect interface to connect Conv and ReLU at L0 and connect ReLU and MaxPool at L1. After the connection, for the sub-graph Conv+ReLU, we can use the Propagate to infer the intermediate reuse-tile shape (i.e., [1, 1]) by specifying the output tile shape of [1, 1]. Similarly, we can also infer the intermediate reuse-tile shape of sub-graph Conv+ReLU+MaxPool (i.e., [2, 2, F]) by specifying the output tile shape of [1, 1, F]. The two scheduling primitives are essentially two interfaces to update the edges and vertices of the tile-graph. Particularly, SetConnect is used to add a connection between two nodes and Propagate is used to set tile configuration for a node. They together form a complete interface for updating the tile-graph. Note that these primitives are only used by WELDER’s scheduling policy and transparent to the end users. WELDER also provides two cost interfaces, MemFootprint and MemTraffic, to calculate the memory

```

1 Func GraphConnecting(g:Graph, d:Device):
2   for node : TopologySort(g.nodes()) do
3     for edge : node.out_edges() do
4       for level : d.MemLevels() do
5         SetConnect(edge, level);
6         s = ExtractSubgraph(node, 0);
7         configs = SubGraphTiling(s, 0, tensor_shapes);
8         if t = Min(d.Profile(configs)) < best_latency
9           best_latency = t;
10          best_level = level;
11        SetConnect(edge, best_level);
12 Func SubGraphTiling(g:Graph, level:Memory, c: Config)
13   configs = PriorityQueue();

34   return SubGraph(nodes);

```

Figure 7: Two-step tile-graph scheduling algorithm.

footprint and the total traffic of a tile-graph, which serve as our cost models to guide the scheduling.

**Scheduling policy.** WELDER adopts a two-step scheduling algorithm to optimize data flow computation effectively. Specifically, a *graph-connecting scheduler* first enumerates different graph connecting plans by setting different memory reuse levels for each edge, and then a *sub-graph scheduler* quickly searches for efficient tile configurations for each sub-graph decoupled by the graph-connecting scheduler. Figure 7 shows the two-step scheduling algorithm in WELDER. First, given a DNN data flow graph  $g$  and an accelerator device  $d$ , the graph-connecting scheduler enumerates all graph nodes and their output edges in a topological order (line 1-3). For each edge, WELDER tries different connection levels (e.g., using the `SetConnect` interface) (line 5). It then extracts the connected sub-graphs where all edges have connection

Allocate	Allocate workspace in a memory layer
LoadTiles	Load input tiles from lower memory layer
ComputeTile	Compute an operator-tile at the top layer
StoreTiles	Store result tiles back to lower memory layer
MemLevels	Query memory hierarchy configurations

Table 1: Device interfaces in abstracted hardware accelerator.

levels higher than 0. Here, we use the number 0 to represent the lowest memory level, and larger numbers for higher levels. The `ExtractSubgraph` function is implemented in line 26-31. For the extracted sub-graph, WELDER calls the `SubGraphTiling` function to get several efficient tile configurations and chooses the optimal one by profiling on the hardware (line 7-10). After comparing with all other connection levels, WELDER sets the best connection level for the current edge.

Then, the sub-graph scheduler (i.e., the `SubGraphTiling` function) takes as input a sub-graph and the last level tile configuration and searches for efficient tile configurations for the current level. First, WELDER enumerates the tile sizes (i.e., `EnumerateSubtiles` in line 14) for output dimensions using a tile shape expanding approach similar to Roller [52], which enlarges initial tile shape (e.g., size of 1) towards the shapes that can reduce total traffic and align with hardware features. After getting the output tile shapes, we can infer the complete tile configuration using the `Propagate` interface and check if it exceeds the memory capacity using the `MemFootprint` interface, or appends it to a sorted result list with the memory traffic as the key (e.g., using the `MemTraffic` interface) (line 15-18). Finally, we choose the top  $K$  configurations with the least memory traffic for the current level, and then extract the upper-level sub-graphs and decide their best tile configurations recursively by calling `ExtractSubgraph` and `SubGraphTiling` (line 20-24).

Note that WELDER has no assumption on the memory size on different memory hierarchies, as our scheduling policy can always try its best to determine the optimal layer and tile size to place intermediate data, so as to minimize the overall latency. While WELDER always favors hardware with large higher-level fast memory (e.g., shared memory) that can hold a sufficiently large intermediate data tile, because too small tile sizes could lead to worse intra-operator data reuse. The scheduling result of a data flow graph in WELDER is a *hierarchical tile-graph*, which starts as a full graph at the lowest memory level and is recursively split into several sub-graphs in the upper layers, all the way to the top level.

### 3.3 Mapping to Hardware Accelerator

The hierarchical tile-graph generated by WELDER is an abstracted execution plan that can be mapped to an executable code for a specific hardware accelerator. To facilitate this mapping, WELDER provides an abstracted accelerator device with hierarchical memory layers. The memory configura-

```

void ExecuteGraph(TileGraph g, MemLevel level,
                 void *in, void *out) {
    void *mem = Allocate(g.MemFootprint(), level);
    LoadTiles(in, mem);
    for (auto n : g.nodes())
        if (level == MemLevel.top)
            ComputeTile(n, mem.in[n], mem.out[n]);
        else
            ExecuteGraph(n.TileGraph(), level+1,
                        mem.in[n], mem.out[n]);
    StoreTiles(mem, out);
}
// execute a full DNN graph at memory level 0
ExecuteGraph(graph, 0, inputs, outputs);

```

Figure 8: Compilation routine of hierarchical tile-graph.

tions, such as the number of layers, memory capacity, and transaction width of each layer, can be obtained through a `MemLevels` interface (e.g., used in Figure 7). With this abstracted memory layer, it is easy to extend an existing accelerator with additional memory layers (e.g., host memory or SSD) as a new device, allowing it to handle very large tensors that may not fit in the single device memory (§5.4 for more details). WELDER’s performance gain mainly comes from the bandwidth gap between memory layers. Thus, as long as a lower-level memory becomes the bottleneck and a high-level memory can hold the intermediate data tile, WELDER can automatically pipeline the inter-operator data transfer on the faster, high-level memory.

In order to execute a hierarchical tile-graph on a hardware accelerator, WELDER provides four computing interfaces: `Allocate`, `LoadTiles`, `ComputeTile`, and `StoreTiles` (listed in Table 1). The routine for executing a hierarchical tile-graph using these interfaces is shown in Figure 8. The process starts by executing the bottom-layer tile-graph (i.e., the full DNN graph). For each tile-graph, it first allocates the necessary workspace in the corresponding memory layer (using the `Allocate` interface) and loads the input tiles into this space (`LoadTiles`). Then, it executes all the nodes in the sub-graph in a topological order. If the current memory layer is the top level, the node is executed directly in the computing cores (`ComputeTile`). Otherwise, the execution of the upper-level tile-graph is called recursively. Finally, the result tiles in the current space are stored in the lower memory layer (`StoreTiles`). This execution routine can be used as both a code generation process or a runtime process, depending on whether a specific accelerator implements these computing interfaces as code emitters or executable function calls. In WELDER, they are currently implemented as code emitters to generate the accelerator-specific computing logic. By executing this recursive routine, the entire hierarchical tile-graph is unrolled and a full-model computation program with all the necessary optimizations is generated automatically.

## 4 Implementation

WELDER is implemented based on open-source DNN compilers, TVM [15], Roller [52] and Rammer [31]. It leverages TVM for writing kernel schedule, Roller for enumerating efficient tile configurations, and Rammer for the end-to-end graph optimization. WELDER’s core mechanisms, including the tile-graph, tile propagation, scheduling algorithm, code generation, etc., are implemented in 5.2k lines of code. WELDER takes an ONNX graph as input and performs common graph optimizations such as constant folding and simple element-wise fusion. It then converts the optimized graph into a tile-graph for holistic memory scheduling optimization. WELDER is implemented on both CUDA and ROCm GPUs, and GraphCore IPU through the unified device interface (Table 1). For CUDA and ROCm GPUs, WELDER schedules data tiles on three memory layers: global memory (DRAM), shared memory, and register. To handle large images on CUDA GPUs and GraphCore IPU, we also extend their device memory by adding a host memory layer.

### 4.1 Hardware-aligned Tile Search

**Enumerate efficient data tile size.** WELDER takes into account several hardware-related factors that could impact the data access efficiency by introducing a penalty factor to the traffic cost model. First, if there is uncoalesced memory access, the total memory traffic will include the additional transactions required for these accesses. For instance, in CUDA GPUs, it is always preferable to use coalesced memory access for a contiguous 128 bytes of data (one transaction). Second, when there is insufficient parallelism due to a large tile size, the memory traffic is increased proportionally based on the utilization percentage of the computing cores. Finally, we add an infinite penalty if the total memory footprint of a given tile configuration exceeds the memory capacity. To avoid enumerating inefficient candidates, WELDER searches for output tiles by only enumerating the dimensions that can reduce traffic the most according to the cost model, and retrieves only top  $k$  candidates with the minimum traffic.

**Decide aligned computation parallelism.** In GPUs, the top-level operator-tiles that are executed in the same thread-blocks must agree on a unified block size (e.g., number of threads). To ensure this alignment, WELDER first enforces sufficient parallel tiles at the register level to align with the hardware parallelism (i.e., by enumerating hardware-aligned tiles). For example, in NVIDIA V100 GPUs, the tile number should be greater than 128, as each SM has 4 warp schedulers and each warp has 32 threads. We then determine the greatest common divisor among the tile numbers of all operators as the common thread-block size, if it is larger than the hardware parallelism (e.g., 128) and less than the maximum limitation (e.g., 1024). Otherwise, we set the block size to a number

that equals the hardware parallelism. Once the block size is decided, we bind all operator-tiles at the register level to these threads. If a single thread needs to run multiple tiles, we use TVM’s virtual thread to bind them, thus allowing concurrent data access over all memory banks and avoiding bank conflicts.

**Support TensorCore.** WELDER leverages TensorCore to accelerate certain operators such as GEMM, BatchMatmul, and Convolution (using implicit GEMM [28]) on CUDA GPUs. We add annotations to these operators indicating which axes will be bound to CUDA’s Warp-Level Matrix Operations. For top-level operator tiles, we bind them to warps (instead of threads) to perform MMA operations. Additionally, we introduce some extra constraints when enumerating tile sizes, such as ensuring that the number of threads is an integral multiple of the warp size and that the axes (M, N, and K) in each tile are an integral multiple of the fragment size of the MMA operations.

## 4.2 Code Generation and Compilation

WELDER’s kernel generation is based on TVM. In particular, the register level tile connection is implemented using TVM’s `compute_inline` schedule primitive. For shared memory level connection, we only use TVM to generate standalone kernels for each connected part above the shared memory, and then apply several additional passes to compose these standalone kernels into a single fused kernel.

**Load/store rewriting.** The standalone kernels generated by TVM load and store data from global memory. We rewrite these global memory accesses to shared memory accesses by adding an additional TIR [11] pass to TVM’s lowering procedure. Additionally, we add memory fences to prevent race conditions and apply padding to handle bank conflicts in the buffers. As a result, the original global kernel can be transformed into a device function, which is included in the final fused kernel.

**Block/thread index remapping.** Some operators cannot be directly connected to others and require remapping of their `blockIdx` and `threadIdx` values. The `BlockIdx` remapping is used for operators such as `Transpose`. The remapping relationship is deduced from their tensor expressions. The `ThreadIdx` remapping is used to connect 2D thread blocks to 1D thread blocks. This is necessary when inter-thread reduction or TensorCore primitives require the use of a 2D thread block (both `threadIdx.x` and `threadIdx.y`), while others may use a 1D thread block (only `threadIdx.x`). A 2D thread block can be mapped to a 1D thread block as long as their total number of threads is equal.

**Memory management.** We manage all shared memory, including that allocated in each standalone kernel and the inter-

operator reuse buffer, in a uniform manner. First, we analyze the liveness of each buffer based on the topology execution order and convert them into a sequence of allocation and free operations. We then use the bestfit algorithm to compute the offset for each shared memory allocation, taking into account any alignment requirements for data types and TensorCore operations (e.g., aligning to 32 bytes to avoid misaligned address access).

**Compilation speedup.** WELDER optimizes the compilation speed through parallel compilations and sub-graph caching. First, by taking advantage of the independence between configurations, WELDER can use multi-processes to build and evaluate each configuration in parallel. Second, in most DNN models, some sub-graph patterns often repeat for multiple times. To avoid the redundant optimization, WELDER leverages a sub-graph signature to cache each unique graph pattern. For example, in a 12-layer BERT model, we can cache the optimization result (kernel code and profiled latency) for the first layer and reuse it for all the remaining 11 layers.

## 5 Evaluation

### 5.1 Experimental Setup

We evaluate WELDER using three servers equipped with different accelerators: NVIDIA GPU, AMD GPU, and Graphcore IPU. Two servers are equipped with the NVIDIA GPUs. The first one is an Azure NC24s\_v3 VM with Intel Xeon E5-2690v4 CPUs and NVIDIA Tesla V100 (16GB) GPUs, running on Ubuntu 16.04 with CUDA 11.0. The second one is a local workstation with Intel(R) Xeon(R) E5-2678 v3 CPUs and NVIDIA GeForce RTX 3090 GPUs, running on Ubuntu 18.04 with CUDA 11.3. The AMD GPU server is equipped with Intel Xeon CPU E5-2640 v4 CPU and AMD Radeon Instinct MI50 (16GB) GPUs, running on Ubuntu 18.04 with ROCm 5.2.3. The IPU server is an Azure ND40s\_v3 VM with Intel Xeon Platinum 8168 CPUs and 16 IPU with Poplar-sdk 3.0.

**DNN workloads.** WELDER is evaluated on 10 DNN models with different model types, including CNNs, Transformer, CNN-Transformer and multilayer perceptrons (MLP), and most of which are the state-of-art in the corresponding tasks. Table 2 characterizes them with a comparison of their model types, tasks, and the years of publication. For all models in the table, we use their official PyTorch implementations without modification.

**Baselines.** We compare WELDER with several DNN frameworks, including PyTorch (v1.12) [10] and ONNXRuntime (v1.12) [8], as well as state-of-the-art DNN compilers such as Ansor (v0.9) [50] and Rammer [31]. We also compare WELDER with TensorRT (v8.4) [7], a vendor-specific inference library for NVIDIA GPUs. For transformer models,

Figure 9: End-to-end model inference performance on NVIDIA V100 GPU (SIMT Core only). (left : batch size of 1, right : batch size of 64).

Model	Type	Task	Year
MobileNet [41]	CNN	Image Classification	2018
BERT [16]	Transformer	NLP	2018
ViT [17]	Transformer	Image Classification	2020
Conformer [20]	CNN+Transformer	Speech Recognition	2020
MobileViT [32]	CNN+Transformer	Image Classification	2021
Swin-Transformer [30]	Transformer	Image Classification	2021
NeRF [33]	MLP	3D-scene Generation	2021
NAFNet [14]	CNN	Image Restoration	2022
Restormer [48]	CNN+Transformer	Image Restoration	2022
BSRN [29]	CNN	Image Super-resolution	2022

Table 2: DNN models evaluated in WELDER.

we further compare WELDER with NVIDIA’s FasterTransformer (v5.2) [2], a hand-crafted C++ library optimized for transformer models. We also include BladeDISC (v0.3.0) [1] that implements the latest AStitch [51] for the kernel fusion optimization. We also include Nimble [25] which implements multi-stream scheduling as a baseline on NVIDIA GPUs.

To evaluate a model on these baselines, we first trace the model in PyTorch and export it to the ONNX format. We then use this ONNX model as input to other frameworks, including WELDER, Anso, ONNXRuntime, and TensorRT. For the ONNXRuntime, we use its CUDA execution provider and set its graph optimization level to "ALL" to achieve the best performance. For TensorRT, we use its Python API to build an engine for the input ONNX model. For Anso, we set the total number of tuning trials to 800× the number of tasks in each model. For all frameworks, we place the input and output tensors in GPU device memory to avoid additional data movement costs. During evaluation, we first perform some warm-up iterations and then run each workload repeatedly for at least 5 seconds. We only report the average speed for each model, as we observe very little variation in all cases. The average performance (e.g., speedup) across models is calculated by geometric mean in all experiments.

## 5.2 Evaluation on NVIDIA GPUs

This section answers the following questions: 1) How does WELDER perform in comparison with state-of-the-art DNN frameworks or compilers? 2) To what extent can WELDER further boost performance with TensorCores? 3) Can WELDER automatically discover new optimization patterns beyond previous expert-designed fusion rules? 4) How well does

WELDER improve both the memory and computational efficiency? 5) What is the search efficiency of WELDER’s holistic optimization?

**End-to-end performance.** Figure 9 shows the performance of WELDER and other baselines for batch size of 1, expressed as the normalized speedup relative to the best result. The geometric mean speedup that WELDER achieves over DNN frameworks is  $4.29\times$  for PyTorch and  $2.07\times$  for ONNXRuntime. PyTorch does not perform well for models with batch size 1 due to high Python overhead in its computation graph. In contrast, ONNXRuntime is a more optimized framework that removes Python overheads and implements pattern-based graph optimizations. WELDER also outperforms Rammer by  $1.96\times$ , as Rammer can only fuse independent parallel kernels instead of dependent ones through shared memory. When evaluating BladeDISC (implementing AStitch), we notice that it encounters "unsupported operator" failures and falls back to PyTorch runtime for the majority of models. For models without encountering any failure (including BERT, MobileNet, BSRN and NeRF), WELDER is  $2.70\times$  faster than BladeDISC. Regarding the Nimble baseline, WELDER achieves an average speedup of  $1.79\times$ , excluding the models where Nimble fails to execute.

Anso improves DNN performance by generating high-performance tensor programs and using rule-based fusion across operators at the register level (e.g., Matmul+BiasAdd, Conv2D+ReLU). However, it cannot exploit further memory reuse opportunities, leading to an average performance gap of  $1.44\times$  compared to WELDER. This is evident in CNN models such as NAFNet ( $1.70\times$ ) and BSRN ( $1.43\times$ ), which mainly consist of convolutions with relatively small channels that can be well optimized by WELDER. WELDER also outperforms Anso by a significant margin on Transformer-based models such as BERT ( $1.71\times$ ), Swin-Transformer ( $1.45\times$ ), and ViT ( $1.56\times$ ), due to Anso’s inability to fuse patterns like LayerNorm or Softmax in the attention block. Furthermore, WELDER performs well for CNN+Transformer models, achieving speedups of  $1.64\times$ ,  $1.39\times$ , and  $1.29\times$  on MobileViT, Conformer, and Restormer, respectively, as WELDER can cover fusion opportunities in both the CNN and Transformer parts of these models. We also observe that

WELDER only slightly outperforms Anso on NeRF (1.09 $\times$ ), mainly due to that the compute-intensive MLP dominates the computation without further optimization opportunities.

Finally, TensorRT is a specialized DNN inference library provided by NVIDIA with highly optimized operators. WELDER is comparable to TensorRT on popular transformer models such as BERT (1.02 $\times$ ) and Swin-T (0.97 $\times$ ). This is because TensorRT has incorporated expert-designed fusion rules and in-house kernels for some popular models, including transformer-based models, thereby leaving limited room for further optimization. In contrast, WELDER identifies optimization patterns automatically and achieves performance that is on par with TensorRT, despite relying on less performant kernels for compute-intensive operators. It is worth noting that kernel optimization is complementary to WELDER, and further optimized kernels may offer even greater benefits for WELDER. Additionally, for newer and more diverse models such as NAFNet, WELDER has demonstrated superior performance to TensorRT, with speedups of up to 3.09 $\times$  due to its generality. Overall, our system outperforms TensorRT with an average speedup of 1.47 $\times$ .

Figure 9 also shows the normalized performance for a larger batch size of 64. The last three models in Table 2 are unable to be traced on PyTorch with large batch sizes due to their use of large input size. Under this setting, WELDER continues to outperform all other baselines, providing an average speedup of 1.83 $\times$  over PyTorch, 1.90 $\times$  over ONNXRuntime, 2.1 $\times$  over Rammer, 1.57 $\times$  over BladeDISC, 1.49 $\times$  over Nimble, 1.47 $\times$  over Anso, and 1.21 $\times$  over TensorRT, respectively. We observe that for large batch sizes, frameworks using CUDA libraries perform much better, compared to the results for a batch size of 1. This leads to smaller speedups over PyTorch, ONNXRuntime, and TensorRT for WELDER, while the speedup over Anso remains similar to the results for a batch size of 1.

**Performance with TensorCore.** The faster computing throughput of TensorCore can put greater pressures on memory access. To understand the optimization behaviors when running on TensorCore, we convert our benchmark models (both weights and activations) to half-precision float type (FP16) with PyTorch, as TensorCore only supports FP16. This is done using the tools in the `onnxconverter_common` package [9], with the exception for TensorRT, which converts through its own converter as it often produces better results.

Figure 10 shows the performance comparisons of WELDER with other frameworks using TensorCore for batch sizes of 1 and 64. For the 10 cases that use a batch size of 1, WELDER outperforms PyTorch, ONNXRuntime, BladeDISC, Nimble, Rammer, and TensorRT. The averaged speedup is 7.18 $\times$  (up to 21.4 $\times$  on MobileNet) to PyTorch, 3.08 $\times$  (up to 8.72 $\times$  to on Conformer) to ONNXRuntime, 5.29 $\times$  (up to 16.9 $\times$  on MobileNet) to BladeDISC, 2.72 $\times$  (up to 5.58 $\times$  on NeRF) to Nimble, 2.76 $\times$  (up to 5.42 $\times$  on NAFNet) to Rammer, and

Model	DT	BS	WELDER(ms)	FT-CPP(ms)
BERT	FP32	1	3.13	3.15
BERT	FP32	64	118.6	119.8
BERT	FP16	1	1.49	1.50
BERT	FP16	64	24.82	22.29
ViT	FP32	1	1.33	1.96
ViT	FP32	64	15.29	15.68

swin-T	FP16	1	1.43	1.60
swin-T	FP16	64	23.12	28.67
<b>geometric mean</b>			6.71	7.46

Table 3: Performance for WELDER and FasterTransformer

1.53 $\times$  (up to 2.98 $\times$  on NAFNet) to TensorRT, respectively.

For the remaining 7 cases in Figure 10 that uses a batch size of 64, WELDER outperforms PyTorch by 1.98 $\times$ , ONNXRuntime by 2.13 $\times$ , BladeDISC by 1.97 $\times$ , Nimble by 3.84 $\times$ , Rammer by 3.45 $\times$  and TensorRT by 1.16 $\times$  respectively.

Some of the speedups are much larger than the ones achieved on SIMT cores. Especially for the NeRF model, WELDER outperforms TensorRT by 2.34 $\times$  on TensorCore, while the speedup on SIMT cores is only 1.16 $\times$ . This is mainly because TensorCore can greatly accelerate the compute-intensive part of the model, making the optimization of the remaining memory-intensive part more critical.

Note that Anso is not included in this experiment as it does not support TensorCore. For a fair comparison, we disable WELDER’s TensorCore feature and evaluate these FP16 models on SIMT cores by comparing with Anso in Figure 11. It shows a slightly higher speedups (1.74 $\times$  on average and up to 2.82 $\times$ ) compared with the ones in FP32.

**Performance on another NVIDIA GPU** We also conduct evaluations on RTX-3090, another widely-used GPU, which utilizes a distinct Ampere architecture. The RTX-3090 exhibits various new features compared to the V100, including advancements in memory load and TensorCore instructions, as well as a different number of streaming multiprocessors (SM). For the sake of conciseness, we solely compared WELDER with TensorRT on the RTX-3090, as TensorRT consistently delivers superior performance compared to other baselines on NVIDIA GPUs. The results, depicted in Figure 12, illustrate that WELDER outperforms TensorRT with an average speedup of 1.40 $\times$ , calculated using the geometric mean of all 34 test cases. Notably, this speedup is similar to the one observed on the V100 GPU, which amounted to 1.36 $\times$ , thereby highlighting WELDER’s adaptability across diverse GPU architectures.

**Patterns automatically discovered.** WELDER automatically discovers around 300 different fused subgraphs, which is counted by unique operator types under all 34 compiled test cases of the 10 models. Among them, 89 patterns contain at least two reduction-based operators which cannot be covered

Figure 10: End-to-end model inference performance on NVIDIA V100 GPU (TensorCore enabled). (left : batch size of 1, right : batch size of 64).

Figure 11: Comparing with AnsoR under FP16 w/o TensorCore

Figure 12: Comparing with TensorRT on NVIDIA RTX-3090 by simple element-wise fusion rule in AnsoR. To the best of our knowledge, many of these patterns are uncommon fusion patterns that have not been explored by manually-designed rules or automatic fusion optimizations. Figure 4 illustrates two examples of such patterns, which fuse multiple Convolution or MatMul (i.e., Dot) operators with other memory-intensive operators into a single kernel. The number of operators fused in each pattern ranges from 2 to 48 and can achieve an average speedup of  $1.87\times$  (up to  $5.4\times$ ) compared to basic fusion methods such as those used in AnsoR. The most common pattern has been used 191 times in all models.

Such a general fusion capability often allows WELDER to outperform the model-specific implementations optimized by experts. For example, FasterTransformer [2] is a manually-optimized benchmark for transformer models from NVIDIA. It supports both element-wise fusion, such as BiasAdd+Transpose, and non-element-wise fusion, such as Layernorm+Softmax. In WELDER, all these patterns can be automatically fused. Even more, WELDER can further fuse Q\*K with the following Softmax in the attention block when the sequence length is not long (e.g., they are fused

Fused operators	# Ops
DepthwiseConv2dNative Broadcast Add Broadcast Divide Erf Broadcast Add Multiply Broadcast Multiply Convolution Broadcast Add Broadcast Divide Erf Broadcast Add Multiply Broadcast Multiply Convolution Broadcast Add Broadcast Divide Erf Broadcast Add Multiply Broadcast Multiply Convolution Broadcast Add	48
Dot Relu Dot Relu Dot Relu Dot Relu Dot Relu Dot Relu Dot Relu Dot	13

Table 4: Examples of fusion patterns discovered by WELDER.

in BERT where the sequence length is 128, but are not fused in Conformer where the sequence length is 512, this is automatically decided by WELDER).

For the three models supported by FasterTransformer, we compare its performance with WELDER in Table 3. In general, WELDER achieves an average speedup of  $1.11\times$  (up to  $1.73\times$  on ViT) over FasterTransformer. Based on our profiled data, The notable speedup for ViT under batch size of 1 can be attributed to a convolution operator with a non-conventional shape, where both stride and kernel size are 32 (ViT’s patch size). For this single operator, WELDER’s generated kernel is 4.4x faster. This highlights WELDER’s adaptability in managing new operator shapes or model patterns.

Another example is NeRF, a popular 3D scene generation model that is typically implemented as a 7-layer MLP. To take full advantage of GPUs, domain experts often need to implement such models from scratch to achieve better fusion result (e.g., fully-fused MLP in [35]). With WELDER, we can automatically fuse this 7-layer MLP into a single GPU kernel. The generated kernel uses TensorCore for the first 6 layers and uses SIMT Core for the output layer, with all intermediate results stored in shared memory. We observe that our automatic fusion result can achieve a similar speedup (over  $5\times$ ) to the values reported in [35] (we are unable to evaluate their code [34] as it does not support V100 GPUs).

Finally, for CNN models such as NAFNet, BSRN, and MobileNet, WELDER is able to fuse different types of convolutions with other operators (e.g., Pooling, PixelShuffle, etc.). For example, in NAFNet, our system can fuse back-to-back pointwise convolutions together with the normalization

Figure 13: Latency, GPU kernel count, global memory transactions executed and intermediate result size (IRS) For 3 selected models (FP32, batch size 64).

Figure 14: Varying input size, comparing with WELDER-base.

operations between them. Another interesting pattern is in models with multiple separable convolution layers, where each layer consists of two operations: a depthwise convolution (DWConv) and a pointwise convolution (PWConv). WELDER is able to determine the optimal fusing order for these two types of operators based on their operator configurations. For example, on the top layers where the feature maps are large and the number of channels is small, WELDER constructs a DWConv+PWConv fusion group because it is better to cache a complete feature map in shared memory. In contrast, on the bottom layers, WELDER constructs a PWConv+DWConv fusion group which caches a complete channel for DWConv to reuse, as the feature map becomes smaller.

**Ablation and sensitivity study.** To demonstrate the benefits of the holistic memory optimization provided by WELDER, we create two variants of WELDER: “WELDER-none” disables all inter-operator tile connection and only searches for intra-operator schedules, and “WELDER-base” only enables inter-operator tile connection at the register layer. We also include AnsoR in this experiment, as it is another codegen-based approach similar to ours. As shown in Figure 13, enabling register layer tile connection, WELDER-base reduces latency by an averaged 52% (i.e.,  $2.08\times$  speedup), kernel launch count by 67%, global memory transactions by 52% and intermediate result size (IRS) by 66% compared with WELDER-none. Note that the metrics of WELDER-base is similar to that of AnsoR, demonstrating the efficiency of our general tile-based memory scheduling compared with the rule-based fusion in AnsoR. Moreover, by enabling tile connection at shared memory layer, WELDER is able to further reduce latency by an averaged 29% (with up to  $1.82\times$  speedup), kernel launches by 60%, transactions by 25% and IRS by

Model	AnsoR time(s)	AnsoR Trials	WELDER Time(s)	WELDER Trials
BERT	15285	8000	244	651
Mobilenet	45527	25600	561	927

Table 5: Compilation time of AnsoR and WELDER

Model	AnsoR	WELDER	TensorRT
Resnet50	2.403	2.327	2.351
Resnet18	1.071	1.094	1.158
UNet	8.670	9.251	4.429
VGG16	4.267	4.123	2.584

Table 6: Performance on compute intensive models

65% compared with WELDER-base. Note that the reduction of memory transactions is less than the reduction of IRS, because memory access on the model weights part cannot be optimized by fusion.

In addition, we conducted a sensitivity study by varying the input sizes of three selected models: BERT (128-512 text length), Conformer (128-512 audio frames), and NAFNet (256x256-1024x1024 image input). The results, as depicted in Figure 14, reveal that the fusion gain significantly increases for NAFNet when employing larger images. Conversely, the gain diminishes for the other two transformer-based models. This discrepancy can be attributed to the fact that transformer-based models exhibit quadratic computational growth with respect to the input sequence length, thereby reducing their memory-intensive nature.

**Compilation time.** Table 5 compares WELDER’s compilation time against AnsoR, which is a search-based compiler requiring many tuning and profiling trails. We chose not to include other baselines in the comparison since they directly invoke library kernels, thereby eliminating the need for extra time dedicated to tuning and code generation. It shows that the end-to-end compilation speed of WELDER is more than an orders of magnitude faster than AnsoR. This is because AnsoR generates a very large search space for all the operators, and implicitly optimizes data reuse through machine learning-based tuning. This often requires a large number of tuning trials (e.g., 800 per operator in our evaluation) and has additional overheads to train a cost model on the fly. In contrast, WELDER decomposes the optimization space using a layered scheduling policy and searches for efficient tiling configurations using an analytic cost model to estimate traffic costs. As a result, WELDER requires significantly fewer tuning trials (20 per subgraph in our evaluation) than AnsoR.

**Performance on compute intensive models.** Traditional models like ResNet [21], VGG [43], and UNet [40] are typically dominated by some large operators such as convolution. For these compute intensive models, although WELDER mainly focuses on memory access optimization, WELDER can mostly achieve comparable performance to state-of-the-art baselines like TensorRT. This is because WELDER

Figure 15: End-to-end model inference performance on AMD ROCm MI50 GPU (left : batch size of 1, right : batch size of 64).

can still generate high performance single operators (using the multi-level tiling abstraction, which is similar to Ansor [50] or Roller [52]) although there might be few chances to connect the tile at a higher memory level. However, for some convolution operators, existing libraries like cuDNN [4] implement them using an optimized numerical algorithm (e.g., winograd [26]), which are difficult to automatically derive from tensor expressions. This can result in WELDER performing worse than TensorRT if there is no additional memory optimization room to compensate for this gap. For example, Table 6 compares the performance of WELDER, Ansor, and TensorRT on four such models. For ResNet, both systems achieve comparable performance, as the majority of convolution operators in this model perform better when implemented with the DirectConv algorithm (which is supported by both Ansor and WELDER) instead of winograd. However, for UNet and VGG16, the dominant convolution operators are mostly implemented using winograd in TensorRT, and there are no further fusion opportunities for WELDER to exploit, resulting in better performance for TensorRT. Given that this is orthogonal to WELDER’s optimization, we leave the support of the winograd algorithm (by rewriting tensor expressions) to our future work.

### 5.3 Evaluation on AMD ROCm GPUs

We evaluate the efficiency of WELDER on AMD ROCm GPUs by comparing its performance with PyTorch, ONNXRuntime and Ansor. TensorRT and AStitch are not included because they are exclusive to NVIDIA GPUs. Figure 15 shows the end-to-end performance of the 10 DNN models. Compared with PyTorch, ONNXRuntime and Rammer, WELDER can outperform them by an average of  $2.62\times$ ,  $1.71\times$  and  $2.14\times$ , respectively. Compared to Ansor, WELDER achieves an average performance improvement of  $1.53\times$ . Figure 15 also shows the performance comparison with a larger batch size of 64, where WELDER outperforms PyTorch, ONNXRuntime, Rammer and Ansor by an average of  $1.69\times$ ,  $1.23\times$ ,  $1.86\times$  and  $1.47\times$ , respectively. Note that we have excluded some CNN models for ONNXRuntime as they fail to execute on it. We notice that WELDER’s speedup on MI50 is slightly smaller than that of V100, this is because MI50’s peak FLOPS is weaker than V100’s, while its peak bandwidth is higher,

Model	Image Size	Device	WELDERBase(s)	WELDER(s)
UNet	8k*8k	GPU	38.2	14.5
VGG16	8k*8k	GPU	15.7	8.30
UNet	2k*2k	IPU	31.1	8.56
VGG16	2k*2k	IPU	4.98	1.61

Table 7: Scale-up large DNN models to host memory

according to the official data-sheet. Such difference makes the workload more compute-intensive on MI50, leaving less optimization chances for memory access optimization.

### 5.4 Scale-up with Host Memory

WELDER’s abstracted device layer allows us to extend the memory hierarchy to support large DNN tasks. For example, in cases where classical CNN models like UNet or VGG16 are used to process high-resolution medical images [42], a single tensor from some layers is often too large to fit in the GPU memory. In these scenarios, tensor-based memory swapping optimization techniques, such as SwapAdvisor [22] or Capuchin [37], may not be effective due to the large tensor granularity. WELDER addresses this issue by generating a tile-based execution plan on the extended memory hierarchy through holistic traffic optimization. This approach allows us to load a data tile from the host memory, compute several connected operator tiles by reusing the data in device memory, and store the result back, as if it was being processed on a single device. To evaluate the efficiency of this scheduling approach, we compared WELDER with a variant that only disables data reuse at the device memory layer.

**Scale-up GPUs.** As a preliminary experiment, Table 7 shows the performance of WELDER when scaling up UNet and VGG16 on large image data by augmenting the GPU memory with a host memory layer. As the results show, by enabling tile-connection at the device memory layer, WELDER is able to achieve average speedups of  $2.63\times$  and  $1.89\times$  for the two models, respectively. It also reduces host memory transfer by  $3.11\times$  and  $2.90\times$ . Note that the ratios of reduced memory traffic are higher than the actual speedup, as we have implemented double buffering (along with pinned memory and CUDA streams) to overlap some memory transfer with computation.

**Scale-up GraphCore IPU.** We also perform a preliminary evaluation of WELDER’s ability to scale up on the Graphcore IPU [3], which is a DNN accelerator with a distinct architecture from NVIDIA and AMD GPUs. The IPU is equipped with massively parallel MIMD processors and a relatively small device memory (i.e., 300MB), which poses a challenge for it to handle even medium-sized tasks. We apply the same tile-based scheduling to the two models for the IPU and set the input image size to 2048\*2048 to adapt to the IPU’s memory capacity. The results in Table 7 show that WELDER’s optimization is able to achieve average speedups of  $3.63\times$  and  $3.09\times$  for the two models, respectively. This improvement ratio is higher than that of the GPU, which is mainly due to that we disable the double-buffer optimization for the IPU due to its limited memory.

## 6 Discussion

WELDER’s design and implementation mainly focuses on static models. For dynamic model execution, there are two practical ways to address this. First, the dynamic graph can be transformed into static sub-graphs through JIT compilation, such as PyTorch JIT compile, which has become a standard practice in PyTorch 2.0. Then, WELDER can concentrate on optimizing the static sub-graphs, which are typically the computationally dominant part. Second, even though tensor shapes may be dynamic, the internal tile in each operator can be statically determined. This presents an opportunity for WELDER to generate a static tile-level fusion plan but leave the number of parallel tasks determined by the input tensor shape.

## 7 Related Work

Compiler optimization like operator fusion is a widely-used technique in DNN computation to reduce kernel launch overhead and improve data locality in faster memory. Compilers such as TVM [15], Ansor [50], XLA [12], DNNfusion [36] all support operator fusion at register level. Other compilers try to further fuse operators at shared memory, relying on either fusion rules for a set of known operator types (e.g., AStitch [51], Apollo [49], DeepCuts [24]) or specific template for a few operator combinations (e.g., Bolt [47]). Specialized DNN runtimes such as TensorRT [7] and ONNXRuntime [8] have incorporated expert-designed fusion rules for some common patterns in popular models such as the transformer-based models. In contrast, WELDER works for general operators implemented in tensor expressions without the assumption on operator types and decides on the best fusion memory layer automatically. This is because an operator’s resource usage behavior (memory- or compute-intensive) often depends on its shape, and therefore the fusion decision.

Systems like Rammer [31], HFuse [27], Nimble [25], etc., exploit better hardware parallelism utilization and reduce kernel launches by either horizontal fusion or scheduling par-

allel tasks through multi-stream and CUDA graph. WELDER builds upon Rammer by further exploring a complementary optimization to these systems, i.e., holistic memory optimization with a vertical fusion, resulting in a further speedup for memory-intensive models.

Ansor [50] and Roller [52] are representative tensor compilers that are focusing on intra-operator optimization through either loop optimization or tiling optimization. Especially, Roller [52] and Triton [44] also utilize the concept of tile to optimize kernel performance (e.g., intra-operator data reuse). In contrast, WELDER complements them by optimizing for intra- and inter-operator memory access holistically. WELDER generalizes the *tile* concept in Roller into a *tile-graph* abstraction, exposes a holistic tile-level scheduling space, and proposes an efficient scheduling mechanism over the holistic space and the explicit memory hierarchy.

Some works optimize for a specific pattern regarding to a type of models with more aggressive operator fusions, such as fully-fused MLP for the NeRF model [35], manually fused kernels for CNN models [46], and attention fusion for transformer models [2, 18]. Our evaluation shows that WELDER can achieve most of these fusions automatically and even produce new fusion patterns to help further optimization.

Moreover, kernel fusion techniques have been used in traditional image processing [38, 39] or HPC [45] areas. These efforts usually leverage domain-specific fusion rules for their workload. WELDER focuses on DNN workload, while it is applicable for general operators represented by tensor expressions. It is also potentially helpful for workload that can be implemented in tensor expressions in other domains.

## 8 Conclusion

By observing that modern DNN models are becoming increasingly memory intensive, we introduced WELDER, a DNN compiler that optimizes the execution efficiency based on a new tile-graph abstraction. WELDER is able to holistically optimize efficient intra- and inter-operator data reuse across multi-level memory hierarchy. WELDER is the first to unify all common operator fusions into a single framework, allowing for the discovery of 89 uncommon fusion patterns, with the largest one fusing 48 operators into a single kernel. This generality enables WELDER to significantly outperform state-of-the-art baselines. More importantly, WELDER provides a systematic approach to take advantage of emerging trends in the memory hierarchy, such as larger and more connected on-chip memory, in the future AI accelerators.

## A Artifact Appendix

### Abstract

WELDER provides end-to-end DNN model compilation with its new tile-graph abstraction. This artifact reproduces the main results of the evaluation on NVIDIA V100 GPU.

### Scope

This artifact will validate the following claims:

- End-to-end model performances. By reproducing the experiments of Figure 9, Figure 10, Figure 11, Table 3 and Table 6.
- Motivation experiments in Figure 1 and Figure 2.
- Ablation study in Figure 13.
- Compilation time in Table 5.
- GPU stale out experiments in Table 7.

### Contents

This artifacts includes all the source code to implement WELDER. We provide a docker file to setup environments. For each figure and table mentioned above, we provide a script to reproduce its result. Since there are more than 50 model test cases to compile to fully reproduce the results, which will cost a long time (especially for the Ansor's baseline), we also provide pre-compiled logs and models for NVIDIA V100 GPU. Please refer to the README.md file in the repository for more details.

### Hosting

The artifact is hosted at github repository<sup>1</sup>. Please use git to clone the repository and checkout to the `osdi2023welder` branch.

### Requirements

This artifacts requires a NVIDIA V100 GPU with CUDA driver supporting CUDA runtime larger than 11.0.

## Abstract

Fully exploiting the computing power of an accelerator specialized for deep neural networks (DNNs) calls for the synergy between network and hardware architectures, but existing approaches partition a computational graph of DNN into multiple sub-graphs by abstracting away hardware architecture and assign resources to each sub-graph, not only producing redundant off-core data movements but also under-utilizing the hardware resources of a domain-specific architecture (DSA).

This paper introduces a systematic approach for effectively scheduling DNN computational graphs on DSA platforms. By fully taking into account hardware architecture when partitioning a computational graph into coarse-grained sub-graphs, our work enables the synergy between network and hardware architectures, addressing several challenges of prior work: (1) it produces larger but fewer kernels, converting a large number of off-core data movements into on-core data exchanges; (2) it exploits the imbalanced memory usage distribution across DNN network architecture, better saturating the DSA memory hierarchy; (3) it enables across-layer instruction scheduling not studied before, further exploiting the parallelism across different specialized compute units.

Results of seven DNN inference models on a DSA platform show that our work outperforms TVM and AStitch by  $11.15\times$  and  $6.16\times$ , respectively, and obtains throughput competitive to the vendor-crafted implementation. A case study on GPU also demonstrates that generating kernels for our sub-graphs can surpass CUTLASS with and without convolution fusion by  $1.06\times$  and  $1.23\times$ , respectively.

## 1 Introduction and Background

Due to the slowing down of Moore’s Law, moving to DSAs is acknowledged as promising to meet the keen desire of DNNs for computing power [24]. After several years of investigation on accelerators specialized for DNNs [7, 8, 15, 22, 25, 29, 32, 55, 58], a commonly used DSA abstraction depicted on the left of Fig.1 has been formed for this application domain, based on which most existing DNN accelerators are manufactured.

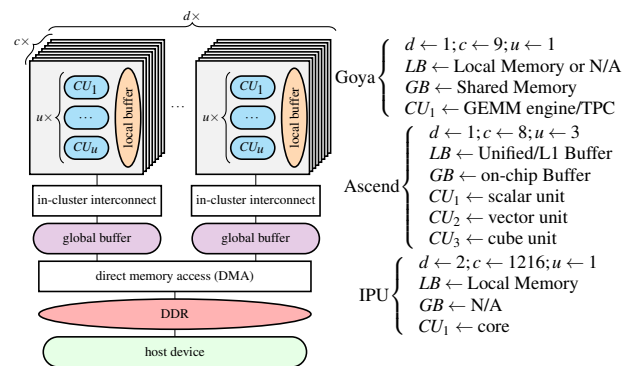

Figure 1: DNN DSA and its vendor customization.

We take the Habana Goya accelerator [32], the customized configuration of which is shown on the right of Fig.1, as an example to explain this abstraction. It is composed of  $d = 1$  cluster, each including  $c = 9$  cores that contains  $u = 1$  compute unit (CU) for different DNN tasks. CUs are either a tensor-processing core (TPC) with a scratchpad local buffer (LB) or a general matrix multiplication (GEMM) engine with no LB. Cores are connected using an in-cluster interconnect mechanism, equipped with a scratchpad global buffer (GB). Clusters, if  $d > 1$ , are stacked, communicating data with DDR via DMA. We also show the customized configurations of a Huawei Ascend 910 platform [29] and a Graphcore IPU device [22] in Fig.1. The Graphcore IPU uses the term “tile” to denote a core and its unique LB. Hardware architecture of others [7, 8, 15] can also be deduced according to the abstraction in Fig.1.

Hence, effectively scheduling DNNs toward this abstraction is essential to exploit the computing power of DNN accelerators for DSA compilers. Specialized for machining learning (ML) applications, these accelerators exhibit a scratchpad-based memory hierarchy and parallelism across both multiple cores and several CUs, but prior work [5, 13, 31, 54] devised to schedule DNNs on these DSA accelerators did not consider hardware architecture when partitioning a computational graph of DNN, introducing redundant off-core data move-

ments (*i.e.*, between LB and GB/DDR) and under-utilizing both faster local memory and parallelism across CUs.

## 1.1 Concepts and Notations

To explain the issues of prior work, we first introduce computational graphs, which are used by existing ML frameworks [1, 38] to represent DNN models. Fig. 2 is an example. As it can contain a large number of nodes, each of which performs a computation task on several tensors, a computational graph usually references memory footprints that exceed the local memory capacity of its target platform and thus cannot be scheduled as a whole. Existing schedulers first partition it into sub-graphs and next assign resources to each sub-graph. A sub-graph, which is also known as a fused operator (*op*), is first initialized by a graph node and next grouped according to its producer-consumer relations with others, implemented as a kernel function or kernel executable on target platform.

Figure 2: Computational graph of ResNet-50 [16]. A node (a circle) represents an *op*, and an edge (a solid arrow) denotes a producer-consumer relation of two *ops*. An *op* is a function that takes as inputs one to several tensors and outputs another. At the bottom is a  $3 \times 3$  convolution (*conv*) layer composed of three nodes. A dashed arrow connects a stage/block with its internal structure; a dotted box denotes a block. Other layers can be expressed in a similar way.

We use the term “layer” to denote a set of nodes connected in a straight-line manner, at most one out of which contains parameters that should be learned using the gradients of the loss. A graph node represents an *op*, which is traditionally referred to as a neural layer in neural networks. Some neural layers, however, do not require parameters to be learned (*e.g.*, ReLU) or learned without using the gradients of the loss (*e.g.*, batch normalization) during the training process, and they can thus be considered as the auxiliary *ops* of those that indeed

require parameters, *e.g.*, the convolution. We define layers as such because this definition summarizes the *op* fusion rules widely used by existing compilers [5, 53].

We also use the term “block” to represent an individual layer or a component composed of multiple layers that is recursively used in a DNN computational graph. For instance, the *conv* block composed of five layers is used once in each stage of Fig. 2, while the identity block is used multiple times within each stage.

The term “stage” is a logical, high-level abstraction used in the architecture of the ResNet-50 model, taking the results of its preceding stage as inputs and generating output tensors. It is used to simplify the design of the network architecture but usually not considered by optimizing compilers.

## 1.2 Challenges of Prior Work

By obscuring hardware architecture, prior work [5, 19, 54] constrains sub-graph grouping within a layer [39] (the bottom level of Fig. 2) and produces fine-grained sub-graphs. As each sub-graph is implemented by one kernel, prior work produces more kernels and **requires more off-core data movements between kernels**. Going one level upper in Fig. 2 can observe five and four layers in the *conv* and identity blocks, so the entire network may require hundreds to thousands of kernels and off-core data movements of the same order of magnitude [21], resulting in high pressure on the limited memory bandwidth of a DSA platform. In addition, managing such a large number of off-core data movements for DSA is non-trivial because, unlike a general-purpose architecture reinforced by its mature hardware mechanisms, the hierarchical scratchpad memory of the later is still controlled by hand or software [37].

Even though managing the data movements across a DSA’s memory hierarchy is possible, generating fine-grained sub-graphs still **misses the across-layer instruction scheduling opportunities**. Once formed, each sub-graph is lowered to a loop nest pipeline, to which memory optimizations and loop transformations like tiling and fusion are applied to better utilize hardware resources. While their different compositions constitute the search space that existing autotuners [2, 6, 26, 57] navigate to select the optimal scheduling, across-layer instruction scheduling opportunities, *e.g.*, overlapping the memory promotion statement of weights and the computation task of a  $3 \times 3$  *conv* layer with those of its preceding  $1 \times 1$  *conv* layer in Fig. 2, are not covered by such spaces.

Finally, since **the imbalanced memory usage distribution**, which refers to a phenomenon where memory usages vary across network architecture [30], **is not exposed/exploited**, the above scheduling paradigm also **under-utilizes the faster local memory of DSA**. On the top of Fig. 2, ResNet-50 is partitioned into four stages, each composed of one *conv* block and two or more identity blocks. A *conv* block converts its input with shape  $[N, C, H, W]$  into  $[N, 2C, H/S, W/S]$ , performing a down-sampling operation when  $S > 1$ , but an

identity block does not change its tensor shapes. The memory usage of stage1 is  $\frac{S^2}{2} \times$  larger than that of stage2, and this property also exists in stage3 and stage4. If the faster memory of the target DSA is saturated when executing stage1, it will be under-utilized when executing the remaining stages.

### 1.3 Our Solution and the Organization of the Paper

To address the aforementioned issues on DSA platforms, we introduce a novel scheduling approach in this paper. First, as redundant off-core data movements are caused by fine-grained sub-graphs produced by existing tools [5, 13, 19, 44], our approach has to construct coarser-grained sub-graphs that can generate larger kernels, which can change massive output tensors originally exchanged through GB/DDR of Fig.1 into intermediate tensors that can stay in LB of the later, thereby converting many off-core data movements between kernels into on-core data exchanges within kernels. Second, to enable across-layer instruction scheduling outside the search spaces of prior work [31, 57, 59], a sub-graph constructed by our work must be able to group layers or even blocks like those of Fig.2, thus better hiding memory latency and exploiting the parallelism across CUs. Finally, to saturate the faster local memory of a DSA platform in the presence of imbalanced memory usage distribution [30], our method should consider the internal relations between coarser-grained sub-graphs such that a better scheduling order can be obtained.

With these considerations in mind, we design and implement a novel scheduling approach—GraphTurbo. §2 exemplifies the core idea and presents the overview of GraphTurbo. §3 explains how GraphTurbo constructs, splits and orders coarse-grained sub-graphs, to the results of which §4 generates larger kernels. §5 reports the experimental results of seven DNN inference models on a DSA platform, which demonstrate that, while achieving performance close to the vendor-crafted implementation, GraphTurbo outperforms TVM [5] and AStitch [60] by  $11.15 \times$  and  $6.16 \times$ , respectively. A case study on GPU also shows that GraphTurbo can surpass CUTLASS [27] with and without *conv* fusion by  $1.06 \times$  and  $1.23 \times$ , respectively. Finally, §6 discusses the related work, and §7 concludes the work.

### 1.4 Contributions

In summary, this paper makes the following contributions.

- We recognize the importance of considering hardware architecture at the graph partitioning level, enabling the synergy between network and hardware architectures.
- This synergy reduces off-core data movements, better saturates the valuable local memory, and empowers across-layer instruction scheduling.

- We design and implement a novel scheduling approach GraphTurbo, addressing the deployment of DNNs on DSA chips and offering insight to other platforms.
- The experimental results demonstrate that GraphTurbo can outperform two state-of-the-art tools and achieve performance comparable to the vendor-crafted code.

## 2 Core Idea and Overview

This section first explains the core idea of GraphTurbo and next presents its overview.

### 2.1 Exemplifying the Core Idea

We use Fig.2 that classifies a batch of input images into different categories as an example to explain our core idea. Data parallelism is exploited across the  $d$  clusters of Fig.1, which is always possible due to the multi-dimensional parallelism of tensors. Decomposing the input tensors of a DNN model into  $d$  clusters can be achieved by splitting one or multiple parallelizable dimensions. We assume the batch dimension of size  $N = 32$  is split across these clusters, so each cluster processes  $n = 8$  images that have been offloaded to GB of Fig.1.

Our work studies how a DNN model is scheduled within one cluster. **The core idea is to maximally preserve the input tensors in LB in order to convert as many off-core data movements as possible into on-core data exchanges.** For the sake of clarity, we reproduce the stages of Fig.2 in Fig.3a and assume that each stage performs a down-sampling operation with  $S = 2$ .

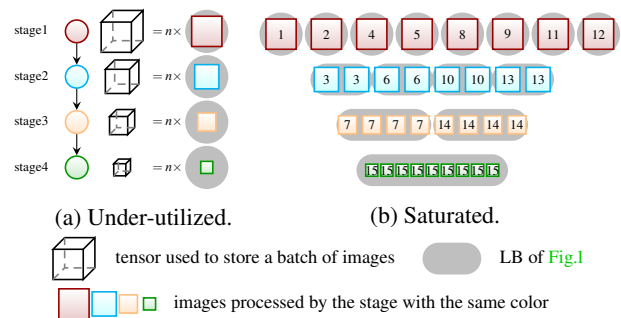

Figure 3: Utilization of LB under different scheduling methods. Timestamps in (b) define the scheduling of GraphTurbo.

Existing approaches [5, 13] can construct a sub-graph larger than a layer by grouping smaller ones, but they do not know when the grouping should terminate without hardware architectural information. Even though larger sub-graphs could be constructed for each stage of Fig.3a, these methods only schedule these sub-graphs according to their coarser-grained dependencies as the arrows show in Fig.3a, which produces a scheduling strategy that distributes each sub-graph of a stage onto the  $c$  cores of Fig.1. Suppose that the batch dimension is

split, then each core processes one image. If an image saturates LB when executing stage1, it will under-utilize this local memory when its core executes the later three stages, since their preceding stages reduce the tensor size by  $2\times$ ,  $4\times$  and  $8\times$ , respectively, by performing down-sampling operations.

GraphTurbo can easily construct large sub-graphs for each stage by synthesizing network and hardware architectures. It splits these large sub-graphs into eight, four, two, and one instance, respectively, converting the coarse-grained dependencies between large sub-graphs into fine-grained ones between sub-graph instances. By eliminating redundant fine-grained dependencies, GraphTurbo executes two instances of stage1’s sub-graph at timestamp 1 and 2 in Fig.3b, saturating LB while exploiting the parallelism across cores by distributing other parallelizable dimensions across them.

Next, GraphTurbo executes one instance of stage2’s sub-graph at timestamp 3, which processes two images, both in LB, as shown in Fig.3b, because the image size is decreased by  $2\times$ . LB is thus not under-utilized. The parallelism across  $c$  cores is exploited by distributing both the batch and other parallelizable dimensions. Readers can follow the timestamps to infer the scheduling order and find that LB is never under-utilized while fully exploiting the parallelism between cores. In particular, this scheduling approach achieves a  $7.97\times$  speedup over TVM on our experimental platform.

## 2.2 Overview of GraphTurbo

To obtain scheduling strategies similar to Fig. 3b, GraphTurbo takes in a computational graph simplified by some standard graph optimizations [13,23] and schedules it at graph level (§3). To construct coarser-grained sub-graphs, e.g., for stages of Fig.3a, GraphTurbo first collects hardware information (§3.1) to guide its grouping process (§3.2) by synthesizing network and hardware architectures. These sub-graphs are then split into instances, which are sorted (§3.3) to achieve the scheduling order like in Fig.3b. How parallelism is exploited and load balance is guaranteed across multiple cores are then explained (§3.4), with core binding and memory scopes automatically inferred. A concatenation step is then used to collect the tensors of producer sub-graph instances (§3.5), followed by some generalization discussions (§3.6).

The graph scheduler produces ordered sub-graph instances, which are delivered to the kernel generator (§4), producing kernels by combining loop fusion (§4.1) and buffer stitching (§4.2), with memory allocation and reuse automatically managed (§4.3). For the example in §2.1, the graph scheduler concentrates on input images. The convolution weights of this model are getting larger but only used within layers and do not result in communications between stages. GraphTurbo only allocates a small, fixed size of buffers in LB to allow for the promotion of such tensors to local memory when handling each layer, and the overhead of such memory promotion statements is hidden behind the computation (§4.4).

## 3 Scheduling Sub-graph Instances

This section constructs coarser-grained sub-graphs and schedules their instances. To achieve this goal, we need to address five issues and thus organize this section into five steps, with the difficulties explained at the beginning of each.

### 3.1 Collecting Splitting Information

GraphTurbo relies on producer-consumer relations between sub-graphs to group them into larger ones. This strategy, however, does not know when to stop without knowing hardware architectural information. Hence, **this section first collects hardware knowledge for sub-graphs**. As it will also be used to split sub-graphs (§3.3), we refer to it as splitting information `SplitInfo`, which is a set of 4D tuples ( $split_d, n_d, f_d, d$ ). Algo.1 summarizes how to compute it.

---

#### Algorithm 1: Compute SplitInfo

---

```

1 SplitInfo  $\leftarrow \emptyset$ ;
2 foreach  $d$  in  $[1, \dots, depth \leftarrow \text{dimof}(\text{output of } SG)]$  do
3    $n_d \leftarrow 0$ ;  $split_d \leftarrow 0$ ;  $f_d \leftarrow \infty$ ;
4   foreach  $v$  in  $[1, 2, 4, 8, 9, \dots, size_{output}^{(d)}]$  do
5     if  $\lceil \frac{peak}{v} \rceil \leq \text{sizeof}(\text{LB})$  then
6        $n_d \leftarrow n_d + 1$ ;  $split_d \leftarrow 1$ ;  $f_d \leftarrow v$ ; break;
7   foreach  $t$  in intermediates do
8     if  $split_d = 1$  then
9        $n_d \leftarrow n_d + \text{num\_of\_op}(t)$ ;
10      if match_dim( $t, d$ ) and  $size_t^{(d)} \% f_d = 0$  then
11        SplitInfo  $\leftarrow$  SplitInfo  $\cup \{(split_d, n_d, f_d, d)\}$ ;

```

---

Before grouped, a sub-graph  $SG$  is a node that represents an *op*. When lowered, it may produce several loop nests since the *op* it represents can be complex such that multiple intermediate tensors are used to realize its function [53]. Except the last one that defines the output tensor, all remaining loop nests write to intermediate tensors. Algo.1 computes `SplitInfo` by first splitting the output tensor (lines 3-6) and next propagating its splitting information to each of intermediate tensors (lines 8-11) due to the following reasons.

First, a sub-graph has one output but its input tensors can be many. Considering only the output tensor simplifies the algorithmic design. Second, it is the output that determines how the loop nests of this sub-graph should be split or tiled [41,52]. Once the information of the output and intermediate tensors is determined, how input tensors should be split is also known.

Indeed, computing `SplitInfo` this way may introduce recomputation of intermediate or input tensors, which would be expensive when fusing multiple *conv* or matrix multiplication *ops*. We thus use a simple cost model to prevent excessive recomputations that offset the benefits brought by fusion.

$depth$  represents the loop nest depth of the output tensor. By iterating a loop dimension  $d$  from the outermost to inner (line 2), Algo.1 makes use of the parallelism across cores as early as possible. Next, Algo.1 defines three metrics (line 3),

$split_d, f_d, n_d$ , that represent whether the current dimension  $d$  can be split, the splitting factor of this dimension, and the number of *ops* split by it, respectively.

$v$  iterates the values of line 4 to instantiate  $f_d$ . We consider  $size_{output}^{(d)}$  that denotes the loop extent of the current dimension  $d$  as the upper bound because  $v > size_{output}^{(d)}$  does not split the current dimension  $d$ . The first three values decompose the dimension  $d$  into eight, four, and two cores, while guaranteeing load balance across them. The first three stages in Fig.3b are split this way. Values between  $8 \leq v \leq size_{output}^{(d)}$  do not exploit the parallelism of the current dimension  $d$  across cores but parallelize other dimensions, with load balance across cores fully considered. The splitting of stage1 in Fig.3b is an example of this case. A value is used to instantiate  $f_d$  (line 6) if the size of memory footprints,  $\lceil \frac{peak}{v} \rceil$ , required by a sub-graph instance does not exceed the memory capacity of LB (line 5).  $peak$  is the size of memory footprints required by  $SG$ .  $n_d$  and  $split_d$  are also updated accordingly. As a smaller  $v$  partitions  $peak$  into larger pieces, the  $v$  loop here is a greedy strategy.

$t$  iterates each intermediate tensor (line 7). It takes in the dimension  $d$  and first inspects whether the dimension can split the output tensor (line 8).  $n_d$  is increased by the number of *ops* in  $t$  (line 9) if this condition is satisfied. In addition, the 4D tuple is added to  $SplitInfo$  (line 11) if the dimension  $d$  matches one loop dimension of  $t$  and the loop extent of the matched dimension  $size_t^{(d)}$  is dividable by  $f_d$  (line 10).

By exactly computing  $SplitInfo$  for sub-graphs, GraphTurbo determines appropriate sizes for its generated kernels. As  $SplitInfo$  usually has several elements and each one encodes a loop dimension that can be split, GraphTurbo needs to select the best dimension for a sub-graph. We consider the following criteria for this issue. First, a loop dimension is better if it splits more *ops*. Second, a loop dimension with a smaller splitting factor is preferred since it tends to better saturate LB. Finally, a dimension with a smaller loop depth is considered superior since it exhibits outer parallelism and fewer communications. These criteria are modeled as computing the lexicographical maximum of an optimization problem

$$\text{lexmax}_{v,d \in SplitInfo} (n_d, -f_d, -d) \quad (1)$$

where the order of the three metrics defines the priorities.

### 3.2 Grouping Sub-graphs

Now we can group sub-graphs. GraphTurbo still performs this step according to producer-consumer relations, but it **constructs larger sub-graphs by leveraging  $SplitInfo$  to determine the termination of grouping**, which is not restricted within layers [5, 19, 54]. Algo.2 outlines the process.

Algo.2 first sorts a computational graph  $G$  by topologically ordering all of its  $g$  nodes (line 1), each of which is treated as one sub-graph  $SG$  and delivered to Algo.1 to compute its

#### Algorithm 2: Group sub-graphs

```

1  $SG[1, \dots, g] \leftarrow \text{topological\_order}(G); b \leftarrow g;$ 
2 foreach  $i$  in  $[1, \dots, g]$  do
3    $SplitInfo[i] \leftarrow \text{Algo.1}(SG[i]);$ 
4    $BestSplit[i] \leftarrow \text{Eq. (1)}(SG[i], SplitInfo[i]);$ 
5 repeat
6    $\{G, s\} \leftarrow \text{straight\_merge}(SG[1, \dots, b], SplitInfo[1, \dots, b]);$ 
7   foreach  $i$  in  $[1, \dots, s]$  do
8      $BestSplit[i] \leftarrow \text{Eq. (1)}(SG[i], SplitInfo[i]);$ 
9      $\{G, d\} \leftarrow \text{diamond\_merge}(SG[1, \dots, s], SplitInfo[1, \dots, s]);$ 
10    foreach  $i$  in  $[1, \dots, d]$  do
11       $BestSplit[i] \leftarrow \text{Eq. (1)}(SG[i], SplitInfo[i]);$ 
12       $\{G, b\} \leftarrow \text{branch\_merge}(SG[1, \dots, d], SplitInfo[1, \dots, d]);$ 
13      foreach  $i$  in  $[1, \dots, b]$  do
14         $BestSplit[i] \leftarrow \text{Eq. (1)}(SG[i], SplitInfo[i]);$ 
15 until  $s, d$  and  $b$  all do not decrease;
```

$SplitInfo$  (lines 2-3). Next, Algo.2 considers three different merging patterns (lines 5-15) to group these sub-graphs, which reduces the number of sub-graphs from  $g$  to  $s, d$ , and  $b$ , respectively. The sub-graph index and  $BestSplit$  are updated each time a merging pattern is grouped.

Figure 4: Merging patterns considered by GraphTurbo. A solid arrow is the producer-consumer relation, and a dashed one denotes a possible connection with another sub-graph.

The merging patterns considered by Algo.2 are defined as follows. First, two sub-graphs  $SG_1$  and  $SG_2$  form a straight pattern (Fig.4a) if and only if (iff)  $SG_1$  is the unique producer of  $SG_2$  and  $SG_2$  is the unique consumer of  $SG_1$ . Second, four sub-graphs make a diamond pattern (Fig.4b) iff there are only one entry, one exit and at least two paths from the entry to the exit. The entry ( $SG_1$ )/exit ( $SG_4$ ) can be a consumer/producer of multiple outside sub-graphs. Third, three sub-graphs constitute a branch pattern (Fig.4c) iff there exists only one exit and multiple paths to it, and  $SG_1$  could be but not necessarily a producer of  $SG_2$ .

Instead of grouping all components of a merging pattern, Algo.2 fuses a subset of them into a larger sub-graph  $SG$ , as shown by a red dotted box in Fig.4. Algo.2 uses two heuristic rules to determine whether the grouping is allowed.

- (i)  $SG_1$  and  $SG_2$  of Fig.4a (or  $SG_2$  and  $SG_3$  of Fig.4c) can be merged if two preconditions are satisfied. First, the splitting factor of  $SG_2$  of Fig.4a (or  $SG_3$  of Fig.4c) is no less than that of  $SG_1$  (or  $SG_2$ ). As a larger splitting factor partitions  $peak$  into smaller pieces, this precondition

prohibits the propagation of a sub-graph’s large splitting factor to its followers in the case of down-sampling operations. Second, the splitting factor of  $SG$  is not larger than that of  $SG_2$ , ensuring that the grouping result does not deteriorate the utilization of LB exploited by  $SG_2$ . `SplitInfo` of  $SG$  can be computed using [Algo.1](#).

- (ii)  $SG_2$ ,  $SG_3$  and  $SG_4$  of [Fig.4b](#) can be merged into  $SG$  if the splitting factor of  $SG$  is not larger than the maximum among the splitting factors of  $SG_2$ ,  $SG_3$  and  $SG_4$ , which is also used to guarantee good LB utilization.

We now explain how the *conv* and identity blocks of [Fig.2](#) are grouped. First, [Algo.2](#) identifies the straight patterns in each layer and obtains [Fig.5a](#). Specifically, the three layers on the left of the *conv* block in [Fig.2](#) is identified as a straight pattern, fused into one sub-graph denoted using label 1. Neither of the *conv* and the ReLU layers of this *conv* block is identified as a straight pattern; instead, they both form individual sub-graphs, represented using labels 2 and 3, respectively. Similarly, the three *conv* layers of the identity block constitute a straight pattern, depicted using the sub-graph with label 4; and its ReLU layer is denoted using label 5.

Figure 5: Merging the *conv* and identity blocks of [Fig.2](#).

Next, [Algo.2](#) finds two branch patterns (*i.e.*, sub-graphs 3 and 5 in [Fig.5a](#)) and produces [Fig.5b](#), the straight patterns of which are first merged into [Fig.5c](#) and finally form a single sub-graph  $\{1, 2, 3, 4, 5\}$ . The preconditions of the above two rules are all satisfied when merging these patterns. In practice, [Algo.2](#) can also group the multiple identity blocks and a *conv* block into a single sub-graph, thus producing four large sub-graphs for stages in [Fig.3a](#). These large sub-graph are no longer grouped because the second precondition of [Rule \(i\)](#) is not satisfied.

### 3.3 Ordering Sub-graph Instances

The synergy between network and hardware architectures enabled by [§3.1](#) and [§3.2](#) partitions a computational graph into larger sub-graphs. In addition, GraphTurbo also uses `SplitInfo` to split each sub-graph into instances, **the order of which is determined in this section**.

For instance, each stage in [Fig.3a](#) is converted into one to multiple labeled sub-graph instances with the same color, forming the new graph in [Fig.6](#). All instances at the same horizontal level are homogeneous and thus can be executed in any order. The edges between these instances are inherited from sub-graphs, but the gray ones are redundant and easily

eliminated. Specifically, we determine whether an edge is redundant or not by checking whether the output of a producer instance is used by one consumer instance. This is achievable because combining `SplitInfo` and the shape of an output tensor can perform this checking. The considered edge is redundant and eliminated if the checking result is true.

Figure 6: Sub-graph instances of the four stages in [Fig.3a](#).

GraphTurbo currently uses two approaches to schedule a computational group  $G$  of sub-graph instances. First, it visits sub-graph instances in a breadth-first search (BFS), producing a schedule order shown in [Fig.7a](#). Second, GraphTurbo visits them in a depth-first search (DFS), as described in [Algo.3](#). We currently only use the BFS and DFS searches because they simplify the algorithmic design of GraphTurbo. As will be reported in [§5](#), this choice achieves promising results. We are currently working on an integer linear programming approach to find a better solution than both of these search heuristics, which will be released soon.

[Algo.3](#) first instantiates a list *visit* by visiting  $G$  in any orders (line 1) and next moves all of its sub-graph instances with no in-degrees from *visit* to another list *ready* in order (lines 3-4). The in- and out-degrees of  $SGI$  are only determined by the black edges in [Fig.6](#). The last  $SGI$  with no in-degrees of *visit* (lines 6-8) is extracted and added into the ordered list *order* (line 9), with its consumers updated (lines 12-13) and moved from *visit* to *ready* (line 14).

---

#### Algorithm 3: Schedule Sub-graph Instances

---

```

1 visit ← get_subgraph_instances(G);
2 while visit ≠ ∅ do
3   foreach indegree(SGI) = 0 in visit do
4     ready ← ready.push(SGI); visit ← visit \ SGI;
5   while ready ≠ ∅ do
6     p ← sizeof(ready);
7     while indegree(SGIp) ≠ 0 do
8       p ← p - 1;
9     order ← order.push(SGIp); ready ← ready \ SGIp;
10    foreach SGI in visit and ready do
11      if SGIp is a producer of SGI then
12        remove_producer(SGI, SGIp);
13        indegree(SGI) ← indegree(SGI) - 1;
14        ready ← ready.push(SGI); visit ← visit \ SGI;
```

---

As an example, [Fig.7](#) illustrates how the three lists change when [Algo.3](#) is applied. In particular, as  $G$  can be visited in any order, we assume that it is visited in a BFS order for illustrative purpose. *order* is inspected from left to right. GraphTurbo finally selects the better one ([Fig.3b](#)) between the two results with respect to memory utilization. The labels

of each circle in Fig.7f would change if  $G$  is visited in other orders but the colors not, which does not matter because all instances of the same sub-graph are homogeneous.

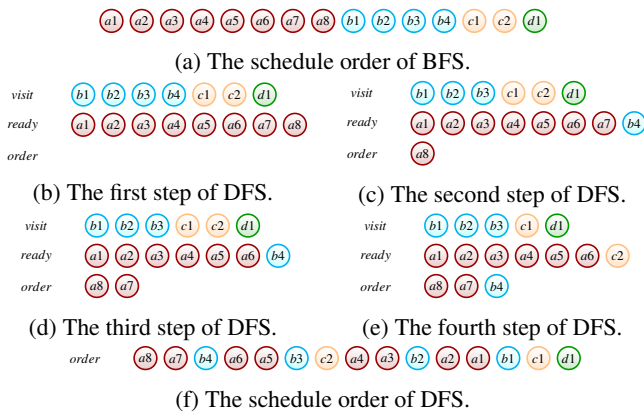

Figure 7: Different schedule orders of Fig.6. We only show the first four steps of Algo.3 for the sake of clarity.

### 3.4 Inferring Core Binding and Buffer Scopes

The next step is to **bind each ordered sub-graph instance to multiple cores**. A sub-graph instance’s binding strategy can be determined by inspecting the loop dimensions of its output tensor. However, determining binding strategies individually may introduce more communications due to the mismatching between them. We use Algo.4 to infer binding strategies.

As Algo.4 can detect the mismatching between a pair of producer-consumer sub-graph instances, it also uses information to **infer at which buffer scopes the output tensor of a sub-graph instance should be declared**. It first visits a schedule order  $O$  like Fig.7f in a reverse order and records all corresponding sub-graph instances in a list  $visit$  (line 1). Defined by default as an empty tuple  $\square$  and LB,  $bind[i]$  and  $scope[i]$  are used to record the binding strategy of a sub-graph instance and at which buffer level its output tensor is declared, respectively (line 2). As an output tensor is taken in by another sub-graph instance, we do not care about where the input tensors of a sub-graph instance should be declared. A sub-graph instance also produces intermediate tensors not considered by Algo.4, which GraphTurbo manages using its kernel generator (see §4.1).

Algo.4 infers binding strategies and buffer scopes for each sub-graph instance denoted by  $visit[i]$  (lines 3-16). If  $bind[i]$  is empty (*i.e.*, no information can be used for inference) or  $scope[i]$  is not LB (*i.e.*, the known information cannot be used for inference) (line 4), Algo.4 instantiates  $bind[i]$  using a plain strategy (line 5) and infers the binding strategy of the input tensors of the current sub-graph instance. A plain binding strategy is obtained by greedily allocating more cores from the outermost to inner loop dimensions of a tensor. The binding factors along multiple dimensions form a multi-dimensional

#### Algorithm 4: Infer Core Binding and Buffer Scopes

```

1  $visit \leftarrow \text{DFS\_visit\_reverse\_order}(O)$ ;  $size \leftarrow \text{sizeof}(visit)$ ;
2  $bind[1, \dots, size] \leftarrow \{\square\}$ ;  $scope[1, \dots, size] \leftarrow \{LB\}$ ;
3 foreach  $i$  in  $[1, \dots, size]$  do
4   if  $bind[i] = \square$  or  $scope[i] \neq LB$  then
5      $bind[i] \leftarrow \text{plain\_binding}$  (output of  $visit[i]$ );
6     if  $\text{infer\_binding}(bind[i]) = \square$  or is invalid then
7       continue;
8     foreach  $producer[j]$  in  $visit$  do
9       if  $bind[j] = \square$  then
10         $bind[j] \leftarrow \text{infer\_binding}(bind[i])$ ;
11       else if  $bind[j] \neq \text{infer\_binding}(bind[i])$  then
12         $scope[j] \leftarrow GB$ ;
13       else
14        continue;
15   else
16      $bind[i] \leftarrow \text{update\_binding}(bind[i])$  uses more cores than
        $\text{plain\_binding}$  (output of  $visit[i]$ ) ?  $\text{update\_binding}$ 
       ( $bind[i]$ ) :  $\text{plain\_binding}$  (output of  $visit[i]$ );

```

tuple. Algo.4 tries to instantiate a binding factor by iterating integers 8, 4, 2, and 1, which guarantees load balance across cores. The iteration turns into its next value if a loop extent  $size^d$  is not dividable by current one. Note that some tensors can have some specific requirements annotated to their loop dimensions, which cannot be bound to cores.

Next, Algo.4 uses  $\text{infer\_binding}$  to infer the binding strategies of  $visit[i]$ ’s input tensors, which are the output tensors of  $visit[i]$ ’s producers (line 8). The inference is achieved by first matching loop dimensions of an input tensor as line 10 of Algo.1 does and next propagating the binding factors of the matched dimension from the output tensor. A binding strategy can be invalid if it does not satisfy the annotated requirements. Hence, Algo.4 falls into one of the following three cases when the inferred binding strategy is neither empty nor invalid: (1)  $bind[j]$  is instantiated by the inferred binding strategy if it has not yet been defined (lines 9-10); (2)  $scope[j]$  is overwritten by GB if the already defined  $bind[j]$  does not match the inferred binding strategy (lines 11-12), since a communication is required here (see §3.5); (3) no mismatching between the already defined  $bind[j]$  and the inference succeeds, and Algo.4 steps into next iteration (lines 13-14).

$bind[i]$  is inferred and not empty in the **else** case (line 15), for which Algo.4 tries to update  $bind[i]$  by reconsidering the possibly annotated requirements of  $visit[i]$ ’s output tensor and computes a plain binding strategy for it. The one using more cores between these two binding strategies is finally used to rewrite  $bind[i]$  (line 16).

### 3.5 Concatenating Instance Outputs

As GraphTurbo splits a sub-graph into multiple instances, the output tensor of a sub-graph is also partitioned into multiple pieces. Hence, **this section introduces the step to concatenate the outputs of these sub-graph instances**.

To implement this step, GraphTurbo detects fine-grained

dependencies between sub-graph instances and introduces concatenation *ops* before each consumer of multiple producers, obtaining Fig.8 for the running example. A concatenation *op* is lightweight since its inputs and output stay in either LB or GB. GraphTurbo needs to insert additional *ops* for moving data across the memory hierarchy if the binding strategies and memory scopes of the tensors taken in by a concatenation *op* are different from each other and/or those of its output.

Fig.9 depicts two scenarios where such (gray) *ops* should be inserted. A sub-graph instance or an auxiliary *op* is denoted using an ellipse that displays the shape, scope and binding strategy of its output tensor. On the left, a copying *op* is introduced once mismatching between the memory scopes is captured, promoting data from its input (GB) to its output (LB). On the right, a redistribution *op* is inserted due to the difference between binding strategies, triggering a communication between cores. This can be achieved by resetting the tuple using the smaller binding factors along each dimension.

Figure 8: Concatenate instance outputs.

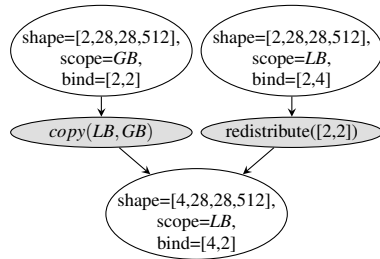

Figure 9: Insert data movement *ops*.

### 3.6 Generalizing the Approach

Now GraphTurbo can effectively schedule a DNN computational graph, but we made some assumptions in its design. This section discusses how they can be generalized. First, §3.1 assumes that a sub-graph has one output tensor, which is often the case in practice. One can repeat Algo.1 for each output tensor of a sub-graph that with multiple output tensors.

Second, the rules defined in §3.2 take into account down-sampling operations in a DNN model. However, our scheduler can also be generalized to target up-sampling operations by simply modifying Rule (i). A further split *op*, which can be considered as the opposite of the concatenation *op* introduced in §3.5 may be required to distribute the output of a sub-graph instance to its multiple consumers. We did not experiment with up-sampling operations in this work.

Third, §3.3 uses two methods to order sub-graph instances, which are simple but effective, as will be demonstrated in §5. We are now investigating another heuristic by allocating higher priorities to sub-graph instances with heavier memory footprints and plan to release it in the future.

Finally, GraphTurbo greedily uses LB, but, as a suggestion, it could be replaced by GB to schedule a computational graph

across the  $d$  clusters of Fig.1. It could also be substituted by faster memory of other platforms, e.g., shared memory of GPU. Interestingly, much larger LB sizes would simplify the algorithmic flow of GraphTurbo. Even when splitting a sub-graph instance is unnecessary, GraphTurbo could obtain a similar scheduling to TVM but with across-layer memory optimizations (§4.4) fully considered. Moreover, making use of the higher-level buffer, e.g., those residing in CUs of Fig.1 if any, is profitable, since data exchanges between such buffers and LB may dominate the communications in such cases.

## 4 Kernel Generation for Sub-graph Instances

Once scheduled sub-graph instances are obtained, the kernel generator can take each of them as input and lower them into loop nest pipelines. **The task of our kernel generator is to generate larger kernels by implementing loop transformations and stitching the intermediate tensor in the faster local memory of a DSA platform.** To minimize the engineering cost, we prototype our kernel generator in TVM [5], but it may fail to produce a single kernel for one sub-graph instance. Fig.10 exemplifies this issue by gradually expanding one sub-graph instance,  $b_3$ , of Fig.8.

Figure 10: Expand  $b_3$  to generate a single kernel for it.  $b_3$  is sub-graph instance of stage2 of Fig.2. It is expanded to one *conv* block and three identity blocks, each of which is then expanded to multiple layers. How the *conv* block is expanded is shown in the middle, which obtains five layers shown on the left of the block level of Fig.2. These layers are labeled, and how layer #2 is expanded is shown on the rightmost, which produces the three *ops* shown at the layer level of Fig.2.

The rightmost part is what TVM’s kernel generator takes in, but Fig.10 shows that  $b_3$  is composed of 38 *ops* (11 for the *conv* block and 9 for each identity block), out of which 13 are *conv ops* (4 for the *conv* block and 3 for each identity block). Performing loop fusion across multiple *conv ops* is outside the power of TVM’s kernel generator. Although CUTLASS [27] was recently integrated into TVM to alleviate this problem for GPU [50], the number of acceptable *conv ops* is still limited. Furthermore, even if a similar vendor-crafted library can be offered on a DSA platform, the kernel generator would still put the output of a sub-graph instance in DDR, which in turn

would regress the benefit created by GraphTurbo.

## 4.1 Loop Fusion within Layers

The kernel generator can easily fuse *ops* within a layer. We use layer #2 in Fig.10 as an example and lower it to the loop nest pipeline shown in the middle of Fig.11. Since TVM requires users to write schedule templates for these loop nests, simply adopting its workflow cannot fully automate GraphTurbo.

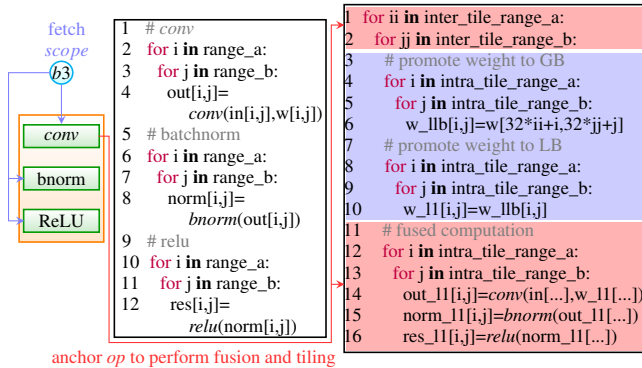

Figure 11: Loop fusion within a layer. Left: fetch the *scope* information of the sub-graph instance *b3* in Fig.8. Middle: the loop nest pipeline of layer #2 in Fig.10. Right: the tiled and fused loop nest, with memory promotion statements of weights automatically inserted. Red arrows connect the anchor *op* with its tiled loop dimensions. Blue arrows represent that the *ops* fetch the *scope* information from Relay IR.

To resolve this issue, GraphTurbo selects an anchor *op* out of each layer and automatically performs loop tiling on this *op*. An anchor *op* should be set using either *conv*/matrix multiplication if the later appears in the current layer, or the last *op* of the layer otherwise. In the later case, the anchor *op* should be an elementwise *op*. The outermost two loop dimensions are selected for tiling because they are parallelizable in both cases. The tile sizes along the two dimensions of an anchor *op* are then selected in a similar way to that used to determine a plain binding strategy in §3.4, which greedily maximizes the memory utilization of LB. In other words, a tile size is instantiated using a largest integer that not only divides the current loop extent but also allows the resulted tiled tensors to stay in LB. Once the tile shape and sizes of the anchor *op* are determined, the loop bounds of other *ops* can be inferred and fused with the anchor *op*, just like what existing techniques [41, 52] did, producing the fused and tiled loop nest shown in the red regions of Fig.11.

By converting the tensors written by the *conv* and *batchnorm* *ops* into intermediate ones, this method automatically allocates them in faster memory, as mentioned in §3.4. Before doing so, the kernel generator fetches the *scope* information of the current sub-graph instance, *i.e.*, *b3* in Fig.11, allocating intermediate tensors at the defined memory level. Memory

promotion statements of a weight tensor are also automatically injected in the same way, as shown by the blue region of Fig.11. Note that some *ops* like batch normalization can be folded, but we keep it here for illustrative purpose.

## 4.2 Buffer Stitching across Layers/Blocks

After the internal of a layer is fused, we do not put its output back to DDR but still let it remain in LB, *e.g.*, *res\_11* in Fig.11. Hence, all layers of the *conv* block can exchange their data via LB, which we refer to as *buffer stitching* and the kernels used to implement these layers can be wrapped into one. The input tensors of the *conv* block are also put in LB, as declared by *scope* in §3.4. An identity block can be handled in a similar way. As the output tensors of each block’s last layer also stay in LB, the four blocks can all be stitched together.

By targeting memory-intensive *ops*, AStitch [60] also implements a similar functionality. However, our work also considers compute-intensive *ops*. In addition, we also try to maximize faster local memory between sub-graph instances. By combining loop fusion and buffer stitching, our implementation generates a single kernel for the sub-graph instance *b3*. In contrast, TVM produces one kernel for each layer, increasing the number of generated kernels (65 in total) and thus requiring more off-core data movements.

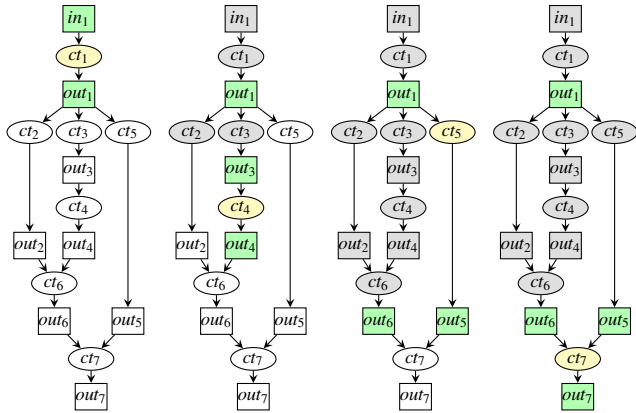

## 4.3 Memory Allocation and Reuse

The remaining task is to allocate space at the memory levels defined by *scope* for each tensor, which is trivial to implement. However, by putting many tensors in the faster local memory, GraphTurbo calls for a careful mechanism to reuse the limited LB’s capacity. We always release the space consumed by an output tensor of a layer/block/sub-graph instance once it is no longer used. The space can thus be reused by other tensors. LB only needs to hold a limited number of tensors simultaneously. In case the total size of these tensors exceed LB’s capacity, the one with the longest liveness across multiple computation tasks is spilled to first GB and next DDR. Fig.12 depicts the liveness of tensors across computation tasks.

Our heuristic is different from prior work [40, 46], which always spills the tensor with the largest memory size to lower memory hierarchy levels. Selecting the one with the longest liveness has a higher probability to spill a smaller tensor, which is likely to reduce the overhead of data movements.

## 4.4 Across-layer Instruction Scheduling

Combining loop fusion and buffer stitching not only produces a single kernel for a sub-graph instance, but also allows for overlaps of different layer computation tasks. On the right of Fig.11, promoting a weight is implemented by first copying its tensor from DDR to GB using DMA and next hoisting the tensor from GB to LB, which is possibly further dispatched

(a) Execute  $ct_1$ . (b) Execute  $ct_4$ . (c) Execute  $ct_5$ . (d) Execute  $ct_7$ .

Figure 12: Liveness of tensors across computation tasks. A (ellipse) computation task ( $ct$ ) can be a sub-graph instance, a block or a layer. A (rectangle) tensor is live when colored in green or released if in gray. A  $ct$  is in execution if colored in yellow or finished when in gray. The space of tensor  $in_1$  is released once it is not live, reused by  $out_3$ .  $out_1$  is spilled to GB or DDR in case LB is insufficient to hold four tensors in (d), since it lives across seven  $cts$  but others across fewer.

to individual CUs of Fig.1. The latency of these promotion statements can be hidden behind an earlier executed layer, and multiple CUs can execute computation tasks simultaneously.

Fig. 13 shows how this optimization is performed. A rounded rectangular represents a layer’s tiled computation task. Across-layer memory latency hiding takes place between the two vertical lines, and CUs can execute different computation tasks of two tiles. Our approach significantly enhances the opportunities of such memory latency hiding and parallelism by increasing the optimization granularity to a degree beyond layers studied by prior work [5, 13, 31, 54].

Figure 13: Across-layer instruction scheduling.

## 5 Experimental Results

We conduct experiments on STCP920 [51], an SoC DSA platform customizing the abstraction in Fig.1 using

$$\begin{cases} d \leftarrow 4; c \leftarrow 8; u \leftarrow 3 \\ LB \leftarrow 64 \text{ KB L1} \\ GB \leftarrow 8\text{MB last local buffer (LLB)} \\ CU_1 \leftarrow \text{vector core}; CU_2 \leftarrow \text{VME}; CU_3 \leftarrow \text{MME} \end{cases} \quad (2)$$

The eight cores connected bidirectionally using LLB. Each core has a 32-bit RISC-V CPU with vector extension, a vector MAC engine (VME) and a matrix MAC engine (MME) to handle different types of  $ops$ . As the target shares the common hardware abstraction of many existing DSA accelerators, one can expect similar results on other DSA platforms.

GraphTurbo resorts to LLVM v12.0.0 to compile its generated kernels on STCP920. The repository will be made publicly accessible soon. We experiment using ResNet-50 v1.5 [16], BERT [9], and DLRM [33], extracted from MLPerf v2.0 [43] and use their standard configurations. For BERT, we also consider three additional configurations. Other MLPerf models are not considered because they involve dynamically shaped tensors that GraphTurbo currently does not support. We also take into account MobileNet v2 [17], Vision\_Transformer [11], DenseNet [18], and Conformer [14] that are not included in MLPerf. Except DLRM implemented using Pytorch v1.8.1 [38], all remaining models are implemented using TensorFlow v1.13 [1]. There are no fundamental reasons that limit the applicability of GraphTurbo to training models, which we intend to experiment in the future.

GraphTurbo is prototyped in TVM v0.8 [5], implemented using 19k Python, 44.2k C/C++ and 2k miscellaneous, among which the code used to implement the graph scheduling approach is about 7k lines. As our algorithms operate on computational graphs, it does not require much effort to target GraphTurbo to a new platform. What the engineers need to do is to feed these algorithms with necessary architectural information required, and a target platform should share the same properties as the DSA abstraction in Fig.1. The code to be changed should be lightweight in such cases.

### 5.1 Task Decomposition across Clusters

We first discuss how the optimal batch size is selected for a cluster of STCP920 using BERT-128, whose sequence length is 128. Table 1 collects the data for both throughput and latency. We report the results of TVM v0.8 for this model, and also consider the result of highly-crafted C++ implementations provided by the vendor of STCP920, which schedules a computational graph in a similar way to our idea and implements kernel generation by hand.

Table 1: Results of BERT-128 under different batch sizes.

approach	batch size	configuration		throughput (sentences/s)	latency (ms)
		iter.	batches/cluster		
TVM	8	1	2	138	6.79
	16	1	4	512	9.48
	32	2	4	512	18.96
	64	4	4	512	37.92
GraphTurbo	8	1	2	138	6.79
	16	1	4	512	9.48
	32	1	8	4052	7.67
	64	1	16	2716	23.58
crafted code	64	2	8	4052	15.34
	32	1	8	4048	7.62

For TVM, a cluster’s LLB is sufficient to retain four data batches. As allocating four batches to each cluster makes two clusters idle, we allocate two batches to each cluster when the batch size is eight, which obtains a 138 sentences/s throughput and a 6.79ms latency. When the batch size increases to 16, TVM can allocate four batches to each cluster; the throughput and latency grow to 512 sentences/s and 9.48ms, respectively. As TVM cannot allocate more batches to a cluster, the throughput cannot further scale with the growth of the batch size. Instead, TVM introduces a loop execution within each cluster, which guarantees the throughput but the latency increases as proportional to the number of loop iterations.

GraphTurbo performs the same as TVM when the batch size is 8 and 16, since a cluster’s LLB is sufficient to handle the allocated batches and we do not need to create larger sub-graphs or split them. This illustrates that **the scheduling of TVM can be considered as a special case of our work**. The difference is observed when the batch size increases to 32, for which GraphTurbo allocates eight batches to a cluster but TVM only allocates four. GraphTurbo creates larger sub-graphs and splits them into instances, achieving a higher throughput of 4052 sentences/s and a lower latency of 7.67ms.

When the batch size increases to 64, GraphTurbo allocates 16 batches to each cluster but suffers from both throughput degradation and latency increase, since such a batch allocation requires larger tensors than the implementation in §4.3 spills more of them to slower buffers. In this case, we also introduce a loop execution within a cluster by allocating eight batches to it. As a result, the throughput stays at 4052 sentences/s and the growth of latency is also alleviated when compared with the case of allocating 16 batches to each cluster.

Table 1 also indicates that GraphTurbo achieves very close throughput and latency to the vendor-crafted implementation. In the following context, we report the results of TVM and GraphTurbo by selecting their optimal numbers of allocated batches for a cluster. Both optimal batch allocation strategies are obtained after a round of beforehand autotuning executions. For the sake of simplicity, we discuss throughout numbers below but the results also apply to latency.

## 5.2 Performance Comparison

We now report the performance. BERT is configured using four sequence lengths, 256, 384 (the default MLPerf configuration), and 512. Table 2 summarizes the configurations of each model. TVM’s throughput is listed in the rightmost column, which is preceded by the throughput units. We show the speedups of each approach over TVM’s data in Fig.14, where we also report the results of AStitch [60].

TVM still fuses *ops* within a sub-graph and produces kernels that exchange data via DDR, and it also misses the instruction scheduling opportunities across layers. By (1) producing fewer kernels and reducing off-core data movements, (2) better saturating L1, and (3) further exploiting across-

Table 2: Summary of the models.

label	model	batch size	batches per cluster		throughput unit	TVM’s result
			TVM	GraphTurbo		
(A)	ResNet-50	64	2	16	images/s	1064
(B)	BERT-128	32	4	8	sentences/s	512
(C)	BERT-256	16	2	4	sentences/s	412
(D)	BERT-384	8	1	2	sentences/s	36
(E)	BERT-512	8	1	2	sentences/s	324
(F)	DLRM	1024	64	256	queries/s	131000
(G)	MobileNet-v2	128	2	32	images/s	1416
(H)	Vision_Transformer	32	4	8	images/s	40
(I)	DenseNet	32	4	8	images/s	456
(J)	Conformer	12	1	3	sentences/s	184

Figure 14: Speedups of throughput over TVM.

layer instruction scheduling, GraphTurbo outperforms TVM by 11.15× on average.

We reproduce the functionality of AStitch for STCP920 by maximally preserving tensors in L1. However, AStitch does not split a sub-graph into instances and thus fails to benefit from the imbalanced memory usage distribution enabled by better schedule orders of sub-graph instances. Hence, GraphTurbo obtains a mean speedup of 6.16× over it. Its performance falls behind that of TVM for ResNet-50 and MobileNet-v2 because AStitch prefers to produce a single kernel for compute-intensive *conv ops* in these models, which spills data to DDR and results in heavier data movements.

The vendor-crafted implementation considers all the optimization opportunities studied in this paper. Manually optimizing a computational graph can better exploit the trade-off between parallelism, load balance and locality, making crafted code sometimes obtain better performance than GraphTurbo, *e.g.*, for BERT-512 and MobileNet-v2. However, a manual scheduler is also non-trivial and thus sometimes misses the imbalanced memory usage distribution, *e.g.*, for BERT-384. Due to the complexity of such a scheduling strategy, the vendor implementation for the last three models is still under construction till now, and their data are thus missing. On average, GraphTurbo achieves a 1.04× speedup over the vendor-crafted implementation.

## 5.3 Performance Breakdown

This section studies how different factors contribute to the overall speedup of GraphTurbo over TVM. We consider four variants of GraphTurbo as follows. First, we only keep the outputs of each kernel generated by GraphTurbo in LLB as

much as possible. Second, we let these outputs stay in L1 to the greatest extent. Third, we split sub-graphs into instances and schedule them based on the second variant, but across-layer instruction scheduling is disabled. Finally, we turn on all optimizations. Fig.15 shows the comparison results.

Figure 15: Individual contributions of each optimization.

The results of the second variant illustrate that converting off-core data movements into on-core data exchanges indeed makes sense. By achieving an average speedup of  $3.67\times$  over TVM, the green bars also outperform the red bars, which do not always obtain positive speedups over TVM. This demonstrates the importance of preserving tensors greedily in LB, *i.e.*, L1 of STCP920.

The third variant outperforms the green bars by  $2.20\times$  on average. ResNet-50, BERT-256, BERT-512, MobileNet-v2, and DesneNet, that exhibit imbalanced memory usage distribution caused by their down-sampling operations, benefit more from the ordering of sub-graph instances. Other models that either do not have such a network property (BERT-128 and Vision\_Transformer) or introduce more concatenation *ops* than the remaining ones (DLRM) observe insignificant improvements. Finally, across-layer instruction scheduling (§4) obtains a mean speedup of  $1.72\times$  over the third variant.

## 5.4 Hardware Utilization

This section evaluates how effectively GraphTurbo can utilize DSA hardware resources. First, as the core idea is to convert off-core data movements to on-core data exchanges, we investigate how the memory hierarchy of STCP920 is utilized. To this end, we report in Table 3 the frequencies of each memory level that different approaches utilize.

Table 3: Comparison of buffer scopes.

label	DDR			LLB			L1		
	TVM	crafted	GraphTurbo	TVM	crafted	GraphTurbo	TVM	crafted	GraphTurbo
(A)	58	1	1	0	11	11	0	291	284
(B)	242	2	1	0	0	0	0	304	305
(C)	242	2	1	0	25	110	0	401	240
(D)	515	2	1	0	49	75	0	968	967
(E)	242	2	1	0	25	76	0	474	337
(F)	76	1	0	0	0	0	0	75	76
(G)	56	1	0	0	7	3	0	619	608
(H)	214	-	24	0	-	60	0	-	340
(I)	247	-	0	0	-	3	0	-	389
(J)	1054	-	4	0	-	813	0	-	250

TVM always puts the output tensors of its sub-graphs in DDR, resulting in abundant off-core data movements. In contrast, GraphTurbo maximizes the utilization of faster local memory, converting many off-core data movements into on-core data exchanges. The vendor-crafted implementation also makes use of the faster local memory. Due to their familiarity with the hardware, the architects of STCP920 sometimes can better manage the memory hierarchy than our heuristics, but this manual scheduler is also tedious.

Second, we evaluate how VME and MME are utilized using ResNet-50 and BERT-128. We report in Fig.16 the data under different batch sizes, with the quantization version of ResNet-50 also considered, to validate the scalability of GraphTurbo. Other models observe similar results. The utilization of both VME and MME increases with the growth of batch size, which is exploited by our work. BERT-128 suffers from a degradation when the batch size changes from 8 to 16, as explained in §5.1.

Fig.17 shows the utilization of VME and MME when executing the four stages in Fig.3a. GraphTurbo performs similar to TVM for stage1, but it outperforms TVM for the other three stages, which demonstrates exploiting the imbalanced memory usage distribution can better utilize hardware resources.

Figure 16: Usage of VME/MME. x axis denotes batch sizes.

Figure 17: Utilization VME (left) and MME (right) when executing the stages in Fig.3a. y axis is the utilization percentage.

## 5.5 Comparison of Compilation Overhead

As compilation time is also a major concern for scheduling DNN models, this section reports the compilation overhead of GraphTurbo and compares it with those of the baseline methods. Table 4 reports the data in seconds, which demonstrates that GraphTurbo can achieve better performance than the state of the art without significantly aggravating the compilation overhead.

Table 4: Comparison of compilation overhead in seconds.

label	TVM	AStitch	GraphTurbo
(A)	102	66	139
(B)	159	128	199
(C)	170	136	224
(D)	312	290	699
(E)	171	143	282
(F)	25	22	23
(G)	74	57	248
(H)	189	146	340
(I)	173	129	189
(J)	382	238	296

## 5.6 Case Study on GPU

We now conduct a case study using the ResNet18-Tailor model to validate that scheduling sub-graph instances can be extended to NVIDIA A100 GPU. We use CUTLASS v2.9 [27] to implement kernel generation, which is compiled using CUDA toolkit v11.4 with `-O3` flag. We did not consider the *conv* and maxpooling *ops* at the start, and avgpooling and softmax *ops* at the end of this model since they do not contribute to imbalanced memory usage distribution, like those before and after the stages of Fig. 2. The other layers, each composed of a *conv* and ReLU *ops* using a circle, are shown in Fig. 18a.

Figure 18: Different schedule orders of ResNet18-Tailor. The numbers define the schedule order of each method.

We let TVM wrap CUTLASS when generating kernels for layers. CUTLASS fuses two *conv* layers, partitioning the model into four larger sub-graphs (Fig. 18b), the first two of which is split by GraphTurbo into two instances (Fig. 18c). The output tensors of the (red) sub-graph instances are stitched via GPU registers and those of the (orange) ones through GPU shared memory. Table 5 summarizes the results.

Table 5: Execution time in milliseconds on A100 GPU.

batch size	TVM	CUTLASS fusion	graph scheduling	Speedup over	
				TVM	CUTLASS fusion
64	0.99	0.84	0.83	1.19×	1.01×
128	1.88	1.62	1.50	1.25×	1.08×
256	3.51	3.04	2.83	1.24×	1.07×
512	6.76	5.83	5.44	1.24×	1.07×
average				<b>1.23×</b>	<b>1.06×</b>

By scheduling sub-graph instances and exploiting GPU registers and shared memory between them, GraphTurbo outperforms TVM by 1.23× on average, which demonstrates that

our idea is also useful on GPU. GraphTurbo also achieves a mean speedup of 1.06× over CUTLASS, because scheduling sub-graph instances also brings about benefits by exposing and exploiting imbalanced memory usage distribution.

The reasons why the performance improvements on GPU is not promising as on STCP920 are two-folded. On the software side, GraphTurbo can construct a larger sub-graph that contains more than two layers, but CUTLASS, which we use for kernel generation here, refused to accept three or more *conv* layers. Enhancing the kernel generator of TVM in the future can address this issue. We also did not apply instruction scheduling here. On the hardware side, the higher memory bandwidth of this GPU also makes the improvements caused by reducing off-core data movements not significant as on STCP920. While STCP920 only delivers a memory bandwidth of 136GB/s, this GPU can reach more than 1500GB/s.

Nonetheless, other NVIDIA software-defined platforms with limited memory bandwidth, e.g., NVIDIA DRIVE AGX Orin [36], could benefit from GraphTurbo. We also believe that the software-controlled inter-cooperative-thread-array shared memory of the latest NVIDIA H100 GPU could be better exploited by the idea presented in this paper. Hence, our work also offers insights to the GPU micro-architectures.

## 6 Related Work

Scheduling its computational graph is the first step to deploy a DNN model on platforms. The difference between our scheduler and prior work is that we consider hardware architecture when grouping sub-graphs, which enables the synergy between network architecture and DSA, while existing methods [13, 19, 44, 49] not. By generating coarser-grained sub-graphs and splitting them into instances, GraphTurbo exposes the imbalanced memory usage distribution, a network property first studied by MCUNetV2 [30]. However, MCUNetV2 only discusses tiny DNN models on microcontroller units, while this paper considers large-scale DNN models and targets a cloud DSA chip. Some optimizations that can only be implemented when sub-graphs are lowered to loop nest pipelines are not considered by MCUNetV2 but studied in §4.

When a sub-graph is lowered to a loop nest pipeline, existing methods like TVM [5] fuse loop nests with the help of manually written schedule templates. As TVM does not scale well with the increase of *op* numbers within a sub-graph, we only use TVM’s loop fusion to group loop nests within a layer. Our implementation also avoids the need to manually write schedule templates and inject memory promotion statements of weight tensors, the later of which is automated by interacting with the graph scheduler.

By expanding a high-level sub-graph into individual low-level *ops*, XLA [13] does not restrict fusion within layers. Nonetheless, retrieving the high-level information via low-level *ops* is critical to fuse low-level *ops* for XLA, and manually forming profitable high-level sub-graphs is considered as

more robust than through automatic pattern matching in this compiler [45]. GraphTurbo fully automates this process and achieves better performance than AStitch, which has already been demonstrated as superior to XLA [60].

IREE [20] is another work that makes use of its graph scheduling logic when communicating data between low-level parallel pipelined hardware/APIs. Our work differs from IREE by focusing on scheduling instances of larger sub-graphs, which tends to produce fewer kernels. By managing an internal map of *op* sequence on the fly, Zero-Infinity [42] exploits the fine-grained overlaps by prefetching the parameters required by future *ops* during the execution of the current *op*. A layer considered by our work usually includes multiple *ops*, the execution of which is more likely to fully hide the data transfer overhead.

Some autotuning frameworks [6, 57, 59] are also devised to enhance the power of TVM with fewer or no hand-written schedule templates. These autotuners use their search heuristics to tune memory optimizations to further improve the performance of their generated code. Unfortunately, their search spaces are all restricted within layers [39], while our work enables across-layer instruction scheduling (§4.4). In particular, Ansor [57] represents the state of the art of this kind, which is orthogonal to our work by neither considering the scheduling of GraphTurbo nor exploiting the fusion possibilities of multiple *conv*/matrix multiplication operators. Loop fusion is also investigated by polyhedral frameworks [3, 47, 54], but they did not consider buffer stitching that has been discussed in §4.2. Similar to GraphTurbo, DNNFusion [34] also studies across-layer fusion for mobile devices. We fail to obtain its repository to conduct an experimental comparison.

Another thread of works [10, 28, 35] investigate horizontal fusion between *ops* with no producer-consumer relations to better utilize the hardware resources of their targets. GraphTurbo tackles the same issue using a different idea. Our scheduler exploits parallelism within a sub-graph instance, which is always homogeneous to other instances of the same sub-graph. It always decomposes one or multiple dimensions of a tensor to exploit parallelism. On the contrary, *ops* grouped by horizontal fusion are heterogeneous, which calls for a more complicated parallelization mechanism.

Recently, schedulers and code generators for DSA platforms are widely studied. Rammer [31] and Roller [62] generate code for Graphcore IPU [22]. They maximize the utilization of faster memory by combining *ops* that cannot saturate hardware resources. AKG [54] targets code generation for Ascend 910 [29] using the polyhedral model [4, 48] to perform loop fusion. XLA [13] and NaaS [61] exploit the scheduling of sub-graphs for generating code on TPU [25].

The distinction between our work and these approaches is that GraphTurbo partitions a sub-graph along one output tensor's dimension while these methods partition tensors by tiles along multiple dimensions. The primary reason why GraphTurbo does this way is because cores in the DSA ab-

straction of Fig.1 are organized in 1D form. For instance, this level corresponds to 32 hardware cores sharing the shared memory of GPU. The partitioning approach of GraphTurbo is also extensible to deal with a multi-dimensional core grid organization by gradually partitioning and mapping multiple loop dimensions to these hardware dimensions. Moreover, as their targets share the DSA abstraction in Fig.1, the idea presented in this paper could also be used on their targets.

## 7 Conclusion

GraphTurbo is a scheduler for DNN models that enables the synergy between network and hardware architectures. This significant difference from prior work produces fewer kernels and thus reduces off-core data movements, better saturates faster local memory of DSA platforms by exploiting the imbalanced memory usage distribution, and opens opportunities for across-layer instruction scheduling. Results of seven DNN models demonstrate the effectiveness of our idea, whose applicability to GPU is also discussed.

GraphTurbo obtains sub-graph instances by selecting an appropriate size to split a DNN computation graph. Indeed, selecting the optimal size to perfectly model a DSA's memory hierarchy is challenging, and only making use of LB in Fig.1 is not the optimal solution. Instead, our method is just a greedy idea that has been demonstrated effective when compared with vendor-crafted implementation, which we believe can be considered as a good result. A more intelligent approach can be explored to catch up or even beat the performance obtained by hand for models like BERT-512 and MobileNet-v2.

GraphTurbo currently has two limitations. First, the optimal batch size for a cluster is still selected by a simple autotuning approach. We intend to develop an intellectual technique to better address this issue. Second, GraphTurbo cannot handle dynamically shaped tensors. Integrating with the recent methods [12, 56] along this direction may alleviate this issue.

## Acknowledgments

We acknowledge Hyeontaek Lim for his shepherding and the OSDI'23 reviewers for their constructive comments that improve the quality of this work. We would also like to express our gratitude to Bojie Li and Jun Yang for their suggestions on the early versions of this paper, Zhongzhou Jiang, Yuqing Wang, Di Mei, and many other toolchain team members of the Streaming Computing Inc. for their help during the use of their vendor-crafted implementation. Jie Zhao and Xiaoqiang Dan are the corresponding authors of this paper, and the work of Jie Zhao is partly supported by the National Natural Science Foundation of China under Grant No. U20A20226. The views and conclusions presented in this paper belong to the authors. Interpreting them as the official policies of the Chinese Government in any way is not acceptable.

## Abstract

Boosting the execution performance of deep neural networks (DNNs) is critical due to their wide adoption in real-world applications. However, existing approaches to optimizing the tensor computation of DNNs only consider transformations *representable* by a fixed set of predefined tensor operators, resulting in a highly restricted optimization space. To address this issue, we propose EINNET, a *derivation-based* tensor program optimizer. EINNET optimizes tensor programs by leveraging transformations between *general* tensor algebra expressions and automatically creating new operators desired by transformations, enabling a significantly larger search space that includes those supported by prior works as special cases. Evaluation on seven DNNs shows that EINNET outperforms existing tensor program optimizers by up to  $2.72\times$  ( $1.52\times$  on average) on NVIDIA A100 and up to  $2.68\times$  ( $1.55\times$  on average) on NVIDIA V100. EINNET is publicly available at <https://github.com/InfiniTensor/InfiniTensor>.

## 1 Introduction

Fast execution of deep neural networks (DNNs) is critical in a variety of tasks, such as autonomous driving [16, 21, 26], object detection [15, 18], speech recognition [5, 17], and machine translation [37, 39]. A DNN is generally represented as a *tensor program*, which is a directed acyclic graph containing tensor operators (e.g., convolution, matrix multiplication) performed on a set of tensors (i.e.,  $n$ -dimensional arrays).

To improve the runtime performance of a DNN, existing frameworks (TensorFlow [3], PyTorch [31], and TensorRT [35]) rely on *manually-designed* rules to map an input tensor program to *expert-written* kernel libraries. Although widely used, these approaches require extensive engineering efforts and miss optimization opportunities hard to manually discover. To address these problems, recent works have proposed a variety of *automated* approaches that optimize DNN computation by searching over a set of candidate

Figure 1: Comparing EINNET’s search space with that of prior work. “POR Trans.” indicates predefined operator representable transformations.

program transformations or generating high performance kernels on specific hardware. We classify these works into two categories based on their search spaces.

The first category of work, including TVM [7] and Anso [40], is motivated by Halide’s idea of compute/schedule separation [33] and optimizes tensor programs at the *operator level*. For a given tensor operator, they automatically generate high-performance kernels by searching over *schedules*, each of which specifies an architecture-dependent execution plan on particular hardware. To optimize the graph structure of a tensor program, TVM and Anso greedily apply a fixed set of expert-designed program transformations.

The second category of work optimizes tensor programs using *graph-level* transformations, which reorganize the DNN computation in more efficient ways. As two representative systems, TASO [20] and PET [38] adopt a superoptimization-based approach to discovering graph transformations. They generate candidate graph transformations by enumerating all possible graphs over a given set of tensor operators up to a fixed size, and search to apply these generated transformations to an input tensor program.

Both operator- and graph-level optimizers only consider program transformations whose nodes are tensor operators predefined by optimizer developers, as shown in the grey box of Figure 1. We call these transformations *predefined operator representable* (POR) transformations. Despite the fact that

<sup>◇</sup>Tsinghua University and BNRist

existing tensor program optimizers only use POR transformations to optimize tensor programs, POR transformations only exhibit limited opportunities for performance optimizations. In this paper, we propose to explore *general* tensor algebra transformations whose nodes are *general* tensor operators<sup>1</sup>. Compared to POR transformations, general tensor algebra transformations constitute a significantly larger optimization space, which includes POR transformations as special cases, as shown in the yellow box of Figure 1.

To discover general tensor algebra transformations, we present EINNET, a *derivation-based* tensor program optimizer. A key difference between EINNET and prior work (e.g., TASO and PET) is that EINNET reveals operator computation semantics in automated graph transformations by applying derivation rules to tensor algebra expressions. By deriving computation at the expression level, EINNET can reorganize computation into arbitrary tensor expressions and map them into both predefined operators with highly optimized implementations and new auto-generated operators desired by derivations. Expression-level derivations allow EINNET to discover a variety of novel program transformations missing in existing frameworks, since these transformations require highly customized tensor operators not predefined in existing optimizers. Example transformations newly discovered by EINNET include: (1) modifying the computation semantics of an operator to improve efficiency, (2) replacing inefficient operators with highly-optimized alternatives and customized tensor operators to bridge the gap, and (3) aggressively reorganizing computation graphs to enable subsequent graph-level optimizations.

EINNET mainly addresses the following three challenges:

The first challenge is automatically discovering transformation opportunities between general expressions. TASO and PET only consider a *fixed* set of predefined operators, but there are infinitely many possible general expressions. Hence, directly applying superoptimization (i.e., enumerating all possible graphs over general expressions) is infeasible. EINNET addresses this challenge by presenting a *derivation-based* mechanism that automatically transforms an expression to equivalent alternatives by applying a collection of derivation rules. Since most derived expressions cannot be simply represented as predefined operators, we introduce *eOperators* (*expression as an operator*) to represent non-POR computation. eOperators enable EINNET to discover a variety of optimizing transformations between expressions.

The second challenge is converting expressions back to kernels that can be executed on DNN accelerators, a process we term *expression instantiation*. Although existing kernel generators (e.g., TVM and Ansor) can generate kernels for a given expression, doing so is suboptimal since existing vendor-provided libraries (e.g., cuDNN [10] and cuBLAS [11]) offer highly-optimized kernels for a set of

<sup>1</sup>An operator is a tensor operator if it can be represented using the tensor algebra expression in Equation (1)

Figure 2: EINNET overview

predefined operators. EINNET opportunistically matches a part of an expression with predefined operators to take advantage of the highly-optimized kernels from vendor-provided libraries; the remaining part of the expression is lowered to an off-the-shelf kernel generator (i.e., TVM [7]).

The third challenge is quickly finding optimizing transformations in the search space of general tensor algebra transformations. In particular, optimizing a tensor program normally requires applying a long sequence of derivation rules (e.g., up to 12 in our evaluation), which cannot be efficiently discovered by a traversal-based search algorithm. To address this challenge, EINNET employs a two-stage search approach to applying derivations, where an *explorative derivation* stage considers applying all possible derivations to the current expression to create a comprehensive collection of expressions, and a *converging derivation* stage uses *expression distance* to guide the search towards promising candidates. This distance-guided approach allows EINNET to discover complex optimizations requiring long sequences of derivations under a reasonable search budget.

We evaluate EINNET on seven real-world DNN models covering a variety of machine learning tasks. We compare EINNET with state-of-the-art frameworks on two GPU platforms, NVIDIA A100 and V100. Evaluation shows that EINNET is up to  $2.72\times$  faster than existing tensor program optimizers. The significant performance improvement indicates that EINNET benefits from the new optimization opportunities enabled by derivation-based optimizations.

This paper makes the following contributions:

- We extend the POR optimization space to the general tensor algebra optimization space by combining operator computation semantics and computation graphs with tensor algebra expressions.

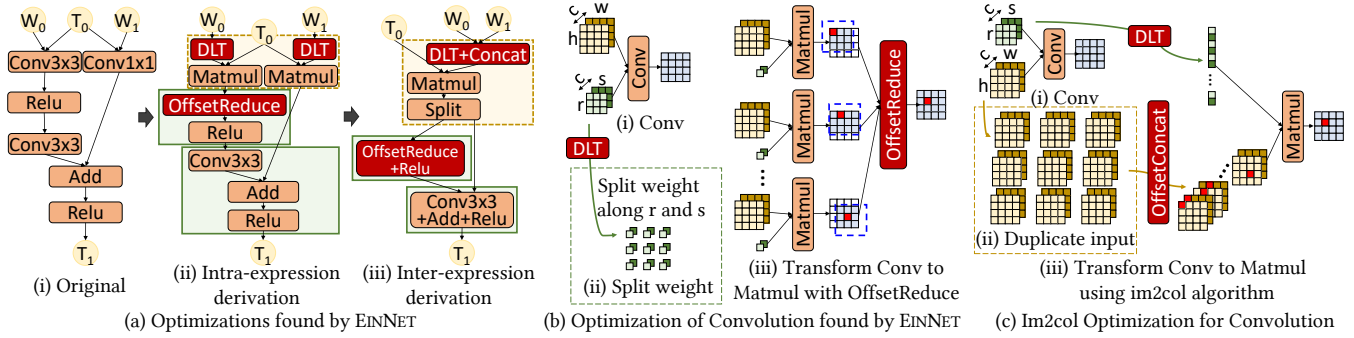

Figure 3: Optimization examples of EINNETH. Figure (a) shows the optimization that transforms a  $\text{Conv}3 \times 3$  operator into a  $\text{Matmul}$  and an eOperator  $\text{OffsetReduce}$ , and a  $\text{Conv}1 \times 1$  operator into a  $\text{Matmul}$ . Then, inter-expression derivation is performed to fuse multiple operators into one. Figure (b) shows the optimization details performed by EINNETH for the  $\text{Conv}3 \times 3$  operator, which first splits the weight tensor into 9 tensors, then multiplies each tensor with the input, and finally adds the nine results together with certain offsets (illustrated by the dashed boxes and red blocks). The  $\text{Matmul}$ s in Figure (b) are further fused into a single one. As a comparison, Figure (c) shows the typical  $\text{im}2\text{col}$  [36] optimization for  $\text{Conv}$ , which performs a different transformation from that in Figure (b) and can also be automatically found by EINNETH.

- We present the first attempt to explore a significantly larger expression search space using a derivation-based mechanism.
- We build EINNETH, an implementation of the above techniques with over 23K lines of C++ and Python code, which achieves up to  $2.72 \times$  speedup over existing tensor program optimizers.

## 2 Overview and Motivating Example

Figure 2 shows an overview of EINNETH, a tensor program optimizer with derivation-based transformations. For an input tensor program, EINNETH first splits it into multiple subprograms consisting of predefined operators. Each subprogram is translated to a tensor algebra expression (§3) by a program translator. Then, EINNETH’s *derivation-based optimizer* uses different derivation rules, including inter- and intra-expression derivation rules (§4) and expression instantiation rules (§5), to generate optimized subprograms for each expression, which consists of both predefined operators and eOperators. Finally, EINNETH selects the best discovered transformation for each subprogram and post-optimizes the expressions to construct an efficient tensor program (§6).

**Motivating example.** As a motivating example, Figure 3(a) shows an optimization found by EINNETH. It first performs an intra-expression derivation to transform convolutions into matrix multiplications, and then performs inter-expression derivation to fuse multiple operators into one. The red operators, such as  $\text{OffsetReduce}$ ,  $\text{DLT}$  (data layout transformation), and  $\text{OffsetReduce+Relu}$ , are eOperators automatically discovered and generated by EINNETH. Figure 3(b) shows the details of the new optimization discovered by EINNETH for

$\text{Conv}3 \times 3$  in Figure 3(a). Figure 3(c) illustrates the classic  $\text{im}2\text{col}$  [36] optimization for convolution, which is widely implemented in existing libraries and also covered by the automatic optimization space of EINNETH. Different from copying input tensors for the kernel size times in  $\text{im}2\text{col}$ , the newly discovered transformation copies output tensors the same number of times. It can be more efficient when the output size is smaller than the input size, and achieves a  $2 \times$  speedup compared with  $\text{cuDNN}$  on the NVIDIA A100 GPU for certain convolutions in ResNet-18 [19] in our evaluation.

Existing tensor program optimizers cannot automatically discover such transformations because: (1) the transformations require eOperators (e.g., adding intermediate tensors with offsets), which are outside of the POR transformation space explored by superoptimization-based frameworks such as TASO [20] and PET [38], and (2) the transformations modify the computation semantics instead of the schedule, and thus cannot be found by schedule-based optimizers like TVM [7] and Ansor [40].

## 3 Tensor Algebra Expression

EINNETH represents a tensor program as *tensor algebra expressions*, which defines how to compute each element of output tensors from input tensors. Figure 4 shows the expression of multiplying three matrices (i.e.,  $A \times B \times C$ ). We now describe the components of an expression. For simplicity, we assume an expression has one output. EINNETH’s expression can be easily generalized to multiple outputs.

**Traversal and summation notations.** A *traversal notation*, denoted as  $L_{x=x_0}^{x_1}$ , consists of an *iterator*  $x$  and an *iterating space*  $[x_0, x_1)$ . The traversal notation corresponds to a dimen-

$$\begin{aligned}
& \prod_{c=0}^C \prod_{r=0}^R \sum_{k_0=0}^K \sum_{k_1=0}^K A[c, k_0] B[k_0, k_1] C[k_1, r] \quad (a) \\
& = \prod_{c=0}^C \prod_{r=0}^R \sum_{k_0=0}^K \left\{ \prod_{c'=0}^C \prod_{k_2=0}^K \sum_{k_1=0}^K A[c', k_1] B[k_1, k_2] \right\} [c, k_0] C[k_0, r] \quad (b)
\end{aligned}$$

Traversal notation    Summation notation    Scope

Figure 4: A tensor algebra expression example for two matrix multiplications  $A \times B \times C$ . The red box highlights a *scope* that instantiates the intermediate result of  $A \times B$ .

sion of the output tensor, where the iterating space is the range of the dimension. The order of the traversal notations indicates the layout of the output tensor. For example, in Figure 4,  $\prod_{c=0}^C$  followed by  $\prod_{r=0}^R$  indicates that the expression’s output is a two-dimensional tensor with a shape  $C \times R$ .

A *summation notation*, denoted as  $\sum_{x=x_0}^{x_1}$ , computes the summation iterating over dimension  $x$  with  $\{x_0, x_0 + 1, \dots, x_1 - 1\}$ , which is hereinafter represented by a range  $[x_0, x_1]$  for brevity. Note that an EINNET expression under different orders of summation notations are considered the same but corresponds to different *schedules* of an expression. Therefore, it is excluded from the expression search space.

Tensors are indexed by an *arithmetic combination* of multiple iterators, including *add*(+), *sub*(-), *mul*(\*), *div*(/) and *mod*(%). For simplicity, we may merge multiple iterators into an iterator vector, whose iterating space can be denoted by an integer set or omitted in the expression. For example,  $\prod_{c=0}^C \prod_{r=0}^R$  can be represented as  $\prod_{cr}$  or  $\prod_{\vec{x}}$ , where  $\vec{x} = (c, r)$  is the iterator vector, and  $\mathbb{X} = \mathbb{C} \times \mathbb{R}$  is the iterating space.

**Scope.** For a tensor program with multiple operators (e.g., two consecutive matrix multiplications  $A \times B \times C$ ), a common optimization is to instantiate and reuse intermediate results (e.g., caching the output of  $A \times B$ ), which avoids repetitive computation for these results. EINNET introduces *scopes* to represent the instantiation of intermediate results to reuse them later. Formally, a tensor algebra expression is a *scope*, denoted by a surrounding  $\{\}$ , if the output of the expression is instantiated into a tensor, which allows subsequent computation to refer to this tensor and therefore avoids repeated computation. In Figure 4(b), the expression corresponding to  $A \times B$  is a scope, allowing subsequent computation to directly refer to the output of this expression. Many of EINNET’s derivation rules are based on transformations between scopes, including generating new scopes from existing ones, transforming a scope to another form, and merging multiple scopes into one (§4). Transformations between scopes are essential to EINNET’s optimizations.

**Padding.** Some computations access an input outside of its region, which we call paddings. E.g., a  $3 \times 3$  convolution may have paddings. Paddings are set to 0 if not specified.

**General format.** We represent a one-scope expression as:

Table 1: Derivation rules for tensor algebra expressions.

Rules	Descriptions
Intra-expression derivation §4.1	
Summation splitting	Split summation from one scope into two
Variable substitution	Replace traversal iterators with new ones
Traversal merging	Merge two scopes by merging traversals
Boundary relaxing	Relax the range of iterators
Boundary tightening	Tighten the range of iterators
Inter-expression derivation §4.2	
Expression splitting	Split an expression into independent ones
Expression merging	Merge multiple independent expressions
Expression fusion	Fuse multiple dependent expressions
Expression instantiation §5	
Operator matching	Match a scope with predefined operators
eOperator generation	Generate an eOperator for a scope

$$\prod_{\vec{x}} \sum_{\vec{y}} f(\mathbf{T}[\tau(\vec{x}, \vec{y})]) \quad (1)$$

where  $\mathbf{T} = \{T_0, T_1, \dots\}$  is a list of input tensors,  $\tau(\vec{x}, \vec{y})$  is the indexing function that computes element indexes for tensors in  $\mathbf{T}$  using iterators  $\vec{x}$  and  $\vec{y}$ , and  $f$  is the computation taking on the indexed elements of  $\mathbf{T}$ .

## 4 Derivation Rules

To discover highly-optimized expressions for an input tensor program, EINNET uses *derivation rules* to apply transformations on an input expression. Table 1 summarizes the derivation rules used by EINNET. Note that the *mathematical equivalence* of derivation rules guarantees the equivalence of derived expressions discovered by EINNET.

Different from schedule primitives of kernel generators that are designed to discover optimized schedules of a given expression on specific hardware, EINNET’s derivation rules focus on transform the computation semantics of tensor expressions, such as reorganizing computation into efficient operators.

### 4.1 Intra-Expression Derivation

Intra-expression derivation rules transform an expression into other functionally equivalent forms, which is essential for constructing a comprehensive search space of expressions for a tensor program. Figure 5 shows the optimization details in Figure 3(b). It splits the expression of `Conv3x3` into two parts, derives one part toward a predefined operator `Matmul`, and then converts the other part to an eOperator. We now describe these intra-expression derivation rules.

**Summation splitting** divides a summation notation  $\sum_{\vec{s}}$  into two separate summations  $\sum_{\vec{s}_1}$  and  $\sum_{\vec{s}_2}$  and instantiates the result of the inner summation by converting it to a scope:

Figure 5: The derivation process of the example in Figure 3(b), which transforms Conv with Matmul and eOperators

$$\mathbf{L}_{\vec{x} \vec{s}_1 \vec{s}_2} \sum f(\mathbf{T}[\tau(\vec{x}, \vec{s}_1, \vec{s}_2)]) \Rightarrow \mathbf{L}_{\vec{x} \vec{s}_1} \left\{ \mathbf{L}_{\vec{x}\vec{s}_1 \vec{s}_2} \sum f(\mathbf{T}[\tau(\vec{x}, \vec{s}_1, \vec{s}_2)]) \right\} [\vec{x}, \vec{s}_1]$$

where  $\tau$  is a mapping from  $(\vec{x}, \vec{s}_1, \vec{s}_2)$  to an input position. EINNETH divides the iterators of a summation into two disjoint groups,  $\vec{s}_1$  and  $\vec{s}_2$ , which splits the summation into two nested scopes  $\mathcal{S}_1$  and  $\mathcal{S}_2$ , where  $\mathcal{S}_1$  is the highlighted part in the above expression and  $\mathcal{S}_2 = \mathbf{L}_{\vec{x}} \sum_{\vec{s}_1} \mathcal{S}_1[\vec{x}, \vec{s}_1]$ . Note that in summation splitting, EINNETH converts the result of the inner summation into a scope, whose output is reused by the outer summation.

To transform a  $3 \times 3$  convolution to a batch of nine matrix multiplications, as shown in Figure 5, EINNETH first transforms the initial expression  $\mathcal{E}_1$  to  $\mathcal{E}_2$  by splitting the summation  $\sum_{crs}$  into two summations  $\sum_{rs}$  and  $\sum_c$ , and instantiating the output of the inner summation (i.e.,  $\{\mathbf{L}_{rshwf} \sum_c A[h+r, w+s, c]K[r, s, f, c]\}$ ). The inner scope only sums along the  $c$  dimension; as a result, an intermediate five-dimensional tensor is instantiated since the summation along the  $r$  and  $s$  dimensions is not performed but converted to traversal notations. The outer scope computes the remaining summation over the  $r$  and  $s$  dimensions, which produces a three-dimensional tensor. Figure 5 (a) and (b) show the change in computation graph.

**Variable substitution** substitutes a set of traversal iterators  $\mathbf{L}_{\vec{x}}$  with a new set of iterators  $\mathbf{L}_{\vec{y}}$  by applying a *bijective* function  $\Phi$  (i.e.,  $\vec{y} = \Phi(\vec{x})$ ). This transformation allows the expression to be computed using a different set of traversal iterators. In particular, for an expression  $\mathbf{L}_{\vec{x}} \sum f(\mathbf{T}[\tau(\vec{x})])$ , variable substitution introduces an intermediate scope that computes  $\mathbf{L}_{\vec{y}} \sum f(\mathbf{T}[\tau(\Phi^{-1}(\vec{y}))])$ , where  $\Phi$  is a bijective function that maps the iterating space  $\mathbb{X}$  to  $\Phi(\mathbb{X})$ , and  $\Phi^{-1}$  is the reverse function of  $\Phi$ :

$$\mathbf{L}_{\vec{x}} \sum f(\mathbf{T}[\tau(\vec{x})]) \Rightarrow \mathbf{L}_{\vec{x}} \left\{ \mathbf{L}_{\vec{y}} \sum f(\mathbf{T}[\tau(\Phi^{-1}(\vec{y}))]) \right\} [\Phi(\vec{x})].$$

A variable substitution constructs an intermediate scope with new traversal iterators. To preserve functional equivalence, the original iterator  $\vec{x}$  is used to construct the final result using the output of the intermediate scope.

Although numerous possible variable substitutions exist for an expression, EINNETH infers legal ones by analyzing indexing functions in expressions and checking whether they can form bijections. In Figure 5, EINNETH applies a variable substitution to transform the expression from  $\mathcal{E}_2$  to  $\mathcal{E}_3$  using a bijective function  $\Phi$  that maps  $(r, s, f, h+r, w+s)$  to  $(r, s, f, t_1, t_2)$ . Specifically,  $h+r$  and  $w+s$  are substituted with  $t_1$  and  $t_2$  in  $\mathcal{E}_3$ . To automatically identify promising variable substitutions among all alternatives, §6.1 introduces expression distance, a novel technique for efficiently exploring the search space.

**Traversal merging** combines the traversal notations in two separate scopes into one scope using an indexing function  $\Phi$ :

$$\mathbf{L}_{\vec{x}} \sum_{\vec{y}} \sum_{\vec{z}} \{ \mathbf{L} f(\mathbf{T}[\tau(\vec{z})]) \} [\Phi(\vec{x}, \vec{y})] \Rightarrow \mathbf{L}_{\vec{x}} \sum_{\vec{y}} f(\mathbf{T}[\tau(\Phi(\vec{x}, \vec{y}))])$$

where indexing function  $\Phi$  maps the outer scope iterators  $\vec{x}, \vec{y}$  to the inner scope iterators  $\vec{z}$  and satisfies  $\Phi(\mathbb{X} \times \mathbb{Y}) \subseteq \mathbb{Z}$ .

In the example of Figure 5, EINNETH applies traversal merging to transform  $\mathcal{E}_4$  to  $\mathcal{E}_5$ . For this transformation, the outer traversal and summation notations and the inner traversal notation both include five iterators (i.e.,  $\vec{x} = (h, w, f)$ ,  $\vec{y} = (r, s)$ , and  $\vec{z} = (r, s, h, w, f)$ ). Traversal merging is applied with an identity mapping function  $\Phi$  and an indexing function  $\tau(r, s, h, w, f) = (r, s, f, h+r, w+s)$ . Traversal merging removes a scope and preserves the same computation graph.

**Boundary relaxing and tightening.** Boundary tightening inspects whether the computation for some output elements can be avoided if these elements are constants for arbitrary

Figure 6: Conv5x5 to Conv3x3 transformation

inputs. EINNET executes constant propagation on expressions to deal with constant numbers in expressions and paddings in tensors. If an output region has constant values, EINNET converts it into an attribute of tensors to avoid unnecessary computation. In contrast, boundary relaxing enlarges tensors by adding extra paddings and redundant computations to explore more optimizations. Figure 6 shows the optimization that pads a Conv5x5 to a Conv6x6 and then converts it to a Conv3x3 with quadrupled output channels. The following formula shows how relaxing and tightening are performed:

$$\int_{\mathbb{X}} f(\mathbf{T}[\tau(\vec{x})]) \iff \int_{\mathbb{X}'} f(\mathbf{T}[\tau(\vec{x})]),$$

where  $\mathbb{X} \subset \mathbb{X}'$ , and  $\mathbf{T}$  has a constant value in  $\mathbb{X}' \setminus \mathbb{X}$ .

To limit the number of possible candidate parameters for this rule, EINNET relaxes and tightens boundaries to a common constant. In the running example in Figure 5, the formula in  $\mathcal{E}_4$  performs boundary relaxing on  $t_1$  and  $t_2$ , transforming their ranges from  $[r, H+r)$  and  $[s, W+s)$  to  $[-1, H+1)$  and  $[-1, W+1)$ , respectively, as the ranges of  $r$  and  $s$  are  $[-1, 1]$  for a  $3 \times 3$  convolution kernel. After boundary relaxing, the computation graph is transformed from Figure 5 (b) to (c). If multiple plans exist, the most strict one is selected to prevent extra redundant computing. Meanwhile, EINNET is still able to find the transformations introducing more redundancy by applying the rule multiple times.

EINNET performs boundary tightening to transform  $\mathcal{E}_5$  into  $\mathcal{E}_6$ . In  $\mathcal{E}_5$ , as the computation performed on  $t_1 = -1$ ,  $t_1 = H$ ,  $t_2 = -1$  and  $t_2 = W$  falls in the paddings of tensor  $A$ , the computation result is zero as well. Hence, the ranges of  $t_1$  and  $t_2$  are tightened from  $[-1, H+1)$  and  $[-1, W+1)$  to  $[0, H)$  and  $[0, W)$ , respectively. After boundary tightening, the computation graph is transformed from Figure 5 (c) to (d).

**Derivation search space.** The derivation rules allow EINNET to explore a large search space of expressions. Figure 7 illustrates the derivation search space of a  $3 \times 3$  convolution. By applying different derivation rules, the initial expression is derived into various equivalent expressions, shown as the computation graphs in Figure 7. The motivating example shown in Figure 5 is identified by the derivation path

(a)  $\rightarrow$  (b)  $\rightarrow$  (c)  $\rightarrow$  (d)  $\rightarrow$  (e). The figure also shows many other expressions discovered by EINNET: By deriving the expression in (d) to Conv1x1 instead of Matmul, EINNET discovers a new expression in (f). By merging summation iterators, expression (i) adopts an eOperator to concatenate multiple inputs with offsets for the following Matmul, which represents the conventional Im2col optimization [36]. Expression (k) shows a group convolution is equivalent to the original one by duplicating its input. Expressions (n) and (p) show two additional candidate expressions, both of which decompose the  $3 \times 3$  convolution into smaller convolutions while preserving output using derived eOperators.

## 4.2 Inter-Expression Derivation

We now introduce the inter-expression derivations rule in EINNET for splitting, merging, and fusing expressions.

**Expression splitting** divides an expression into two *independent* ones by partitioning the original expression's traversal space  $\mathbb{X}$  into two subspaces  $\mathbb{X}_1$  and  $\mathbb{X}_2$ , where  $\mathbb{X} \subseteq \mathbb{X}_1 \cup \mathbb{X}_2$ :

$$\int_{\mathbb{X}} f(\mathbf{T}[\tau(\vec{x})]) \implies \int_{\mathbb{X}_1} f(\mathbf{T}[\tau(\vec{x})]) \sim \int_{\mathbb{X}_2} f(\mathbf{T}[\tau(\vec{x})])$$

where  $\sim$  denotes the independence of the two expressions.

**Expression merging** is the reverse of expression splitting. It merges two *independent* expressions with the same computation by merging their traversal spaces  $\mathbb{X}_1 \cup \mathbb{X}_2 \subseteq \mathbb{X}$ :

$$\int_{\mathbb{X}_1} f(\mathbf{T}[\tau(\vec{x})]) \sim \int_{\mathbb{X}_2} f(\mathbf{T}[\tau(\vec{x})]) \implies \int_{\mathbb{X}} f(\mathbf{T}[\tau(\vec{x})])$$

**Expression fusion** fuses multiple *dependent* expressions into one using the following rule:

$$\int_{\mathbb{Y}} g(\mathbf{T}'[\pi(\vec{y})]) \circ \int_{\mathbb{X}} f(\mathbf{T}[\tau(\vec{x})]) \implies \int_{\mathbb{Y}} g(\{\int_{\mathbb{X}} f(\mathbf{T}[\tau(\vec{x})])\}[\pi(\vec{y})])$$

where  $\mathbf{T}'$  is equal to the computation result of the highlighted part in the above expression, and  $\mathcal{E}_1 \circ \mathcal{E}_2$  denotes that the result of expression  $\mathcal{E}_2$  is fed as inputs to expression  $\mathcal{E}_1$ .

Figure 3(a) shows a sequence of derivations involving inter-expression derivation. EINNET first applies intra-expression derivation rules to transform Conv3x3 and Conv1x1 to two Matmuls and an eOperator. Since the two Matmuls share the same input and computation pattern, EINNET is able to apply the expression merging rule upon them. As shown in the dashed box, EINNET transposes and concatenates the two weight tensors as the input for Matmul. The outputs of Matmul are split to get two equivalent outputs. Furthermore, EINNET applies the expression fusion rule to perform vertical operator fusion, an optimization fusing a chain of operators into a single kernel to reduce data movement and kernel launch overhead. In the solid boxes in Figure 3(a), EINNET fuses memory-bound operators (e.g., OffsetReduce and Relu) into one eOperator by applying expression fusion.

Figure 7: Derivation procedure for a subgraph of a convolution. Data layout transformation operators and intermediate derivation steps are omitted for conciseness. The output channel dimension of convolution kernel is only shown in (j) and denoted by  $f$ .

## 5 Expression Instantiation

Although EINNET can treat all expressions as eOperators and use an off-the-shelf kernel generator (e.g., TVM in our implementation) to generate executable programs, doing so would result in suboptimal performance. This is because existing vendor-provided tensor libraries such as cuDNN [10] and cuBLAS [11] include a collection of highly optimized tensor algebra kernels that outperform their counterparts generated by tensor compilers. The performance and expressiveness trade-off between hand-tuned and auto-generated kernels introduces both challenges and opportunities: we should opportunistically lower some expressions to vendor-provided kernels to realize their performance advantages and use kernel generators to generate executable programs for remaining expressions. We refer to this task as *expression instantiation*.

EINNET considers two derivation rules for expression instantiation: (1) *operator matching* allows EINNET to opportunistically use existing highly optimized kernels (e.g., cuDNN [10] and cuBLAS [11]) to achieve high performance, and (2) *eOperator generation* enables flexible kernel generation for an arbitrary eOperator. After applying these rules, the instantiated scopes are replaced with tensors in the original expression and are separated from the following derivation.

To lower expressions to kernels, EINNET uses a strategy that maps compute-intensive expressions to predefined operators and employs a kernel generator for memory-bound expressions. This strategy allows EINNET to benefit from existing vendor libraries and maintain low compilation time, since memory-bound expressions usually involve a small schedule space in existing code generation frameworks [7]. While a more aggressive utilization of kernel generators has the potential to outperform the opportunistic strategy, it introduces significant kernel tuning overhead for millions of

Figure 8: Match an expression to BatchMatmul. Expression (a) and (b) show iterator groups and Expression (c) and (d) show matching attributes with flattened expressions.

possible expressions during the program optimization. This is due to the difficulty in accurately estimating the performance of a kernel without actually tuning and profiling it.

To determine whether an expression is compute-intensive or memory-bound, EINNET analyzes its arithmetic intensity, calculated as the ratio between its FLOPs and tensor sizes. Expressions with arithmetic intensity lower than a threshold (4 in our evaluation) are considered memory-bound eOperators. EINNET decides whether to perform operator matching or eOperator generation for this expression based on this metric. The following introduces these two instantiation rules.

### 5.1 Operator Matching

Mapping an expression to a predefined operator is challenging since an operator can be represented in various expressions. For example, while expressions in Figure 8(a-b) have distinct forms, they can both be instantiated as batched matrix multiplication kernels in cuBLAS as it supports tensors with flexible data layouts.

Table 2: Iterator mapping table. Iterators are categorized by where they appear in expressions. For each iterator group, Y and N indicate whether the iterators appear in the index of corresponding tensors.

Operators	Tensor algebra expressions	Iterator groups ( $\mathbf{I}_0/\mathbf{I}_1/\mathbf{O}_0$ )			
		Y/Y/Y	Y/N/Y	N/Y/Y	Y/Y/N
Add	$\mathbf{O}_0[m, n] = \mathbf{L}_{mn} \mathbf{I}_0[m, n] + \mathbf{I}_1[m, n]$	$m, n$			
BatchMatmul	$\mathbf{O}_0[b, m, n] = \mathbf{L}_{bmn} \sum_k \mathbf{I}_0[b, m, k] \mathbf{I}_1[b, k, n]$	$b$	$m$	$n$	$k$
Conv	$\mathbf{O}_0[n, h, w, f] = \mathbf{L}_{nhwf} \sum_{crs} \mathbf{I}_0[n, h+r, w+s, c] \mathbf{I}_1[r, s, f, c]$		$n, h, w$	$f$	$c, r, s$
G2BMM	$\mathbf{O}_0[b, m, w] = \mathbf{L}_{bmw} \sum_k \mathbf{I}_0[b, m, k] \mathbf{I}_1[b, k, m+D*(w-W)]$	$b, m$		$w$	$k$

EINNET uses an *iterator mapping table* to determine if a given expression can be mapped to a predefined operator, where iterators of each operator are grouped based on whether the iterator appears in the operator’s input/output tensors. Table 2 shows the iterator mapping table for several operators with two input and one output tensors, including element-wise operators, batched matrix multiplication, convolution, and G2BMM [23] (general to band matrix multiplication). Each row in the table corresponds to an operator, while each column shows an *iterator group*. The iterator mapping table also records the coefficients of iterators in the index of each tensor for operator matching. It can be extended to support operators with an arbitrary number of inputs and outputs.

The iterator mapping table allows EINNET to determine if an expression can be mapped to an operator as follows:

- Match tensors.** To map a given expression to an operator, EINNET enumerates all possible one-to-one mappings between the expression and operator’s input/output tensors. For example, to map the expression in Figure 8 (b) to BMM (i.e., expression in Figure 8 (a)), there exist two possible mappings,  $\{A \rightarrow X, B \rightarrow Y\}$  and  $\{A \rightarrow Y, B \rightarrow X\}$ .
- Match iterators.** For each tensor mapping, EINNET further enumerates all possible ways to match iterators between the expression and operator using the iterator mapping table described above. For example, assuming a tensor mapping  $\{A \rightarrow X, B \rightarrow Y\}$  in Figure 8, iterators  $\{u, v, x, w\}$  in (b) are mapped to iterators  $\{b, m, k, n\}$  in (a) based on the iterator mapping table (iterators in the same group are marked in the same color). When there are multiple iterators in the same group, EINNET enumerates all possible mappings between these iterators.
- Match operator attributes.** Many predefined operators contain attributes to specify computation. E.g., modern BLAS libraries use *lda* and *ldb* to control the data layouts for input tensors in matrix multiplication. To match these attributes, EINNET flattens the input and output tensors (i.e., reshapes them into one-dimensional tensors) to hide the complexity of tensor shapes. EINNET then matches the operator attributes by examining the variable coefficients of the flattened tensors. Figure 8(c-d) show how EINNET determines the attributes  $l_{B0}$  and  $l_{B1}$  for a BMM operator. It flattens the tensor B in both expressions and compares their coefficients:  $l_{B0} = l_{Y0} + l_{Y1}$ ,  $l_{B1} = l_{Y2}$ , where  $l_{Yn}$  is the stride of  $n$ -dimension of tensor  $Y$ . The coefficient of  $w$  in Expression (d) is also checked to be equal to that of  $n$

```
T1 = tvn.te.compute((H, W, F), lambda h, w, f:
    tvn.te.sum(T1[r, s, h+r, w+s, f], axis=[r, s]))
```

Figure 9: Lowering  $\mathcal{E}_7$  in Figure 5 to TVM.

in Expression (c), as they are a pair of matched iterators.

## 5.2 eOperator Generation

For expressions that cannot be mapped to vendor-provided predefined operators, EINNET converts them into eOperators. Since an eOperator precisely defines its computation, EINNET can directly feed it to an off-the-shelf kernel generation framework (e.g., TVM [7]). For example, for expression  $\mathcal{E}_7$  in Figure 5, which corresponds to `OffsetReduce` in the transformed computation graph, EINNET feeds it to TVM by converting its iterator space into a tensor and the computation expression into a lambda function. Figure 9 shows the TVM code generated by EINNET for expression  $\mathcal{E}_7$ , which can be an input program to TVM to generate an executable kernel.

## 6 Program Optimizer

This section describes EINNET’s *program optimizer*, which uses the expression derivation and instantiation techniques described in §4 and §5 to optimize input tensor programs. These derivation rules create a large and complex search space of programs functionally equivalent to the input. EINNET uses a *distance-guided* search algorithm to explore the space (§6.1) and develops a *fingerprinting* technique to prune redundancy (§6.2). Finally, §6.3 describes how EINNET orchestrates these techniques to perform end-to-end optimizations.

### 6.1 Distance-Guided Search

To explore the search space created by EINNET’s derivations, a purely randomized search strategy can only explore either a limited set of paths or small searching depths, leading to suboptimal performance. To address this challenge, EINNET develops a two-stage *distance-guided* search algorithm to apply derivations. It includes an *explorative derivation* stage and a *converging derivation* stage, as shown in Figure 10.

**Explorative derivation.** During explorative derivation, EINNET iteratively applies *all* derivation rules to the current expression. A hyperparameter *MaxDepth* determines

Figure 10: Distance-guided search

the maximum number of derivation rules EINN<sub>ET</sub> applies during explorative derivation. As described in §5, EINN<sub>ET</sub> opportunistically uses vendor-provided kernel libraries to maximize performance. Thus, EINN<sub>ET</sub> leverages converging derivation to quickly derive an expression toward a target operator (e.g., operators in cuDNN and cuBLAS). EINN<sub>ET</sub> automatically generates necessary eOperators to bridge the gap between the current expression and target operator.

**Converging derivation.** During converging derivation, EINN<sub>ET</sub> first selects a target operator and uses a novel metric, *expression distance*, to guide the applications of derivation rules in this stage. Expression distance measures the difference between a given expression  $\mathcal{E}_1$  and the canonical expression of a given operator  $\mathcal{E}_2$ . To calculate the distance between  $\mathcal{E}_1$  and  $\mathcal{E}_2$ , EINN<sub>ET</sub> first matches all iterators in  $\mathcal{E}_1$  and  $\mathcal{E}_2$  using the iterator mapping table (see §5.1) and counts the total number of mismatched iterators as their distance.

Specifically, each iterator mismatch between the current expression and target operator indicates that the two expressions have a different number of iterators in an iterator group (see Table 2). EINN<sub>ET</sub> applies derivation rules to fix mismatches, such as variable substitution rules to merge/split iterators, resulting in reduced expression distances. For example, to derive the expression in the inner scope of  $\mathcal{E}_6$  in Figure 5 to a Matmul, EINN<sub>ET</sub> compares their iterators (Table 2) and obtains the following matches:  $t_1, t_2 \rightarrow m; r, s, f \rightarrow n; c \rightarrow k$ . To fix mismatches, EINN<sub>ET</sub> applies variable substitutions to merge iterators  $t_1$  and  $t_2$  into  $m$  and merge  $r, s, f$  into  $n$ .

After all iterators are matched, EINN<sub>ET</sub> infers the shape of each input/output tensor according to the target operator and constructs new tensors from existing ones by adding eOperators. For example, the new input tensor  $\mathbf{A}'$  and weight tensor  $\mathbf{K}'$  for Matmul are constructed by the following expressions:

$$\mathbf{A}'[m, k] = \mathbf{A}'[t_1 \times W + t_2, c] = \mathbf{A}[t_1, t_2, c] \quad (2)$$

$$\mathbf{K}'[k, n] = \mathbf{K}'[c, r \times S \times F + s \times F + f] = \mathbf{K}[r, s, f, c], \quad (3)$$

where the mapping functions are  $(m, k) = \Phi_A(t_1, t_2, c) = (t_1 \times W + t_2, c)$  and  $(k, n) = \Phi_K(r, s, f, c) = (c, r \times S \times F + s \times F + f)$ , and  $W, S,$  and  $F$  are the range of the iterators  $w, s$  and  $f$ . EINN<sub>ET</sub> automatically generates Expression (2) and (3) to fix the mismatch and reduce the expression distance.

During converging derivation, EINN<sub>ET</sub> only considers derivations that reduce the expression distance of the current expression and target operator, allowing EINN<sub>ET</sub> to prune

most derivations and quickly converge to the target operator. By enumerating operators in the iterator mapping table as the target operator, EINN<sub>ET</sub> finds transformations involving different operators.

**Delayed code generation.** To accelerate the search, EINN<sub>ET</sub> estimates the performance of derived programs to avoid frequent code generation for eOperators. Specifically, the execution time of a predefined operator is measured by profiling its kernel on hardware. Meanwhile, the run time of an eOperator is estimated based on its input/output sizes and hardware memory bandwidth. We observe that this estimation is accurate since eOperators are memory-bound and usually account for a small part of the total execution time.

## 6.2 Redundancy Pruning

Applying different sequences of derivations may result in the same expression. For example, splitting an iterator into two and then merging them results in the original one. To prune redundancy, EINN<sub>ET</sub> uses a *fingerprint* technique to detect duplicate expressions. A *fingerprint* is a hash of an expression and can eliminate the following sources of redundancy:

- **Summation reordering:** summations can be reordered, e.g.,  $\sum_{\vec{x}} \sum_{\vec{y}} f(\vec{x}, \vec{y})$  is equivalent with  $\sum_{\vec{y}} \sum_{\vec{x}} f(\vec{x}, \vec{y})$ . Note that traversal reordering does not imply equivalence since it involves layout transformations.
- **Operand reordering:** operands of commutative binary operations can be reordered, e.g.,  $L_{\vec{x}}(\mathbf{T}_1[\vec{x}] + \mathbf{T}_2[\vec{x}])$  is equal to  $L_{\vec{x}}(\mathbf{T}_2[\vec{x}] + \mathbf{T}_1[\vec{x}])$ . Operand reordering should be applied for both iterator computation and tensor computation.
- **Iterator renaming:** iterators should be distinguished by their iterator space instead of names, e.g.,  $L_{x=0}^N L_{y=0}^M f(x, y)$  and  $L_{y=0}^N L_{z=0}^M f(y, z)$  are equivalent, and  $(x, y)$  in the former one should be mapped to  $(y, z)$  in the latter one.
- **Tensor renaming:** tensors introduced by different scopes may have the same value.

To eliminate the above sources of redundancy, EINN<sub>ET</sub> adopts the following methods to calculate fingerprints. For a traversal iterator, EINN<sub>ET</sub> uses its iterator space and its order relative to all other traversal notations in the current scope as its fingerprint. Since order is considered, fingerprint can differentiate traversal iterators with the same iterator spaces but in different locations of the traversal notations. For a summation iterator, EINN<sub>ET</sub> only uses its iterator space as its fingerprint. Thus expressions under summation reordering have the same fingerprint. To account for operand reordering, EINN<sub>ET</sub> uses the operation type and an *order-independent* hash for commutative operations (e.g., addition) and an *order-dependent* hash for other operations. The fingerprint of a tensor depends on its source. For an input tensor, EINN<sub>ET</sub> calculates its fingerprint by hashing its name. For an intermediate tensor generated by a scope, its fingerprint is identical to that of the expression that produces the tensor.

### 6.3 End-to-End Workflow

Algorithm 1 shows EINN<sub>ET</sub>'s workflow for optimizing an input tensor program in an end-to-end fashion. For an input program, EINN<sub>ET</sub> first splits it into multiple subprograms using non-linear activation operators as the splitting points. This is because activation operators often do not provide further optimization opportunities other than fusion, as discovered by prior work [38]. For each subprogram, EINN<sub>ET</sub> translates it into expressions using the canonical expression of each operator. Since a subprogram may include multiple operators and thus multiple expressions, EINN<sub>ET</sub> applies inter-expression derivation rules (Line 11) and feeds each expression to the distance-guided search (§6.1) for performing *intra-expression* derivations (Line 12). Instead of integrating intra- and inter-expression optimizations in a unified search space and performing them jointly, the separate search prioritizes the transformations that can map expressions into operators. Thus, EINN<sub>ET</sub> is able to find promising transformations quickly and prune unnecessary search states according to the execution time of transformed results.

Finally, EINN<sub>ET</sub> selects the best-discovered expression of each subprogram, performs post-optimization, and generates an optimized tensor program. Figure 11 shows two types of post-optimization: eOperator fusion and compile-time expression evaluation. EINN<sub>ET</sub> generates eOperators to facilitate optimizing transformations when optimizing a subprogram. During post-optimization, consecutive eOperators are fused into a single eOperator by applying inter-expression

derivations. The dashed boxes in Figure 11(b) and (c) show such cases. EINN<sub>ET</sub> also detects compile-time computable expressions to reduce runtime overhead. For example, the data layout transformation  $E_2$  in Figure 11 can be processed during post-optimization.

## 7 Evaluation

### 7.1 Experimental Setup

**Implementation of EINN<sub>ET</sub>.** EINN<sub>ET</sub> is built with over 23K lines of C++ and Python code. We realize the tensor expression derivation system from scratch and implement an execution runtime for tensor programs. Users can both define tensor programs in EINN<sub>ET</sub> directly and load existing ones in the ONNX format [29]. To support an operator in derivation, EINN<sub>ET</sub> requires its tensor expression and operator attribute constraints to automatically convert it between expressions and operators. We set the default maximum search depth of explorative derivation to 7, which is an empirical configuration satisfying both optimization quality and search time.

**Platform.** We evaluate EINN<sub>ET</sub> on a server with dual Intel Xeon E5-2680 v4 CPUs, NVIDIA A100 40GB and V100 32GB PCIe GPUs. All experiments use CUDA 11.0.2, cuBLAS 11.1.0, and cuDNN 8.0.3.

**Workloads.** We evaluate EINN<sub>ET</sub> on seven DNN models, spanning various fields and covering both classic and emerging DNNs. InfoGAN [9] is a generative adversarial network learning disentangled representations from objects. DCGAN [32] leverages deep convolution structures to get hierarchical representations. FSRCNN [13] is used for fast image super-resolution. GCN [30] is an image semantic segmentation model. ResNet-18 [19] is a famous image classification network. CSRNet [25] adopts dilated convolution for congested scene analysis. LongFormer [6] is an improved Transformer model dealing with long-sequence language processing. We adopt typical input shapes based on the papers and implementations of models to keep the evaluation meaningful in real scenarios.

### 7.2 End-to-End Performance

We first compare the end-to-end inference performance of EINN<sub>ET</sub> against today's DNN frameworks, including TensorFlow v2.4 [4], TensorFlow XLA [2], Nimble [22], TVM v0.10 with Ansor [7], TensorRT v8.2 [35], and PET v0.1 [38]. All frameworks use the same version of cuBLAS and cuDNN as their backend and the same data type FP32 in computation for a fair comparison. For the new attention operator in Longformer, we provide an auto-tuned kernel for TVM, TensorRT, PET, and EINN<sub>ET</sub>, and implement it by

Figure 12: End-to-end performance comparison with other systems on an A100 and a V100 GPU with batch sizes of 1 and 16. OOM means out of memory. Bars over 4× are truncated, and their relative execution times to EINNET are marked on the bars. The numbers above EINNET’s bars show EINNET’s speedups over the best baseline.

Figure 13: End-to-end performance comparison with TensorRT on an A100 with TF32 and batch sizes of 1. The numbers above EINNET’s bars show EINNET’s speedups over the best baseline.

einsum in other frameworks. Figure 12 shows the results on NVIDIA A100 and V100 GPUs under batch sizes 1 and 16.

EINNET outperforms the best existing baseline by up to 2.72× on A100 and 2.68× on V100. For both CNNs (e.g., GCN) and language models (e.g., Longformer), EINNET is able to improve their performance by more than 2×. Among the seven models, ResNet-18 has been heavily optimized by existing tensor program frameworks and optimizers; however, EINNET still outperforms existing optimizers by 1.2× on V100, by applying the novel transformations shown in Figure 3. For CSRNet, a typical optimization case of PET, EINNET discovers similar transformations by derivations and eliminates extra introduced transposes, indicating that EINNET’s derivation rules can perform PET’s optimizations and uncover additional improvements.

Figure 13 shows the speedup with the computation data type of TF32 and Tensor Cores on A100. To show the benefits provided by EINNET, we create a baseline EINNET-Base which executes models in EINNET with derivation optimizations disabled. As shown in Figure 13, while EINNET usually brings significant speedups over EINNET-Base and TensorRT, TensorRT can have better performance in models like ResNet-18. Though TensorRT is not open source, the profiling results

		Optimized	N/A	1.57	20.6	817

show that it leverages many efficient GPU kernels besides cuBLAS and cuDNN. This can be an important source of its high performance, which is beyond the current space of EINNET.

### 7.3 Optimization Analysis

This section analyzes the optimizations discovered by EINNET on these DNNs. To highlight transformations beyond the scope of existing tensor program optimizers, we focus on transformations involving eOperators.

**Transforming operator types.** EINNET is able to opportunistically substitute an inefficient operator with well-optimized operators of different types. In ResNet-18 and InfoGAN, the transformations from Conv and ConvTranspose to Matmul are profitable. Table 3 shows a detailed performance analysis. As shown in Figure 3(b), EINNET transforms a Conv3x3 to a Matmul and an eOperator (OffsetReduce), which significantly reduces GPU DRAM accesses from 56.7 MB to 10.5 MB and achieves a 2.7× speedup. As another

Figure 14: Optimization for Longformer Attention block.  $T_1$  and  $T_2$  are two reciprocal data layout transformations.

example, EINNET also derives a strided `ConvTranspose` to a `Matmul` and another eOperator that selectively aggregates the output of `Matmul` according to the derived expression. This transformation significantly reduces L2 access, a key contribution to performance optimization.

**Transforming operator attributes.** EINNET can also transform operator attributes by leveraging eOperators. Figure 6 shows such an optimization for convolution, which converts its kernel size from  $5 \times 5$  to  $3 \times 3$ , allowing EINNET to use more advanced convolution algorithms best suited for  $3 \times 3$  convolutions. To realize this transformation, an eOperator is added to split the output of `Conv3x3` across the channel dimension and reduce the intermediate results with corresponding offsets. Although padding the convolution kernel introduces additional computation, Table 3 shows it enables using the Winograd algorithm for convolution, which further reduces compute time and memory access.

**Transforming tensor layouts.** eOperators allow EINNET to accelerate DNN computation by optimizing tensor layouts. Figure 14 shows such a layout optimization for Longformer, which uses a dilated G2BMM (general to band matrix multiplication) to compute sparse attention. G2BMM has the same computation pattern as `Matmul` and only computes a subset of output. The blue boxes in Figure 14(a) show the output locations with a dilation of 2. EINNET discovers an optimizing layout transformation that reorders the odd and even rows or columns, converting the dilated G2BMM to a non-dilated one, as shown in Figure 14(b), which greatly reduces non-contiguous memory accesses at the cost of introducing two redundant elements (marked as red in the figure). As shown in Table 3, this transformation can reduce L2 cache access by 95.9% and execution time by 78.0%.

**Transforming graph structures.** For the Longformer case shown in Figure 14(d), four data layout transformations are

Figure 15: Optimization for the spatial separable convolutions in GCN.  $c$  and  $f$  are the numbers of input and output channels.

Figure 16: Operator performance before and after optimization (opt) on the math libraries and code generation framework Anso. The input settings are shown in Table 3.

introduced to accelerate dilated G2BMM. While they are not predefined operators, EINNET finds that the middle two are reciprocal through expression fusion and eliminates them since they do not affect the `Softmax` computation in between.

A more complex example is in GCN, which has a repeated structure of spatially separable convolutions (i.e., sequential `Conv1xKs` and `ConvKx1s`). As shown in Figure 15(b), EINNET first transforms convolutions to `Matmul`s and eOperators, and then merges the first two `Matmul`s into a single `Matmul`. While the two following `Matmul`s do not share common inputs, they have an identical computation pattern and can be merged into a `BatchMatmul` by applying the expression merging and operator matching rules. Note that the left part of Figure 15(c) is computed at compile-time by EINNET since it only involves weight tensors. These transformations optimize subgraph execution time by  $4.9\times$  on A100 with batch size of one.

## 7.4 Integration with Different Backends

Since EINNET searches expression space, it can cooperate with different backends, including math libraries and schedule-based code generation frameworks. To show the improvements of EINNET on these backends, we evaluate EINNET with cuBLAS/cuDNN, AutoTVM [7], and TVM auto-scheduler Anso [8]. The evaluation is carried out on the same transformations illustrated in §7.3.

Figure 16 shows EINNET can optimize tensor programs on different backends. For the `Conv3x3` in ResNet-18 and the `ConvTranspose` in InfoGAN, transforming them to `Matmul`s and eOperators has significant speedup over all three platforms. While the transformation from `Conv5x5` to `Conv3x3` is beneficial for cuDNN, it does not have perfor-

Figure 17: Speedup under different maximum search depths

performance improvement on AutoTVM and Ansoer even if efficient algorithms such as Winograd [24] are adopted. This result shows while many transformations are effective on different backends, customizing transformations for each backend is beneficial. For the G2BMM operator in Longformer, which is not a predefined operator in current math libraries, the transformation on Ansoer brings a speedup of  $4.54\times$  since less non-contiguous memory access happens.

## 7.5 Analysis of Automated Derivation

The search space of EINNET is determined by heuristic parameters, e.g., the maximum search depth for the distance-guided search algorithm (§6.1), which specifies the largest steps of derivation applied to an expression. A larger search depth enables more potential optimizations but introduces larger searching overhead. Figure 17 analyzes the speedup EINNET can achieve with different maximum search depths on InfoGAN and Longformer. On InfoGAN, EINNET has improvement when the searching step increases from 2 to 4, as new transformations are explored with a deeper search. While for Longformer, the major speedup comes from the transformation found in a 4-step derivation. In conclusion, the key takeaway is that EINNET can achieve most of the performance improvement at moderate depth.

To evaluate the proposed techniques for derivation, we evaluate the searching process on the four cases in Table 3 with and without converging derivation and expression fingerprint.

**Distance-guided derivation (§6.1)** provides a deterministic derivation direction to reduce search overhead. As shown in Figure 18(a), the search time grows exponentially with the maximum depth of explorative derivation (i.e., *MaxDepth* in Figure 10). EINNET adopts converging derivation to reduce the search depth of explorative derivation. Figure 18(b) shows the number of applied explorative derivations in these cases.

In the case of ConvTranspose, the explorative derivation requires a search with *MaxDepth* = 12 to discover the target expression. But with converging derivation, EINNET only requires a search with *MaxDepth* = 6, which means that matching a vendor-provided operator needs a six-step (12 – 6) search and converging derivation can reduce this unnecessary search. Thus, this optimization leads to a significant reduction of the search time by more than 99.0%.

**Expression fingerprint (§6.2)** prunes redundant searching states. Figure 19 shows the intermediate states and search time with and without the fingerprint mechanism. During

Figure 18: (a) Search time with different *MaxDepth*. (b) The number of explorative derivation steps with and without converging derivation.

Figure 19: Ablation study of expression fingerprint pruning

the derivation, fingerprint effectively prunes 98.0% of intermediate states by recognizing and eliminating duplicate expressions and reduces 98.2% of search time on average.

With the distance-guided derivation and expression fingerprint, EINNET finishes searching within two minutes for most subprograms and is on par with existing frameworks like TASO and PET. The search spends no more than two hours for most models, which depends on the number of operators contained in models. EINNET is able to be deployed in real production environment since the search cost is one-off for a model and brings persistent benefits.

## 8 Related Work

**Rule-based approaches** such as TensorFlow XLA [2], TensorRT [35], and Grappler [1], are widely used and perform optimizations like constant folding and layout optimization. While they can efficiently optimize computation graphs, it requires extensive expert efforts and only performs manually discovered optimizations. For operator fusion, DNNFusion [28] adopts operator-level mathematical-property-based graph rewrite rules, such as associative and commutative properties. However, such rewriting rules are mainly designed for element-wise operators and cannot be easily extended to arbitrary operators since many complex operators, such as convolution and matrix multiplication, do not follow associative and commutative properties. EINNET derives tensor programs at expression level to exploit general program transformations, including splitting, fusing, and reorganizing computation into operators and eOperators. This avoids manually summarizing rules for each operator.

**Superoptimization-based approaches.** TASO [20] and

PET [38] use superoptimization techniques to generate graph transformations for a given set of operators. TASO adopts formal verification techniques to assure the equivalence of transformations. PET further introduces partially-equivalent transformations and correction mechanism to find more optimizations. Compared with these frameworks, EINNET extends the search space from POR transformations to general expressions by tensor algebra expression derivation.

**Schedule-based approaches.** Halide [24] decouples a program into computation and schedule and performs schedule space transformations. This idea is widely adopted by code generation frameworks, including TVM [7], FlexTensor [42], and Ansor [40]. Orthogonal to schedule-based optimizers, EINNET focuses on high-level graph transformation space and designs the architecture-independent expression derivation rules to reorganize computation into efficient operators.

**Task-based approaches.** Task, an abstraction of computation and memory operation workload, is introduced into tensor programs recently to optimize their performance. Rammer [27] divides operators into fine-grained tasks and proposes a sub-operator-level task scheduling method to exploit both intra- and inter-operator parallelism. Hidet [12] leverages task mapping in kernel generation to explore more aggressive optimizations. EINNET is compatible with these optimizers by utilizing them as execution and kernel generator backend.

**Tensorization.** TensorIR [14], AMOS [41], and Glenside [34] aim to generate tensorized code on tensor accelerators. While computation mapping is stressed in their workflows, these works focus on generating performant native code leveraging special circuits, such as fixed-shape matrix multipliers Intel AMX and NVIDIA TensorCore. In contrast, EINNET adopts expression matching to match arbitrary linear tensor algebra expressions, which are more flexible and contain undetermined parameters in the pattern expressions.

## 9 Conclusion

We propose EINNET, a derivation-based tensor program optimizer, which extends the optimization space of tensor programs from predefined operator representable transformations to general expressions and can create new operators desired by transformations. EINNET can outperform state-of-the-art frameworks by up to  $2.72\times$  on NVIDIA GPUs.

## A Artifact Appendix

### Abstract

This artifact appendix helps the readers reproduce the main evaluation results of the paper: EINNET: Optimizing Tensor Programs with Derivation-Based Transformations.

### Scope

This artifact can be used for evaluating and reproducing the main results of the paper, including the model-level evaluation, operator-level evaluation, and the ablation studies and hyperparameter studies on search strategies.

### Contents

The following evaluation results are contained in the artifact:

**E1:** An end-to-end performance comparison between EinNet and other frameworks. (Figure 12)

**E2:** Performance studies on the cases in §7.3. (Table 3)

**E3:** Operator performance before and after optimization on the math libraries and code generation framework Anso. (Figure 15)

**E4:** Speedup under different maximum search depths. (Figure 16)

**E5:** Search time with different MaxDepth and the number of explorative derivation steps with and without converging derivation. (Figure 17)

**E6:** Ablation study of expression fingerprint pruning. (Figure 18)

### Hosting

The source code of this artifact can be found on GitHub: <https://github.com/zhengly123/OSDI23-EinNet-AE>, the main branch, with the commit ID 26a47d9.

### Requirements

#### Hardware dependencies

Dual Intel(R) Xeon(R) CPU E5-2680 v4 @ 2.40GHz, NVIDIA A100-PCI-40GB GPU, NVIDIA V100-PCIE-32GB

GPU.

#### Software dependencies

The artifact is evaluated on Ubuntu 22.04 LTS (Linux kernel 5.15.0-58). The artifact relies on CUDA 11.0.2 and cuDNN 8.0.3. The following frameworks are required as baselines:

1. TensorFlow 2.4
2. TensorRT 8.0
3. PET 1.0
4. Nimble with the commit ID bac6d10
5. TVM v0.10.0

#### Experiments workflow

The installation instruction and the following experiments are included in this artifact. All DNN benchmarks use synthetic input data in GPU device memory to remove the side effects of data transfers between CPU and GPU.

#### End-to-end performance (E1)

This experiment reproduces Figure 12 in the paper. Refer to OSDI23-EinNet-AE/0\_model/README.md to prepare the environment and data. The detailed commands for each baseline are provided in separate run.sh and readme files in subdirectories.

#### Performance studies on the cases in §7.3 (E2)

See README.md and run.sh in OSDI23-EinNet-AE/1\_op.

#### Operator performance (E3)

See README.md and run.sh in OSDI23-EinNet-AE/2\_kernel\_generator.

#### Speedup & Depth (E4)

See README.md and evaluate\_max\_depth.py in OSDI23-EinNet-AE/3\_search\_depth.

#### Search Time (E5)

See README.md and run.sh in OSDI23-EinNet-AE/4\_search\_time.

#### Ablation Study (E6)

See README.md and run.sh in OSDI23-EinNet-AE/5\_fingerprint.

# Hydro: Surrogate-based Hyperparameter Tuning Service in Datacenters

## Abstract

Hyperparameter tuning is an essential step in deep learning model development that provides better model performance at the cost of substantial resources. While existing systems can improve tuning efficiency, they still fail to handle large models with billions of parameters and efficiently leverage cluster resources. Motivated by these deficiencies, we introduce Hydro, a surrogate-based hyperparameter tuning service that optimizes tuning workloads in both the job-level and cluster-level granularities. Specifically, it consists of two key components: (1) *Hydro Tuner* automatically generates and optimizes surrogate models via scaling, parametrization and fusion; (2) *Hydro Coordinator* improves tuning efficiency and cluster-wide resource utilization by adaptively leveraging ephemeral and heterogeneous resources. Our comprehensive experiments on two tuning algorithms across six models show that Hydro Tuner can dramatically reduce tuning makespan by up to  $78.5\times$  compared with Ray Tune and no reduction in tuning quality. Hydro’s source code is publicly available at <https://github.com/S-Lab-System-Group/Hydro>.

## 1 Introduction

Over the years, we have witnessed the incredible performance and rapid popularity of Deep Learning (DL) across many domains, such as vision and speech. However, it is non-trivial to acquire a qualified DL model because its performance is highly sensitive to the *hyperparameters*, which control the training process and require to be set before training [71]. Poor hyperparameters result in training instability and inferior model quality. Conversely, well-tuned hyperparameters can significantly improve model performance. For instance, PyTorch [91] recently applies a new hyperparameter recipe on ResNet-50 [41] and achieves 80.9% ImageNet classification accuracy [18], which is 4.8% higher than the former version (76.1%). Besides, RoBERTa [75] also demonstrates the critical impact of hyperparameters on the performance of large language models. Accordingly, hyperparameter tuning becomes a common practice during DL model development.

Due to the high dimensionality of the search space, a hyperparameter tuning job typically contains a large group of *trials*, each with a unique configuration [125]. To accelerate the tuning process, tech companies and researchers build hyperparameter tuning systems as cloud services [1, 8, 39, 92]

or standalone frameworks [32, 71, 72, 82, 125, 127] (Table 1). However, we argue that state-of-the-art tuning systems are still expensive and inefficient in practice, as they suffer from several fundamental problems:

- **Unacceptable cost of tuning large models.** The extraordinary performance of large foundation models (e.g., BERT [30], GPT-3 [24]) attracts wide downstream applications [3, 4, 6]. Meanwhile, the hyperparameter tuning demand for these models increases rapidly. However, all of the existing tuning systems require training multiple trials using several times of resources, which is unaffordable for large models with billions of parameters. For example, training a SOTA language model PaLM [27] of Google takes over 6,000 TPU-v4 [59] for around 2 months. Performing a hyperparameter sweep on such model is intractable [23]. Consequently, hyperparameters of most large models are not well-tuned and can lead to subpar performance [75].
- **Inefficient hardware utilization.** Recent scheduling works [46, 114, 115, 124] report that GPUs are commonly underutilized in DL clusters due to massive training jobs involving mid- or small-scale models. Moreover, despite the growing trend of foundation models being employed in clusters, large-scale models often fail to fully utilize hardware resources due to the huge communication overhead and the presence of bubbles in the pipeline parallelism [106]. To improve resource utilization, some novel tuning systems incorporate features such as elastic training [32, 71, 82], GPU sharing [125], and inter-trial fusion [110]. However, these systems have certain limitations (§8) and often require substantial resources to explore trivial trials, which results in limited resources being contributed to the final model.
- **Agnostic to cluster-wide resources.** Hyperparameter tuning jobs are pervasive and occupy enormous resources in GPU clusters. As reported by Microsoft [50, 78], “approximately 90% of models require hyperparameter tuning, with each tuning job containing 75 trials in median.” However, existing tuning systems only manage trials over the requested resources and lack interaction with cluster schedulers. Meanwhile, DL schedulers [36, 40, 46, 87, 94, 114, 123] also overlook the distinct characteristic of gradually diminishing hardware demand inherent in hyperparameter tuning jobs [71]. Consequently, the cluster encounters imbalanced resource problem: the active tuning jobs consistently occupy static resources,

leaving some of them vacant, while the queued jobs are unable to request these idle resources from the scheduler. This leads to severe queuing delay, which is exacerbated when long-term large-scale model training jobs coexist and they occupy the majority of cluster resources.

To bridge these gaps, we design Hydro, a surrogate-based hyperparameter tuning service that optimizes tuning jobs in both the job-level and cluster-level granularities via automated model scaling, fusion and interleaving. The core design of Hydro derives from the following three insights. First, *it is feasible to search hyperparameters with a smaller model*. Instead of tuning hyperparameters directly on the target model, we find it is possible to tune a model with a much smaller surrogate model by applying a novel hyperparameter transfer theory [117, 121]. Second, *cross-model fusion can be used to improve resource utilization*. Since the scaled surrogate model is prone to incur GPU underutilization, we can utilize the model architecture consistency of different trials to fuse them into a single one, achieving much higher GPU utilization and training throughput. Third, *ephemeral bubble resources in the datacenter can be leveraged for tuning*. Large model training jobs exist in the long term and occupy the majority of resources, which incurs the starvation of other jobs. We can leverage pipeline bubbles of large models to greatly extend the tuning job resources in an interleaving execution way, without hurting the training throughput of large models.

Incorporating the above insights, we build Hydro service to minimize the makespan of tuning workloads and improve the cluster-wide resource utilization. It consists of two key system components: (1) **Hydro Tuner** is the user interface that automatically generates surrogate models by *scaling* and *parametrization*. It optimizes tuning efficiency via *inter-trial* and *intra-trial fusion*, which involve combining multiple models into a single entity and subsequently performing compiler-based optimization. Besides, it efficiently orchestrates the tuning process with *adaptive fusion* and *eager transfer* mechanisms. (2) **Hydro Coordinator** is the datacenter interface that interacts with the scheduler to dynamically allocate resources and execute trials. It extends tuning resources by *interleaving training* with pipeline-enabled large model training tasks, effectively utilizing idle time intervals on each node known as *bubbles*, which are caused by the gaps between the forward and backward processing of microbatches [106]. Besides, it improves resource utilization and cluster-wide performance by *heterogeneity-aware* allocation.

To extensively assess the performance of Hydro, we conduct evaluations across 6 models, such as GPT-3 XL [24] and ResNet [41]. Experiments on Hydro Tuner show that it substantially outperforms Ray by 8.7~78.5× on makespan reduction with single-fidelity tuning algorithm, while obtaining better final model quality. Besides, our experiments on Hydro Coordinator demonstrate that interleaving with a large pipelined model can further extend the resource of tuning workload, without sacrificing the throughput of the large model.

Features	Cloud Services		HPO Frameworks		Hydro
	Vizier	SageMaker	NNI	Ray	
Distributed Environment	✓	✓	✓	✓	✓
Elastic Training	◆	◆	◆	✓	✓
Auto Model Scaling	✗	✗	✗	✗	✓
Surrogate HP Transfer	✗	✗	✗	✗	✓
Inter-Trial Fusion	✗	✗	◆	✗	✓
Intra-Trial Fusion	✗	✗	✗	✗	✓
Heterogeneity Awareness	✗	✗	✗	✗	✓
Interleaving Training	✗	✗	✗	✗	✓

Table 1: Comparison between Hydro and existing popular HPO systems: Google Vizier [39, 105], Amazon SageMaker [28, 92], Microsoft NNI [9, 127] and Anyscale Ray [72, 84]. ◆ denotes system cannot support the feature for many cases.

Table 1 compares Hydro with existing tuning systems. To summarize, we make the following contributions:

- ★ We build a holistic system that automatically applies the novel hyperparameter transfer theory together with multiple system techniques to jointly improve the tuning efficiency.
- ★ We identify the opportunities for cluster-wide optimization in the datacenter, including squeezing bubble resources with interleaving and heterogeneity-aware trial allocation.
- ★ We demonstrate the excellent performance of surrogate-based hyperparameter tuning across general models.

## 2 Background and Motivation

### 2.1 Hyperparameter Tuning

*Hyperparameter Tuning* (i.e., Hyperparameter Optimization, HPO) aims to identify the optimal hyperparameters via massive configuration exploration [71, 82]. In the general workflow of an HPO job: (1) the user designates a *search space* of hyperparameters to explore; (2) the tuning algorithm creates a set of training *trials* and each trial contains one unique hyperparameter configuration sampled from the search space; (3) the HPO system coordinates trials execution until the best hyperparameter configuration is found.

Existing research works typically optimize HPO efficiency from the tuning algorithm [33, 47, 63, 64, 67, 68, 70, 79, 104] or system [32, 60, 69, 71, 82, 110, 125, 127] aspects:

**Algorithm taxonomy.** Depending on whether to enable early stopping, tuning algorithms can be divided into two categories [100]: (1) *single-fidelity* (e.g. Random [22], Bayes [104]) algorithms require each trial to be fully trained, which is accurate but inefficient; (2) *multi-fidelity* (e.g., ASHA [63], BOHB [33]) algorithms stop unpromising trials via successive halving [53] or curve fitting [31] strategies. They are efficient but may miss the best hyperparameter configuration due to the use of “low-fidelity” evaluations. Hydro well supports both the single- and multi-fidelity algorithms.

**System optimization.** To further improve the tuning efficiency and resource utilization, there are two advanced techniques applied in state-of-the-art HPO systems: (1) *elastic training* dynamically allocates more GPU resources to the top

performing trials [71] and further adjusts the entire requested resources [32, 82, 94]. (2) *GPU sharing* (i.e., trial packing) allows multiple trials to share the GPU using the NVIDIA MPS [13] or MIG [12] technologies to achieve higher utilization [125]. Different from them, Hydro combines scaling, fusion and interleaving for ultimate efficiency.

## 2.2 Hyperparameter Transfer Theory

Recently, the remarkable success of foundation models has ignited a keen interest in exploring the relationship between model size and its optimal hyperparameter. *Scaling Laws* [42, 43, 52] empirically study the power-law functions of batch size and learning rate across varying model sizes. Nevertheless, the authors [52] candidly admit that only limited configurations are tested and the rule-of-thumb formulas break down when dealing with models that exceed one billion parameters.

Beyond heuristic exploration, some novel hyperparameter transfer strategies [49, 117, 121] are proposed by DL theorists. For simplicity, we call them *parametrization*, the rule of how to adjust hyperparameters accordingly when models grow/shrink in both the width and depth. Different from existing HPO systems, Hydro enables automatic hyperparameter transfer based on parametrization. To make the obscure theory more accessible, we present a concise background overview of the underlying theory. [116] systematically builds a coherent theoretical framework for parameterization: the feature learning effect  $\gamma$  of a MLP model is proportional to

$$\gamma \equiv \frac{L}{w^{1-p}}, \quad p \in [0, 1] \quad (1)$$

where  $w, L$  indicates the width and depth of the neural network respectively. For the purpose of simplicity, we assume that the numbers of the hidden-layer neurons are all of similar order,  $w_1, w_2, \dots, w_{L-1} \sim w$ .  $p$  is a metaparameter that interpolates different parametrization strategies into a unified framework, which is determined by inherent strategy. The objective is two-fold: first, to maintain a fixed  $\gamma$  that allows hyperparameters transfer across different model sizes, and second, to strive for a larger  $\gamma$  that facilitates better feature learning. To this end, there are two directions of parametrization:

(1) *Neural Tangent (NT) parametrization* ( $p = 0$ ) [49]. It naturally arose from the study of infinite-wide neural network as Neural Tangent Kernel (NTK) [49, 89], which can keep  $\gamma$  fixed by scaling the depth along with the width as  $L \sim w$ . NTK is a kernel method to explain the evolution of neural networks during training, which is derived by applying the first-order Taylor expansion to linearized models. It belongs to the *lazy training* regime where the weights move very little [121], so that linearization approximately holds around the initial parameters and does not learn features, which is a fatal weakness of the NTK theory in practice. Moreover, NT parametrization does not make sense since the wider model does not always perform better in this context [117], which conflicts with common observations [43, 52].

(2) *Maximal Update (MU) parametrization* ( $p = 1$ ) [121].

Figure 1: Effect of Hydro parametrization. The training loss against the learning rate on MLP (a, b) and Transformer (c, d) with different widths.  $S$  denotes the model scaling ratio.

It generalizes the mean-field limit of the 1-hidden-layer case [25, 80] and should be the unique parametrization that retains the representation-learning capability (non-rigorously referred to *active training*, in contrast to lazy training of NT parametrization) for a large-scale neural network, which means training does not become trivial or stuck at the initialization in the large width limit. Colloquially, it is designed to solve the issue that the input layer is updated much more slowly than the output layer, and make all hidden activations update with the same speed in terms of width [117].

Hydro adopts the MU parametrization, which will be further elaborated in §4.1 and we refer readers to [98, 117–122] for a comprehensive review of the theory.

## 2.3 Opportunities for Efficient Tuning

**Lightweight surrogate-based tuning.** Current HPO systems search hyperparameters directly on the *target model*, which is intuitive but inefficient. In contrast, Hydro makes it possible to tune a model with a much smaller *surrogate model* via applying a novel hyperparameter transfer technique (aforementioned in §2.2). For a clearer illustration of the surrogate-based tuning effect, we employ Hydro parametrization on two toy models and plot their converged training loss against a range of learning rates as shown in Figure 1. Specifically, the target MLP model contains two hidden layers (width=4096) and we train it with SGD on CIFAR-10. Similarly, the target Transformer model contains two TransformerEncoder layers (width=4096, i.e.,  $d_{model}$ ) and we train it with Adam on WikiText-2. Besides, we generate surrogate models with different scaling (shrinking) ratios  $S$ , and the smaller model is depicted by the lighter blue line. For instance,  $S=2$  represents the model with width=2048. Obviously, the conventional training paradigm (Figure 1 (a, c)) cannot share the best hy-

Figure 2: (a) GPU utilization distribution of one partition in our cluster and a GPU production cluster in Alibaba [115]. (b) Exponential growth of NVIDIA datacenter GPU capability. x-axis: GPU model name & release year.

Figure 3: Model scaling effect of WideResNet-50. (a) Model GFLOPs (Giga Floating Point Operations). (b) GPU memory.

perparameter across different sizes of models and there are orders of magnitude optimal learning rate shifts. However, Hydro parametrization (Figure 1 (b, d)) makes surrogate models stay approximately the same optimal learning rate as the target model, which implies the feasibility of surrogate-based tuning. Furthermore, Hydro parametrization can deliver better performance since both tuned MLP and Transformer achieve lower training loss than their counterparts. An intuitive explanation is that the learning rate of the conventional paradigm must tame logits’ surge, but preceding layers do not learn appreciably. We perform a comprehensive evaluation of several models in §6.3 and demonstrate the superiority of Hydro.

**Fusion of numerous repetitive models.** GPUs are commonly underutilized in DL clusters [45, 46, 115, 124, 125]. Figure 2 (a) plots the Cumulative Distribution Function (CDF) of one-week GPU utilization in one partition of our cluster, as well as an Alibaba trace [115] for reference. We find there are only 16% and 35% of GPUs achieving higher than 50% GPU utilization in Alibaba and Shanghai AI Laboratory respectively. This issue will be exacerbated if the Hydro surrogate-based tuning technique is applied. For instance, Figure 3 presents the model scaling effect of training WideResNet-50 on ImageNet, where GFLOPs follows approximately inverse-square ( $c_1/S^2$ ) trend drop and memory footprint follows roughly  $c_1/S + c_2$  trend decrease ( $c_i$  indicates constant). This implies model scaling can significantly reduce the computation overhead, but resources are more prone to be underutilized. To this end, inspired by JAX vmap function [35, 112], Hydro implements an *inter-trial fusion* mechanism to automatically combine multiple models into one. Operators of multiple trials can be

fused owing to the property of HPO tasks: essential is a set of identical models (or with minor mutation). Compared with the conventional GPU sharing mechanism (e.g., MPS), Hydro can achieve higher training throughput, GPU utilization and lower memory footprint (Figure 8).

**Cluster resource awareness.** Although HPO jobs are pervasive in GPU datacenters, cluster schedulers typically regard them as general training workloads without any specific design. On the other hand, HPO systems [9, 72, 84] are cluster resource agnostic. This causes cluster-level inefficiency, such as long job queuing delay and low GPU utilization. However, the unique features of HPO jobs bring opportunities for more efficient tuning. (1) *Trial throughput insensitivity.* Unlike general DL jobs, HPO jobs are more tolerant to throughput slowdown of partial trials. Therefore, we can run more trials by leveraging ephemeral bubble resources of large language model training jobs, which are long-term existing in our datacenter (§5.1). (2) *Diminishing resource requirements.* Multi-fidelity HPO jobs usually explore plenty of trials at the beginning and gradually decrease the search concurrency [32, 71, 82]. At the final stage, only a few trials are exploited. Therefore, we can not only reduce the total resource amount progressively, but also properly leverage the heterogeneous GPU resource (§5.2). With the rapid evolution of GPU computing capability as shown in Figure 2 (b), they become more prone to be underutilized for most small-scale trials [87]. Allocating trials to appropriate GPUs can significantly improve cluster-wide efficiency without hurting a single HPO job makespan.

### 3 Hydro Overview

**Design principles & goals.** For practical adoptions, Hydro follows three design principles: (a) *Automatic and simple.* Manually converting surrogate models is tedious and error-prone. Hence, the whole tuning workflow should be automated and easy to use, which requires minimum user code modification. (b) *Incentive and interference-free.* Although our system focuses on optimizing HPO jobs, it does not sacrifice other workload performance. Instead, it is altruistic and requires fewer resources than conventional systems, which benefits all cluster users. (c) *Modular and extensible.* Each component in Hydro can work independently to support more scenarios (e.g., cloud). Moreover, Hydro can be applied to general HPO tasks, and more tuning algorithms can be easily integrated. In addition, Hydro has two primary objectives: (1) minimizing the makespan of HPO workloads; (2) improving the cluster-wide resource utilization.

**System architecture.** Figure 4 depicts the architecture of the Hydro service. It consists of two key system components: *Hydro Tuner* (blue block) as a user interface to automatically generate surrogate models and optimize tuning trials, and *Hydro Coordinator* (purple block) for improving tuning efficiency and datacenter-level resource utilization. Each component contains several modules for different purposes. Specifically, there are three main modules in Hydro Tuner:

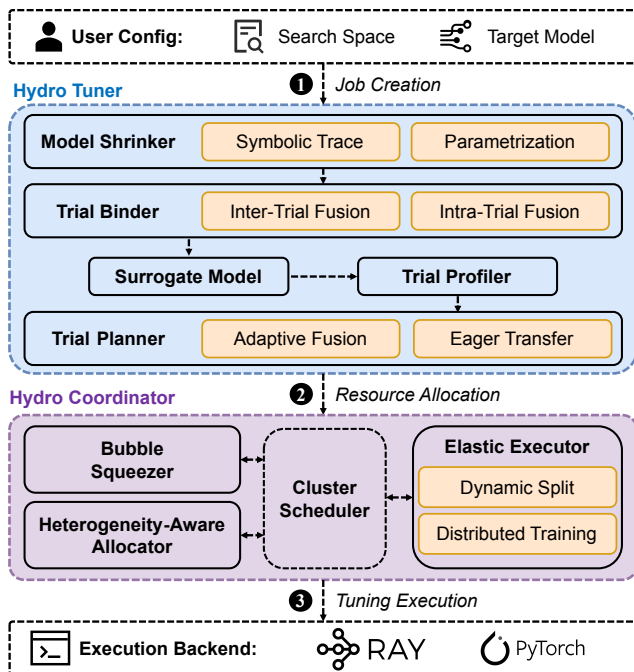

Figure 4: Overview of Hydro architecture and workflow.

- *Model Shrinker*: to obtain surrogate models by automatically tracing, scaling and parametrization.
- *Trial Binder*: to better utilize accelerators by binding multiple trials and fusing internal operators.
- *Trial Planner*: to adaptively determine the tuning strategy based on the profiling information and intermediate results.

Additionally, Hydro Coordinator also includes three modules:

- *Bubble Squeezer*: to extend tuning workload resources by interleaving training with a pipeline-enabled large model.
- *Heterogeneity-Aware Allocator*: to improve resource utilization and cluster-wide performance by allocating proper accelerators on different tuning stages.
- *Elastic Executor*: to dynamically execute trials by splitting fused trials and enabling distributed training.

**API Design.** Hydro enables high-efficient surrogate-based hyperparameter tuning with a few lines in the developer’s code, as shown in Figure 5. It follows the Ray Tune [72] API to define the search space and invoke the `fit()` function. To support Hydro functions, developers only require to wrap their model, dataloader and optimizer with the `prepare_xxx()` API (lines 6~8). Hydro traces the whole function to control the trial execution, convert surrogate model, enable model fusion and elastic training.

**Tuning Workflow.** The system workflow of Hydro is presented by black arrows in Figure 4. Specifically, when a developer wants to tune a model, she only needs to define the search space and invoke the Hydro APIs (①). After job creation, Hydro Tuner automatically generates and optimizes surrogate models by scaling and fusion. Furthermore, it adopts *Trial Planner* to efficiently orchestrate the tuning process. Then Hydro Coordinator is responsible for contacting the cluster

```

1 import ray, hydro
2 import hydro.train as ht
3
4 def train_func(config):
5     # Wrap model, dataloader and optimizer
6     model = ht.prepare_model(model)
7     data_loader = ht.prepare_data_loader(data_loader)
8     optimizer = ht.prepare_optimizer(SGD, lr=config["lr"])
9     for _ in range(1): # User defined training loop
10        train_epoch(...)
11        result = validate_epoch(...)
12        ray.session.report(result)
13
14 search_space = {"lr": ray.qloguniform(1e-4, 1, 1e-4)}
15 trainer = hydro.Trainer(train_func)
16 tuner = hydro.Tuner(trainer, search_space, scaling_num=8)
17 results = tuner.fit()

```

Figure 5: A code example of how to use Hydro APIs to define the search space and perform hyperparameter tuning.

scheduler to dynamically allocate resources and execute trials (②). It supports two novel mechanisms, which leverage ephemeral bubbles and heterogeneous resources to further improve datacenter efficiency. Finally, the tuning job is successfully scheduled and starts running, where Ray [84] and PyTorch [91] serve as the execution backend (③). More details are introduced in the following sections (§4 & §5).

## 4 Hydro Tuner

Hydro Tuner is a core component of the Hydro service for job-level optimization. It consists of three modules: Model Shrinker, Trial Binder and Trial Planner.

### 4.1 Model Shrinker

Model Shrinker aims to obtain surrogate models by automatically tracing, scaling and parametrizing the target model. The upper part of Figure 6 depicts its workflow. It first traces the target model and edits each layer’s configuration to build a scaled model (①). To enable hyperparameter transfer, it then automatically parametrizes the scaled model by reinitializing the weight and adjusting the learning rate of each layer accordingly (②). Below we first summarize the MU parametrization theory that Hydro parametrization relies on, and then introduce how Hydro brings it into practice.

**Maximal Update parametrization.** As introduced in §2.2, Hydro employs the MU parametrization theory [117, 121] to search hyperparameters on a small surrogate model and transfer them to the large target model. The theory is built atop Tensor Programs [117–122], a unified theoretical framework that formulates the computation of common neural networks components as Gaussian Processes (GPs), including multi-layer perceptrons (MLPs), recurrent neural networks (RNNs) (e.g., Long-Short Term Memory (LSTM) [21]), skip connections [41], convolutions [62] or graph convolutions [55], pooling [62], batch normalization [48], layer normalization [20],

Figure 6: Illustration of Model Shrinker (①, ②) and Trial Binder (③, ④). The length of each bar represents layer width.

and attention [108]. As a result, many practical models like ResNet [41] and Transformer [108] can be expressed as GPs and apply MU parametrization, since they inherently consist of these basic components.

► **Theory assumption.** In contrast to prior works such as NTK [49] that necessitate unnatural conditions, MU parametrization only requires standard Gaussian initialization for the model, which is easily achievable in practice. In terms of data, MU parametrization requires i.i.d. samples, which is typically present in the same dataset. However, this requirement also limits its ability to support fine-tuning (§7).

► **Key insight and mechanism.** The main idea of MU parametrization is: every activation vector has roughly i.i.d. coordinates at **any time** during training neural networks in the infinite-width limit. It aims to overcome the imbalanced per-layer learning speed issue in practice. To this end, MU parametrization performs layer-wise fine-grained adjustment, including per-layer initialization variance, learning rate and other optimizer-related hyperparameters (e.g., SGD momentum, Adam beta). Specifically, since the output layer is updated much faster than the input layer, MU parametrization suppresses the learning rate and initialization variance of output weights by  $w$  (width) times. In addition, for SGD-like optimizers (linear tensor update), the learning rate of input weights and all biases is multiplied by  $w$ . For Adam-like optimizers (non-linear tensor update, normalizes the gradient coordinate-wise), the learning rate of hidden weights is divided by  $w$ . Hence, MU parametrization ensures consistent magnitude updates for each layer during training regardless of its width so that hyperparameters can be transferred across models with different widths at any time (i.e., same converge speed across scaled models).

To summarize, in the large width limit, MU parametrization reveals that hyperparameters yielding lower training losses for narrower models also result in better performance for wider models through a specific transfer mechanism. Hydro leverages this effect to obtain better test accuracy efficiently via surrogate-based tuning, albeit without a rigorous theoretical guarantee for every model.

► **Instructive example.** To provide a clearer explanation of why parametrization is necessary and how it operates, we recapitulate the key insights of [121] with an instructive example [117]. Consider a 1-hidden-layer linear model  $f(x) = V^T U x$  with scalar inputs and outputs, as well as  $w$ -width layer weights  $V, U \in \mathbb{R}^{w \times 1}$ . In common practice (e.g., Xavier initialization [37]), we initialize them with  $V \sim \mathcal{N}(0, 1/w)$  and  $U \sim \mathcal{N}(0, 1)$ , which ensures  $f(x) = \Theta(|x|)$  at initialization ( $\Theta(\cdot)$  indicates asymptotically tight bound). After one step of SGD with learning rate 1, the new weights are  $V' \leftarrow V + \theta U$  and  $U' \leftarrow U + \theta V$ , where  $\theta$  is some scalar of size  $\Theta(1)$  depending on the inputs, labels, and loss function. Then

$$\begin{aligned} f(x) &= V'^T U' x \\ &= \left( V^T U + \theta U^T U + \theta V^T V + \theta^2 U^T V \right) x \end{aligned} \quad (2)$$

which will blow up with width  $w$  in the infinite limit because  $U^T U = \Theta(w)$  by Law of Large Numbers. In other word, it only allows  $O(1/w)$  learning rate so as to avoid float overflow, and yield kernel limits (§2.2). Consequently, it fails to perform feature learning (learning rate  $\rightarrow 0$ ) to update weights after random initialization.

However, by applying maximal update parametrization, we have  $V \sim \mathcal{N}(0, 1/w^2)$ ,  $U \sim \mathcal{N}(0, 1)$ , learning rates  $\eta_V = 1/w$  and  $\eta_U = w$ . After one step of SGD, now we have

$$f(x) = \left( V^T U + \theta w^{-1} U^T U + \theta w V^T V + \theta^2 U^T V \right) x \quad (3)$$

and one can verify this is  $\Theta(1)$  and remains bounded. In contrast to common practice, MU parametrization has  $\Theta(1)$  learning rate and admits feature learning *maximally*, which allows every parameter to be updated maximally (in terms of scaling with width) without leading to float overflow.

► **Heuristic adaptation.** While Tensor Programs support more versatile model components (e.g., convolution), obtaining a closed-form solution for arbitrary models is infeasible. The efficacy of the MU parametrization has been rigorously demonstrated on a 2-hidden-layer MLP trained with SGD for multiple steps, and the proof can be readily extended to deeper MLPs [121]. For more general models in practice, some heuristic tricks are adopted to enhance their hyperparameter transferability. For example, Transformer [108] models require two additional operations in the self-attention: (1) scaling the attention logit by  $1/d_k$  rather than  $1/\sqrt{d_k}$ , where  $d_k$  is the attention head size; (2) zero initialization on query layer  $q$ . We also empirically find that using a larger sequence length provides a better transfer effect for Transformer models. For models with some special components or architecture (e.g., MoE [101]), hyperparameters may not well transfer with MU parametrization alone. Hence, additional analysis and tailored adjustments may be required.

**Hydro parametrization.** It is arduous and error-prone to implement MU parametrization manually to generate a surrogate model. Developers are required to not only thoroughly understand the MU parametrization theory, but also manually

Figure 7: Hydro parametrization implementation. Illustration on a simple 4-layer model with SGD or Adam-like optimizer.

adjust the model width, initialization function and learning rate layer by layer. Any incorrect adjustment may directly incur hyperparameter transfer failures. To this end, we implement Hydro parametrization, an automated and simplified parametrization strategy based on MU parametrization. We demonstrate the excellent effect of Hydro parametrization with visualized results in Figures 1 and 10.

For a clearer illustration, we present the Hydro parametrization process in Figure 7, which applies different strategies to the input, hidden and output layers. Developers only need to specify their desired *scaling ratio*  $S$  ( $S = 8$  by default) and then Hydro will parametrize the model accordingly. Concretely, at the model initialization stage, we apply zero-variance initialization to the output layer instead of  $1/w^2$ , which will not be detrimental to performance and can remove this mismatch issue between the surrogate model and target model in the initial Gaussian process [117]. Moreover, we apply zero initialization to all biases, and weights as well as learning rate scaling strategies are annotated in the figure, which is invoked by the `prepare_optimizer` API to build a `hydro_optimizer`. Besides, we insert a Multiply layer in front of the output layer to scale its input by  $S$ .

**Applicable Scope:** Hydro parametrization works well for most ubiquitous hyperparameters that control model initialization and training, including learning rate, batchsize, `lr_scheduler`, momentum, etc. However, it has limited support on regularization-related hyperparameters, such as weight decay and dropout, because they naturally depend on both the model size and data size. Although parametrization cannot be applied to all hyperparameters, it is sufficient to achieve qualified performance in most cases. After most hyperparameters are tuned with the surrogate model, developers can further tune the regularization hyperparameters within a much smaller search space on the target model if needed. Moreover, we provide a comprehensive summary of additional limitations associated with Hydro parametrization in Section 7.

**Trace and scale.** Before performing the above parametrization, we need to first trace the target model and build a scaled model. Since there are various model definition styles in the PyTorch ecosystem, it is necessary to obtain a uniform and equivalent modality from disparate community model codes. We implement HydroTracer based on `torch.fx` [97], which

allows developers to trace and edit the model. Specifically, we replace `call_function` nodes (e.g., `torch.nn.functional`) with the corresponding `call_module` nodes (e.g., `torch.nn`) for subsequent layer scaling and fusion (§4.2). We apply different scaling rules to the input, output and hidden layers. For instance, we parse `nn.Linear` kwargs and modify both the `in_features` and `out_features` values by dividing  $S$  for hidden layers. In addition, we only scale the `out_features` of input and `in_features` value of output layers. To handle the data-dependent control-flow, we use proxy nodes along with developer-provided concrete values to determine the execution flow [61]. According to our evaluation of notable models, including torchvision [18] (e.g., ResNet [41], MobileNet [44], VGG [103]) and HuggingFace Transformers [113] (e.g., BERT [30], GPT [95], Swin [76]), developers can trace and scale these models with Hydro without modifying the code.

**Correctness check.** While Hydro has achieved automatic parameterization, there are still potential failures due to certain special model components that require heuristic adaptation as previously mentioned, as well as other corner cases that have not been considered. To this end, we further implement a safeguard mechanism to check the correctness of the parametrization and notify users whether they should use Hydro to prevent misleading hyperparameters and resource wastage. Firstly, Hydro performs a simple per-layer width check when scaling to avoid too narrow layers (e.g., only 1 neuron width for a Linear layer). Additionally, taking inspiration from gradient checking as a simple method for verifying the correctness of an autograd implementation, Hydro has a quick parameterization profiling stage that checks whether the average size (L1 value) of each activation vector is bounded to avoid possible parameterization failure based on [117]. It only lasts for very few steps at the beginning of the HPO job.

## 4.2 Trial Binder

Although Model Shrinker dramatically reduces the computation of each trial (Figure 3), it inevitably incurs the resource underutilization issue, which deteriorates small- or mid-size target models (e.g., deployed on edge devices). To address this problem, Trial Binder further optimizes surrogate models by binding multiple trials and fuses internal operators to better utilize accelerators. We illustrate its mechanism in the bottom part of Figure 6. It merges a set of fusible trials into a *HydroTrial* with grouped operators and optimizer (③). To further accelerate training, we automatically just-in-time (JIT) compile the fused (*inter-*) surrogate model to obtain fast and flexible fusion (*intra-*) kernels (④). Note that the last model with closer layer distance represents the reduced memory-bounded operations through intra-trial fusion.

**Inter-trial fusion.** There are plenty of trials with the same or similar model structure in a HPO job. Inspired by JAX `vmap` [35, 112], which returns a batched version of the target function by vectorizing each input along the axis specified, we can batch multiple trials into a single one by fusing their opera-

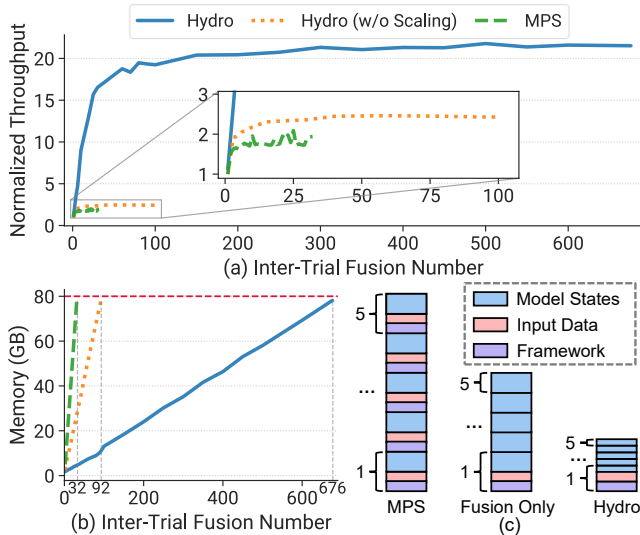

Figure 8: Inter-trial fusion effect on ResNet-18. (a) Accumulated throughput of fused surrogate model w.r.t the target model. (b) GPU memory footprint of different fusion counts. Red horizontal line denotes the A100 memory bound. (c) Schematic diagram of memory occupation detail of 5 models GPU sharing with MPS, Hydro and Fusion (w/o Scaling).

tors. Hydro implements an *inter-trial fusion* mechanism to automatically bind surrogate models. Specifically, Trial Binder traverses the traced surrogate model and replaces the `torch.nn` operators with grouped `hydro.nn` operators according to the predefined fusion rule and fusion count  $F$  determined by Trial Planner. `hydro.nn` provides mathematically equivalent implementations of batched original PyTorch operators based on HFTA [110]. For instance, `hydro.nn.Linear` is implemented atop `torch.baddbmm` (i.e., batch matrix-matrix product and add), which adds an additional dimension batch (i.e.,  $F$ ) compared with `torch.nn.Linear (addmm)`. Besides, for each `hydro.nn` operator, we reimplement the initialization function to support independent model-wise Hydro parametrization and realize the defusion mechanism to extract a specific sub-model. Additionally, `hydro_optimizer` and `hydro_lr_scheduler` are designed to support both the model fusion and parametrization simultaneously. These are performed automatically, and developers typically do not need to understand the rationale and modify codes.

Figure 8 plots the extraordinary effect of integrating model scaling with inter-trial fusion on ResNet-18 ( $S = 8$ ), tested on CIFAR-10 with batchsize=256. It is evident that Hydro is capable of concurrently training impressive 676 models on a single A100 GPU. Compared with the conventional GPU sharing mechanism MPS [13] (MIG [12] has similar performance), Hydro achieves over  $10\times$  training throughput improvement and over  $20\times$  GPU memory conservation. If we directly apply inter-trial fusion to the target model (without scaling), the throughput improvement is relatively much limited. Furthermore, we provide an intuitive interpretation

of how memory footprint reduction occurs in Figure 8 (c). The model states (blue blocks) encompass all aspects associated with model training such as model weights, gradients, activations, and optimizer states [96]. MPS has repetitive memory overheads incurred by CUDA context of DL framework (purple blocks) and independent data loading (pink blocks). In contrast, Hydro avoid such redundancy and further reduce model-related memory footprint. Note that here we only compare with vanilla training paradigm without considering more advanced memory optimization techniques like Salus [124]. Moreover, beyond the better GPU utilization and higher throughput, inter-trial fusion also alleviates the I/O pressure owing to the accompanied data-loading fusion.

**Lazy intra-trial fusion.** Hydro supports automatic model fusion to further accelerate training based on the nvFuser [10] compiler backend. Although plenty of previous works [51, 107, 129] demonstrate that operator fusion can improve training throughput via better memory locality, it does not always bring benefits to HPO workloads due to its high compiling overhead. For instance, nvFuser [10] takes approximately 2-epoch time to compile a ResNet-18 model to deliver around 10% speedup per epoch, which means a trial needs to run at least 20 epochs to avoid slowdown. However, most trials will end up in a few epochs for multi-fidelity tuning algorithms. To this end, Hydro apathetically adopts the intra-trial fusion. For simplicity, Hydro currently only applies to trials with *deterministic* training steps, such as all HydroTrials when applying single-fidelity tuning algorithms and the trial that trains the target model with transferred hyperparameters.

### 4.3 Trial Planner

Trial Planner is the key module that interacts with the tuning algorithm and trial executor. We introduce two mechanisms that improve the surrogate-based tuning efficiency.

**Adaptive fusion.** The trial count and resource amount vary significantly across different HPO jobs. Hence, the fusion count  $F$  of each HydroTrial should be adaptively determined to achieve the desired performance. Hydro contains the following steps to fuse trials and assign GPUs: (1) Trial Planner invokes the tuning algorithm to generate a set of hyperparameter configurations (trials). (2) Since inter-trial fusion requires trials with the same operator shapes, we split them into different *trial groups* according to their batchsizes. (3) Based on the linear growth of GPU memory shown in Figure 8 (b), we can profile the trials with  $F = 1$  and  $F = 2$  for each *trial group* and estimate the upper bound of the fusion count  $F_{max}$ . (4) Hydro assigns all available GPUs to each *trial group* according to group’s weight, which equals to  $B \times N$  (denoted as the product of batchsize and trial count of the group). (5) Each *trial group* evenly distributes trials based on the group GPU amount and  $F_{max}$ , and Hydro fuses them as a HydroTrial on each GPU. In this way, Hydro can leverage as many GPUs as possible and achieve the optimal global throughput.

**Eager transfer.** As the HPO job progresses, more and more

Figure 9: Illustration of (a) 1F1B Pipeline and (b) Hydro Bubble Squeezer, with four pipeline stages and four micro-batches. Note the right-side memory diagrams can only reflect the relative relation of the *same* color blocks across workers.

trials terminate and the degree of the parallelism gradually decreases, resulting in underutilized or idle resources. On the other hand, the best hyperparameter configuration sometimes appears in the early stage. Therefore, instead of training the target model after all the surrogate-based tuning trials are done, we can eagerly transfer the intermediate best hyperparameters and leverage vacated resources to validate the configuration on the target model. Hydro records all evaluated hyperparameters and schedules a *TargetTrial* for the target model training when 50% (customizable) of the surrogate-based tuning trials are done and there exist idle resources. If a better hyperparameter is searched, Hydro terminates the on-going *TargetTrial* or starts a new *TargetTrial* depending on the resource utilization. This mechanism efficiently shortens the job makespan and improves the resource utilization.

## 5 Hydro Coordinator

Hydro Coordinator focuses on cluster-level optimization. It consists of three modules: Bubble Squeezer, Heterogeneity-Aware Allocator and Elastic Executor. It is important to highlight that the first two modules are tailored for specific cluster scenarios. Specifically, Bubble Squeezer can only be activated when a pipeline-enabled foundation model pretraining job is running within the cluster. The Heterogeneity-Aware Allocator is meticulously designed to better leverage multiple generations of GPUs coexisting in the cluster.

### 5.1 Bubble Squeezer

In addition to HPO jobs, there are many kinds of workloads that coexist in the GPU datacenter, such as inference, debugging and large-scale distributed training jobs [45, 50, 111]. With the rapid popularity of foundation models (e.g., GPT-3 [24]) in recent years, some large model pretraining workloads exist in our datacenter in the long term. As complained by many users, the majority of machines are occupied by large model training jobs that usually last for days to weeks,

which incurs the starvation of other jobs. Additionally, the pipeline parallelism [85, 88] is usually adopted to support a larger model by splitting it into several stages and placing them across multiple workers. However, bubbles inherently exist in the synchronous pipeline parallelism [106], such as the commonly used 1F1B [34, 86] strategy. Besides, the imbalance peak memory issue (Figure 9) between different pipeline stages further exacerbates the resource inefficiency [65].

Hydro designs Bubble Squeezer, which leverages bubbles to greatly extend the tuning job resources in an interleaving execution way, almost without hurting the training throughout of large models. HydroTrials are perfectly suitable for the bubble interleaving execution due to the following unique features: (1) *Throughput insensitivity*. Unlike general DL training jobs, tuning jobs are more tolerant of the slowdown of partial trials. This inspires us to squeeze the spare resources of the bubbles and execute trials in a pause-and-resume way. (2) *Deterministic resource pattern*. General small-scale workloads (e.g., debugging) have unknown and unpredictable resource requirements. However, Hydro profiles and records the resource consumption of HydroTrials, mitigating the potential out-of-memory (OOM) issues if they are colocated with large models. (3) *Elastic trial size*. Based on Model Shrinker, the scaled model has a much smaller memory footprint (Figure 3) than the original model, which means we typically do not need to swap out its GPU memory during collocation. Besides, we can dynamically adjust the trial fusion count according to the remaining GPU memory with Trial Binder.

To clearly illustrate how Bubble Squeezer works, we first introduce the 1F1B pipeline parallelism in Figure 9 (a). It transfers intermediate activations of the partial model at the forward and backward passes between different workers using point-to-point communication [130], thus each worker cannot continuously utilize the GPU. For Worker 1, after the forward pass of the last micro-batch (blue block 4), it has to wait for the backward pass of the first micro-batch (green block 1), leaving GPU idle for a long time. Other workers also present similar bubble patterns but occupy less GPU memory since fewer activations of micro-batch needed to store.

In Figure 9 (b), Hydro interleaves four HydroTrials of different sizes with the large model training workload. Each trial executes in a pause-and-resume paradigm to squeeze the bubbles. Since Hydro Tuner has traced and canonicated each layer with `hydro.nn`, we further register hooks on each module of the trial to support on-demand pause and resumption in the forward and backward passes of each layer. When a large model training job exists, Hydro coordinates with datacenter scheduler to acquire more GPUs from this model and tags them as *ephemeral* resources. For the large model, we also implement a corresponding hook inside its training framework (i.e., DeepSpeed [96]) to report its training progress and resource consumption. Each worker executes its corresponding pipeline under DeepSpeed’s pipeline parallelism. Therefore, we implement a fine-grained synchronization mechanism to

guarantee that `HydroTrials` only could be executed within the bubbles, by intercepting the status of the CUDA streams of the NCCL kernels. Hydro can further adjust the fusion count to adaptively fit in the remaining memory and improve GPU utilization. At the beginning and end of the bubble of large model training, we control the resumption and pause of trial model training by Linux signals. The fine-grained suspend-resume control eliminates the performance interference caused by CUDA kernels running simultaneously.

In general, the effectiveness of Bubble Squeezer varies depending on multiple factors, and we present the scenarios where it works best. Regarding the HPO job aspect, Hydro is more effective when using (1) *multi-fidelity tuning algorithms* because they allow most trials to be terminated in a few epochs using the ephemeral resources and execute immediate top trials on exclusive resources to avoid possible blocking caused by interleaving slowdown. In addition, (2) *models with fewer layers* are preferred as they are prone to complete the entire iteration within the bubble time and require relatively less memory to support a higher fusion number. As for pipelined large model aspect, Hydro can achieve better performance when the pretraining job has (3) *more pipeline stages across more servers*, which implies a higher bubble ratio and more ephemeral resources. A large model pretraining job typically can support multiple different HPO jobs interleaving simultaneously and accelerate dozens, even hundreds of HPO jobs (depending on its resources and duration scale) during its pretraining process. In addition, there may be cases where some scaled models are still too large to be allocated on any GPU of the pretraining model. Due to the high memory swap overhead in our scenario, Hydro does not support offloading techniques like Bamboo [106]. As a result, Bubble Squeezer is unable to support such models.

## 5.2 Heterogeneity-Aware Allocator

HPO workloads generally have diminishing resource requirements [71]. They usually explore plenty of trials at the beginning and gradually decrease the search concurrency. At the final stage, only a few trials are exploited. Hence, tuning with fixed GPU resources can lead to underutilization. Existing HPO systems [32, 82] support autoscaling to dynamically adjust the tuning resources. However, they do not consider the GPU heterogeneity in the datacenter.

Inspired by Gavel [87], a novel heterogeneity-aware cluster scheduler for general DL jobs, we design a resource allocator to allocate appropriate GPUs to trials, which can improve the cluster-wide efficiency without sacrificing the job makespan. Hydro supports both resource autoscaling and heterogeneity-aware allocation. Specifically, if there is any node or GPU idle for over 1 minute (customizable), Hydro will interact with the cluster scheduler to release the resource. Other affiliated resources like CPU will also be released as a bundle. Additionally, Hydro creates *TargetTrial* with the eager transfer mechanism and makes the target model training process well

hidden inside the tuning time. Since the *TargetTrial* typically trains alone without fusion, it may not be able to fully utilize the GPU resources. So Hydro will place it on an GPU of old version (e.g., V100) if its SM Activity rate (measured by NVIDIA DCGM [11]) is lower than 50% (customizable). Similar action will be applied to surrogate models if their allocated resources are underutilized and there exist other HPO jobs pending in our service queue.

## 5.3 Elastic Executor

Elastic Executor is designed to improve the job efficiency by leveraging all assigned GPU resources. It supports two elastic mechanisms: (1) dynamic split and (2) automated distributed training. Specifically, when an idle GPU emerges, the *fused* `HydroTrial` will not directly increase its GPU count by conventional distributed training. Instead, Hydro will evenly split this `HydroTrial` into multiple `HydroTrials` and exclusively place them on the idle GPUs to reduce the communication overhead. Furthermore, since the memory footprint of some large models is high even though scaled, Hydro supports two types of elastic strategies for *unfused* surrogate models: (a) *Evenly distribute*: allocating idle GPU resources to all unfused surrogate models evenly. (b) *Performance-aware* (default): allocating idle GPU resources to the top performing trial. For the target model, Hydro automatically increases the number of workers to enable distributed training.

## 6 Evaluation

Hydro is implemented on top of Ray [72, 84] with about 12K LoC. For Hydro Tuner, Model Shrinker relies on torch.fx [97] and mup [117], while Trial Binder is built with HFTA [110] and nvFuser [10]. As for Hydro Coordinator, we modify DeepSpeed [96] to further support Bubble Squeezer and validate the interleaving execution as a prototype. And the Elastic Executor based on Ray Train as well as PyTorch FSDP [17].

We evaluate Hydro Tuner and Hydro Coordinator independently for a fair comparison. Our experiment search space does not include weight decay because Hydro is unable to transfer regularization hyperparameters, but it is sufficient to achieve qualified performance without tuning it.

### 6.1 Experiment Setup

**Testbed.** We conduct our experiments on a GPU datacenter of Shanghai AI Laboratory. Each node has 8 NVIDIA A100 80GB GPUs, 2 AMD EPYC 7742 CPUs (128 cores) [2] and 1TB memory. GPUs are interconnected to each other by NVLink and NVSwitch [14], and inter-node communication is achieved via NVIDIA Mellanox 200Gbps HDR InfiniBand [7]. All the experiments are conducted on A100 GPUs, unless explicitly stated in §6.5.

**Workloads and search spaces.** We evaluate Hydro tuning performance over six popular CV/NLP models, as listed in Table 2. Specifically, *GPT-3 XL* is a large language model architecture belonging to GPT-3 family. It contains 1.3B parameters and we use an open source implementation by GPT-

Task	Search Space	Model	Dataset	Optimizer	# of GPU	# of Trial	Avg. Time Reduction	Avg. Quality Difference	Size
Language Modeling	1r: $U_{Q\log}(10^{-5}, 10^{-1}, 10^{-5})$	GPT-3 XL [24]	OpenWebText [38]	AdamW	128	100	78.5 ×	-0.48 ppl	XL*
	gamma: $U_Q(0.01, 0.9, 0.01)$	Transformer [108]	WikiText-103 [81]	Adam	8	200	8.7 ×	-0.15 ppl	M
Image Classification	1r: $U_{Q\log}(10^{-4}, 1.0, 10^{-4})$	WideResNet-50 [126]	ImageNet [29]	SGD	32	200	20.3 ×	+1.18% acc	XL*
	momentum: $U_Q(0.5, 0.999, 10^{-3})$	MobileNetV3 Large [44]	Flowers102 [90]	Adam	16	500	12.3 ×	+0.05% acc	L
	batchsize: [128, 256, 512]	VGG-11 [103]	CIFAR-100 [57]	SGD	8	500	10.8 ×	+0.09% acc	M
	gamma: $U_Q(0.01, 0.9, 0.01)$	ResNet-18 [41]	CIFAR-10 [57]	SGD	8	1000	16.2 ×	+0.02% acc	M

Table 2: Summary of (1) workloads used in the evaluation and (2) single-fidelity tuning improvements over Ray. *Model Quality*: ppl indicates perplexity (the lower the better) and acc denotes accuracy (the higher the better). \* For XL tasks, we estimate the time cost of Ray based on simulation and use the official hyperparameter setting as the model quality baseline.

Figure 10: Hydro Tuner mechanisms validation. (a)~(d) *Scaling validation*: randomly select 10 hyperparameter sets ([batchsize, 1r, momentum]) to visualize the transfer effect of multi-dimensional hyperparameters across different scaling ratios  $S = 1, 2, 4, 8$  on model ResNet-18. (e) *Fusion validation*: loss curves of the standard model (solid line) and inter-trial fused model (dash line).

Neo [5, 23]. We further enable mixed precision training for *WideResNet-50* and two language modeling tasks. For the dataset, we crop Flowers102 into  $224 \times 224$  images, whose input size is the same as ImageNet. And we swap its train and test dataset split to get a larger training dataset to make it similar to more general jobs. Moreover, we denote single-node tasks as M-size, and distributed tuning tasks as L/XL-size.

We adopt three kinds of optimizers for above models, including SGD [99], Adam [54], and AdamW [77]. We use StepLR to decay the learning rate (1r) of each parameter group by gamma at every fixed step for all tasks. Additionally, we design two groups of search spaces for CV and NLP tasks respectively (Table 2), where  $U_Q(lower, upper, q)$  represents uniformly sampling a quantized (increment of  $q$ ) float value between *lower* and *upper*. Similarly,  $U_{Q\log}$  uniformly samples in different orders of magnitude. Note that the search space of *MobileNetV3 Large* excludes momentum due to the incompatibility of Adam.

**Tuning algorithms.** Hydro supports multiple popular single-fidelity and multi-fidelity tuning algorithms, such as Random [22], HyperBand [64], ASHA [63]. Since our work focuses on system aspect optimization instead of tuning algorithms, we select two representative tuning algorithms in our evaluation: (1) *Random* (single-fidelity): fully evaluates each randomly generated trial; (2) *ASHA* (multi-fidelity): eliminates

unpromising trials via asynchronous successive halving strategy. They are common hyperparameter tuning paradigms in practice. Besides, their asynchronous and prior-independent nature makes them more suitable for large-scale distributed tuning with numerous trials [71].

**Baselines.** We consider the following two systems as baseline: (1) *Ray* [72, 84]: performs HPO with the vanilla Ray Tune library; (2) *Ray+ES*: applies two advanced techniques in Ray Tune (*Elastic training* and *GPU Sharing*). Our implementation of *Ray+ES* refers to HyperSched [71] and Fluid [125]. Specifically, we place multiple trials on the same GPU using NVIDIA MPS [13] and allocate more GPU resources to the top performing trials if idle GPUs are available. We do not employ A100 MIG [12] sharing due to its similar performance with MPS but less flexibility [110]. Additionally, since existing popular HPO systems (Table 1) mainly differ in the application scenario and API design, and their system performance on the same tuning algorithm is similar, the Ray-based systems are sufficient for representing SOTA.

## 6.2 Surrogate-based Tuning Validation

Before performing end-to-end evaluations, we first give an intuitive experiment to validate the effect of surrogate-based tuning, which is the foundation of Hydro. As shown in Figure 10 (a)~(d), we randomly choose 10 hyperparameter configurations (denoted as A~J) on the ResNet-18 model and build

Model	# of GPU	# of Trial	Avg. Time Improvement	Avg. Quality Difference
GPT-3 XL	64	100	33.4 ×	-0.43 ppl
Transformer	4	200	5.8 ×	-0.09 ppl
WideResNet-50	16	200	9.7 ×	+0.87% acc
MobileNetV3 Large	8	500	8.0 ×	+0.08% acc
VGG-11	4	500	9.4 ×	+0.19% acc
ResNet-18	4	1000	14.5 ×	+0.05% acc

Table 3: Summary of multi-fidelity tuning improvements.

Deadline (s)	# of GPU	Model	Avg. Accuracy		
			Ray	Ray+ES	Hydro
900	4	VGG-11	65.42%	66.39%	<b>68.68%</b>
		ResNet-18	89.66%	90.71%	<b>91.32%</b>

Table 4: Summary of tuning performance with a deadline.

surrogate models with Hydro using different scaling ratios  $S = 2, 4, 8$ , where  $S = 1$  represents the target model. We train each model for 100 epochs on the CIFAR-10 dataset with a fixed seed=1. Since the HPO job is essentially a ranking problem of hyperparameter configurations, we mainly care about whether the order is maintained especially for the top configurations, namely hyperparameter transfer effect. From the result, it is obvious that the performance ranking of hyperparameters transfers well across different scaling ratios. Admittedly, configurations G and H are swapped when  $S \geq 4$ , but it has no influence on the final tuning result since they perform poorly and top configurations keep a consistent ranking. Besides, the wider model always outperforms the narrower one under the same hyperparameters, which is inline with MU parametrization theory and demonstrates that surrogate model can effectively transfer multi-dimensional hyperparameters.

Additionally, we also validate the inter-trial fusion effect, which is another key mechanism of Hydro. Figure 10 (e) shows the training loss curves of trials C, E, H and their fused versions. We select these three trials because their batch size and momentum are consistent and only differ in lr. As we can see, the convergence curves of the fused model well overlap with the original standalone training curves, which demonstrates that inter-trial fusion is a mathematically equivalent transformation and does not affect the model convergence.

### 6.3 End-to-End Performance of Hydro Tuner

To cover most hyperparameter tuning scenarios in practice, we conduct end-to-end experiments across 6 workloads with different settings and 3 common tuning paradigms (case I~III). Note that Hydro Tuner adopts a fixed resource size (without enabling Hydro Coordinator) for fair comparisons.

**Case I: single-fidelity tuning.** When a user seeks for extremely excellent model performance with ample resources, single-fidelity tuning is applied to avoid missing the best hyperparameter configuration. Table 2 summarizes the Hydro

Figure 11: Summary of the end-to-end results. Bars indicate tuning makespan and points represent final model accuracy.

improvement on single-fidelity tuning over different sizes of workloads, where we apply  $S = 16$  for XL models and  $S = 8$  (default value) for other models. Since HPO jobs require completely training massive trials, we perform each experiment twice and report their average results on time reduction and tuned model quality over Ray. Besides, we obtain Ray tuning time of XL experiments based on simulation due to their unacceptable tuning cost, and adopt the official hyperparameter configurations [16, 24] to train the model as quality baselines. The target model training time is included in Hydro.

From the table, we can see that Hydro substantially outperforms Ray by 8.7~78.5× in time reduction, while obtaining better final model quality. The time reduction mainly derives from two aspects: (1) *Less resource demand of trials*. For instance, the scaled GPT-3 XL trials do not require distributed training. For smaller models, Hydro further applies inter-trial fusion to improve trial concurrency and resource utilization. (2) *Smaller model trains faster*. Each trial has fewer FLOPs (Figure 3) to compute, which is more obvious on larger models. Additionally, we also observe that the effect of Hydro is more evident for larger models, with more intensive trials and fewer resources. This reflects Hydro is more suitable for large-scale HPO jobs with limited resources, which is hard to handle by existing systems.

**Case II: multi-fidelity tuning.** When a user desires to obtain a good model with a relatively lower cost, multi-fidelity tuning is applied to search hyperparameters efficiently. Table 3 reports the Hydro performance on multi-fidelity tuning. We keep the same experiment settings as Case I, except using half GPU resources. Besides, we configure ASHA [63] with  $bracket = 1, grace = 3, reduction = 3$ . We observe that Hydro can achieve 5.8~33.4× reduction over Ray. Hydro can further benefit ASHA due to its much higher concurrency, which prevents the inaccurate promotion issue of ASHA [66]. Furthermore, we find that Hydro can also slightly improve the final model quality, which is mainly due to the different model initialization and more balanced layer-wise training rate configuration by Hydro parametrization. The results are also in line with Figure 1 that Hydro delivers a lower loss.

**Case III: tuning with a deadline.** When a user wants to get a model as good as possible by a fixed deadline, budget-bounded ASHA is applied. We simply evaluate two models with a deadline of 15 minutes as shown in Table 4. Hydro

Figure 12: Ablation study. (a) Effect of inter- or intra-trial fusion. (b) Makespan of different scaling ratios.

Figure 13: Sensitivity analysis of  $S$  and AMP on ResNet-18. (a) Accumulated throughput. (b) GPU memory footprint.

outperforms other baselines in final model accuracy within a limited time since it can well hide the target model training time inside the surrogate model tuning with Eager Transfer.

**End-to-end result visualization.** Figure 11 summarizes the makespan and accuracy of VGG-11 and ResNet-18 across different tuning algorithms and baselines. We note that Ray and Ray-ES share the same accuracy point since elastic and GPU sharing have no effect on the final model quality. The surrogate-based tuning (Hydro) can significantly reduce the search makespan without sacrificing the model accuracy. Due to the page limit, we only select these two models for presentation because of their relatively obvious efficacy of Ray-ES. Ray-ES has less improvement over Ray for larger models like WideResNet-50, since it cannot benefit from GPU sharing and the elastic improvement is limited (only for later stage).

## 6.4 More Evaluation on Hydro Tuner

**Ablation study of fusion.** Figure 12 (a) reveals an interesting observation that Hydro can only achieve very limited improvement over Ray if inter-trial fusion is disabled, even though we have scaled the model by  $8\times$ . This is because GPUs are underutilized for such small models and there is no evident training speedup although we scale the model. Hence, it is important to combine Model Shrinker and Trial Binder to achieve the desired performance. Additionally, we also evaluate the effect of intra-trial fusion. However, we find its improvement is limited on small models.

**Sensitivity analysis of scaling.** Figure 13 clearly presents the effect of the scaling ratio  $S$  on GPU memory and accumulated fused trial throughput, where the normalization base is the throughput of the target model. We find that the peak throughput increases linearly along with  $S$ . GPU memory also shows

Figure 14: GPU utilization of HPO systems on ResNet-18.

Figure 15: Visualizing Bubble Squeezer effect via DCGM. Two iterations of the first pipe stage are presented. The execution periods of the HydroTrial are highlighted by red arrows.

a similar pattern. In Figure 12 (b), we further evaluate the effect of the scaling ratio  $S$  on the overall tuning time. Hydro can continuously obtain benefits from higher scaling ratios. Besides, the final model accuracy maintains stable.

**Sensitivity analysis of AMP.** Figure 13 analyzes the effect of mixed precision training (i.e., AMP [15]), where solid and dashed lines represent the settings without and with AMP, respectively. We can find that the peak throughput can be further improved via enabling AMP. Besides, its effect on memory is also obvious, improving nearly  $2\times$  maximum fusion count.

**Impact on GPU utilization.** Figure 14 plots the GPU utilization traces on one GPU for 300 seconds using different HPO systems. We employ NVIDIA DCGM [11] to record SM Activity as GPU utilization. It is obvious that Hydro can achieve much higher GPU utilization than other baselines owing to the superior capability of inter-trial fusion [110].

**Overhead analysis.** We perform the overhead analysis on the ResNet-18 multi-fidelity tuning workload. Its overhead mainly derives from two aspects: (1) *profiling* accounts for 0.8%; (2) *defusion* (including trial restart) accounts for 3.3%. The associated overhead is minor when weighed against the substantial enhancements in the tuning efficiency of Hydro.

## 6.5 Hydro Coordinator Evaluation

**Bubble Squeezer.** To evaluate the impact of Bubble Squeezer, we interleave HydroTrials with a large GPT model over 32 A100 GPUs containing 4 pipeline stages on 4 nodes, which is implemented based on DeepSpeed [96] along with MegatronLM [56, 88, 102]. We measured the SM activity with and without Bubble Squeezer in Figure 15. Two traces are collected separately and we align them at the beginning of the figure. For the original GPT training, since the only active

kernel in the bubble is NCCL kernel for communication, the SM activity is extremely poor (about 2%) during the bubble. Hydro utilizes the unused SMs and achieves a relatively high SM utilization at about 50%, with no evident slowdown to the GPT model training. Here the HydroTrial is ResNet-18 model with fusion count  $F = 16$ , obtaining around 15% of exclusive throughput. We also measure the throughput influence of direct colocation and find it causes unacceptable interference (about 12% slowdown for the large model). Additionally, we further simulate the end-to-end performance of Bubble Squeezer. Here we set that the Hydro tuning job can only apply 1 exclusive GPU since most resources are occupied by the large model. We find the makespan of the tuning job can be greatly reduced by  $2.7\times$  with the free lunch.

**Heterogeneity-Aware Allocator.** We create a tiny cluster partition with 2 A100 and 2 V100 nodes (32 GPUs in total) to evaluate the impact of Heterogeneity-Aware Allocator. Besides, we uniformly sample 20 middle-size HPO jobs from Table 3 and randomly generate their job arrival time within one hour. Compared to resource-agnostic allocation, we find Heterogeneity-Aware Allocator achieves approximately a 1.3x reduction in the average job completion time.

## 7 Discussion

**Limitations.** Despite the extraordinary performance, Hydro’s surrogate-based tuning paradigm does have three limitations: (1) Hydro parametrization does not support regularization hyperparameters, such as weight decay and dropout, as elucidated in §4.1. (2) Hydro does not allow for any customized initialization techniques because Hydro implements its own automatic layer-wise re-initialization mechanism, which plays a crucial role in parameterization. (3) Hydro does not support fine-tuning since its theory is built atop i.i.d. samples (requiring the same dataset). Nevertheless, Hydro can deliver qualified models for most cases.

**Future work.** In the future, we plan to improve our work in following directions. (1) Supporting more DL frameworks like TensorFlow [19] and JAX [35]. (2) Considering more resource dimensions like CPU and network bandwidth besides GPU [83, 128], such as implementing the dataloader fusion of trials to further alleviate I/O contention. (3) Expanding the application scenarios such as cloud environments. It presents an opportunity for dynamic selection of heterogeneous spot instances, which can yield substantial cost savings [82, 106]. (4) Enabling partial model fusion across trails with minor architectural differences (e.g., add/remove/modify a few layers/blocks). Furthermore, Hydro can integrate model matching technique from ModelKeeper [60] to identify the models with similar architectures across jobs from different users and achieve cross-job level fusion, which can significantly improve cluster efficiency.

## 8 Related Work

**AutoML systems.** Automated Machine Learning (AutoML) refers to the process of automating the tasks associated with

optimizing ML model performance. In general, AutoML comprises two essential components: HPO and Neural Architecture Search (NAS). NAS systems (e.g., Retiarii [127], ModularNAS [74]) aim to discover the optimal model architecture for a specific task. On the other hand, HPO focuses on optimizing the hyperparameters of a fixed architecture, usually separate from NAS. Our work primarily concentrates on HPO.

Prior HPO systems like HyperSched [71], Rubberband [82] and Seer [32] support elastic training to allocate more GPU resources to promising trials, which is also supported in Hydro. Elastic training can make use of idle GPUs but fails to improve single GPU utilization. On the other hand, Fluid [125] further leverages NVIDIA MPS [13] technique to allocate multiple trials on a single GPU. HFTA [110] achieves inter-trial fusion on a shared accelerator. They can improve hardware utilization but only work well on tiny models (e.g., AlexNet [58], PointNet [93]). Based on the unique surrogate-base tuning nature, Hydro significantly extends the fusion application scope via model scaling and achieves automatic model fusion with minimum manual effort.

**Pipeline parallelism and interleaving execution.** Recent studies exploit bubbles induced by pipeline parallelism from multiple angles. Bamboo [106] fills redundant computations into bubbles to provide resilience and fast recovery for preemptible cloud instances. EnvPipe [26] selectively lowers the SM frequency of bubble periods to save energy. Unlike them, Hydro leverages bubbles to train HPO trials via interleaving execution, which is inspired by some prior works. For instance, Wavelet [109] and Zico [73] reduce the GPU peak memory based on interleaving. Muri [128] supports multi-resource interleaving to reduce contention.

## 9 Conclusion

This paper presents Hydro, a surrogate-based hyperparameter tuning service that provide job and cluster level optimization via automated model scaling, fusion and interleaving. Our experiments show that Hydro can dramatically reduce the tuning makespan and improve the cluster resource utilization.

## Acknowledgments

We sincerely thank our shepherd, Mathias Lécuyer, and the anonymous OSDI reviewers for their valuable comments on this paper. We also want to thank Greg Yang from Microsoft for the theory part support, Richard Liaw and Antoni Baum from Anyscale for the system development assistance, Shang Wang and Xin Li from UofT for their insightful discussion on inter-trial fusion, Shenggan Cheng and Shenggui Li from NUS for their constructive feedback on bubble squeezer. Additionally, we thank Li Ma and Shixin Yu for their technical support, as well as generous hardware resources from Shanghai AI Laboratory. This study is supported under the RIE2020 Industry Alignment Fund - Industry Collaboration Projects (IAF-ICP) Funding Initiative, as well as cash and in-kind contributions from the industry partner(s). Zhisheng Ye, Meng Zhang and Qiaoling Chen contribute equally to this work.

## Abstract

The increasing size of input graphs for graph neural networks (GNNs) highlights the demand for using multi-GPU platforms. However, existing multi-GPU GNN systems optimize the computation and communication individually based on the conventional practice of scaling dense DNNs. For irregularly sparse and fine-grained GNN workloads, such solutions miss the opportunity to jointly schedule/optimize the computation and communication operations for high-performance delivery.

To this end, we propose **MGG**, a novel system design to accelerate full-graph GNNs on multi-GPU platforms. The core of MGG is its novel dynamic software pipeline to facilitate fine-grained computation-communication overlapping within a GPU kernel. Specifically, MGG introduces GNN-tailored pipeline construction and GPU-aware pipeline mapping to facilitate workload balancing and operation overlapping. MGG also incorporates an intelligent runtime design with analytical modeling and optimization heuristics to dynamically improve the execution performance. Extensive evaluation reveals that MGG outperforms state-of-the-art full-graph GNN systems across various settings: on average  $4.41\times$ ,  $4.81\times$ , and  $10.83\times$  faster than DGL, MGG-UVM, and ROC, respectively.

## 1 Introduction

Over the recent years, graph-based deep learning has attracted lots of attention from the research and industry communities. Among various graph-learning methods, graph neural network (GNN) [21, 43, 49] gets highlighted most due to its success in many deep learning tasks (e.g., node feature vector (embedding) generation for node classification [11, 13, 19] and link prediction [7, 22, 42]). GNNs consist of several layers, where layer  $k+1$  computes the embedding for a node  $v$  based on the embeddings at the previous layer  $k$  ( $k \geq 0$ ) by applying

$$a_v^{(k+1)} = \mathbf{Aggregate}^{(k+1)}(h_u^{(k)} | u \in \mathbf{N}(v) \cup h_v^{(k)})$$
$$h_v^{(k+1)} = \mathbf{Update}^{(k+1)}(a_v^{(k+1)})$$

where  $h_v^{(k)}$  is the embedding of node  $v$  at layer  $k$ . The *Aggregate* function accumulates neighbors'  $\mathbf{N}(v)$  embeddings of node  $v$ . The *Update* function consists of a fully-connected NN layer. The neighbor aggregation (*Aggregate*) is the key bottleneck that dominates the overall computation due to its high computation sparsity and irregularity [46, 50]. Compared with conventional graph analytics (e.g., random walk [14, 39]), GNN features higher accuracy [21, 49] and better generality [16, 55] on various applications.

GNN computation on large input graphs (millions/billions of nodes and edges) usually counts on powerful multi-GPU platforms (e.g., NVIDIA DGX [35]) for scaling up the performance. The multi-GPU system (that can potentially store all data required for the computation in the aggregate memory of all GPUs on a single machine) can benefit from aggregated memory capacity and bandwidth (HBM and NVLinks) with more GPUs. There is also a popular trend for state-of-the-art hyper-scale systems employing GPU-centric building blocks. For example, the recent NVIDIA DGX SuperPod [33] consists of  $32 \times$  DGX-H100 servers (each with  $8 \times$  H100). Unfortunately, the runtime performance of GNNs does not scale proportionally with the aggregated compute capability and memory capacity of the platform. This is mainly because the irregular and sparse local memory access of neighbor aggregation in the single-GPU settings now “scales” to more expensive inter-GPU communication (i.e., remote memory access). Such intensive inter-GPU communication becomes the new critical path of multi-GPU GNN execution and offsets the performance gains from multi-GPU computation parallelism.

Based on this observation, we highlight a more promising way of formalizing GNN computation on multi-GPU systems. Our key insight is that GNN execution can be more precisely abstracted as a fine-grained dynamic software pipeline to encourage communication and computation overlapping, which will largely hide the communication cost. The opportunities for building such fine-grained pipelines widely exist at different granularities in GNNs. For instance, on a single graph node, the remote neighbor access can be overlapped with the local neighbor computation. Among different graph nodes,

Figure 1: Overview of MGG.

the remote neighbor access for certain nodes would potentially be overlapped with the local neighbor computation of some other nodes. However, prior research could hardly exploit such benefits since they rely on hardware and software infrastructures tailored for coarse-grained [18, 28] and regular communication patterns [12, 26]. To capitalize on the fine-grained pipelining benefits, there are three major challenges.

The first challenge is *how to craft the pipeline structure*. A work-efficient pipeline for GNNs demands comprehensively considering multiple factors (e.g., the operations and the number/granularity of each pipeline stage) to best fit the GNN algorithm and multi-GPU computation/communication. The second challenge is *how to map the pipeline to the GPU processing units*. Given the GPU’s architectural complexity (e.g., multi-granular processing units and multi-layer memory hierarchy), different mapping and primitive choices would bring performance and design flexibility tradeoffs. The third challenge is *how to find and adapt toward the “optimal” pipeline configuration swiftly*. Given the diversity of GNN inputs (e.g., graph structures) and hardware (e.g., different types/numbers of GPUs), pinpointing the best-off design configuration with high-performance delivery relies on combined insights from the properties of the software pipeline, GNN inputs, and GPU programming and execution paradigms.

To this end, we introduce a set of principles for multi-GPU GNN acceleration via a fine-grained dynamic software pipeline. *To construct fine-grained pipelines*, the original coarse-grained irregular GNN computation should be broken-down into fine-grained operations. The joint optimization of the GNN workload granularity and data layout should be carried out to facilitate operation overlapping. *To map pipelines to GPUs*, the proper GPU logical processing units (e.g., thread, warp, and block) should be selected for promoting GPU kernel efficiency and design flexibility. In addition, the right choice of communication primitives (e.g., NVSHMEM [36]) should be determined to provide fine-grained inter-GPU communication support. *To adapt pipelines dynamically*, customized kernel templates with tuning knobs should be devised. This will help to maintain pipelining effectiveness across a diverse range of GNN inputs and hardware platform settings.

We crystallize the above principles into MGG<sup>1</sup>, a holistic system design and implementation for multi-GPU GNNs (Figure 1). Given the GNN models and inputs, MGG will automat-

ically generate pipeline-centric GPU kernels for multi-GPU platforms and dynamically improve the kernel performance based on runtime feedback. The core of MGG is its **Kernel & Runtime Manager**, which constructs GNN-tailored pipelines and maps such pipelines to proper communication primitives and GPU logical processing units. It can also dynamically orchestrate GPU kernels based on new configurations. MGG also incorporates a **Runtime Parameter Optimizer**, which will monitor the performance (e.g., latency) from the actual execution and generate new configurations for the next iteration based on the analytical performance model and optimization heuristics. To the best of our knowledge, we are the first to explore the potential of GPU kernel operation pipelining for accelerating irregular GNN workloads. Moreover, MGG can be generalized to other applications (e.g., deep-learning recommendation model (DLRM) [31]) that are sharing similar irregular communication demands (§7.3).

Overall, we make the following contributions in this paper:

- We propose a GNN-tailored pipeline construction technique (§4) with pipeline-aware workload management and hybrid data placement, for efficient communication-computation pipelining in a GPU kernel.
- We introduce a GPU-aware pipeline mapping strategy (§5), encompassing warp-based mapping and pipelining, and specialized memory designs and optimizations to comprehensively promote kernel performance.
- We devise an intelligent runtime with lightweight analytical modeling and optimization heuristics to dynamically improve the performance of GNN training (§6).
- Comprehensive experiments demonstrate that MGG can outperform state-of-the-art multi-GPU GNN systems across various GNN benchmarks. Additionally, MGG can be generalized to other DL applications, like DLRM.

## 2 Related Work

Recent deep-learning applications expand their scope from handling structured dense inputs (e.g., images) to unstructured sparse inputs (e.g., graphs). Along with such algorithmic/application expansion is the exploration of new system designs and optimizations for more efficient deep learning. One of the most important topics is the ability to handle large-scale inputs, which are usually out of the computation and memory capacity of one GPU. For scaling regular deep-learning applications, like dense DNNs, various abstractions (e.g., data and model parallel) and high-performance communication libraries (e.g., NCCL [34]) have been developed. While the scaling approach for irregular GNN applications is still initial and suffers from unsatisfactory performance.

Compared to scaling dense DNNs, scaling sparse GNNs is significantly more challenging. The irregular fine-grained sparse GNNs workload cannot fit the regular coarse-grained

<sup>1</sup><https://github.com/YukeWang96/MGG-OSDI23-AE.git>

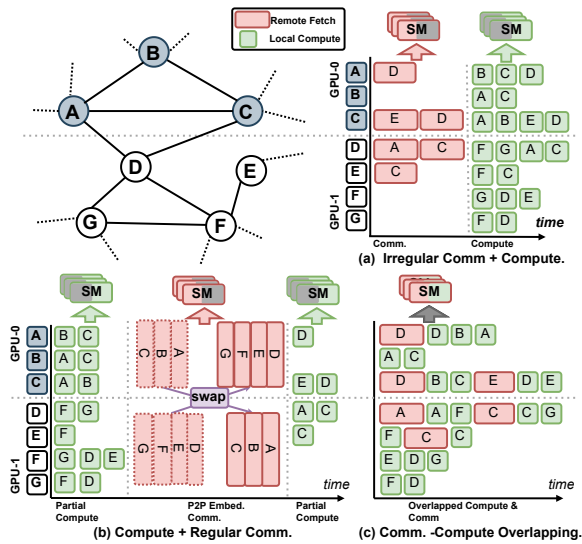

Figure 2: Different Multi-GPU GNN strategies for computation and communication. Note that red and green boxes indicate aggregation workload on remote and local neighbors. “SM” boxes with grey areas indicate potential idleness.

workload abstraction for dense DNNs. The cost of irregular communication in GNNs cannot be easily amortized by simply batching more requests as dense DNNs due to their randomness and sparseness. Scaling strategies largely vary among different GNN inputs while tiling/schedule strategies would be reused across different inputs of dense DNNs. Therefore, an array of dedicated designs have been introduced to scale the sparse GNNs, focusing on three major directions.

**Operator Specialization for Sparse Communication:**

This is the mainstream solution that treats the communication as a standalone operator for irregularly sparse GNN communication (Figure 2(a)). DGL [45] is the state-of-the-art GNN framework and its most recent update incorporates PyTorch-Direct [28] (a GNN-tailored communication design based on zero-copy memory [41]) for large-scale GNN training across GPUs. Work from [6] introduces a communication planning algorithm for distributed GNNs by considering links, communication, contention, and load balancing. However, these efforts optimize the communication standalone and thus miss the opportunities to jointly optimize computation and communication operations/schedules which can potentially reduce the overall latency and improve GPU utilization.

**Algorithm Modification for no Communication:**

The second typical type is to eliminate irregular communication by altering algorithms [25, 45, 51]. They harness various algorithmic adaption solutions, such as neighbor sampling and mini-batch to prefetch the remote neighbors to local devices, and then train the GNN model in a data-parallel fashion as the traditional dense DNN. However, existing research [8, 18] shows that such an algorithmic modification would compromise the accuracy of GNN models compared to the original

GNNs. It would also destabilize the algorithmic performance (e.g., the lower convergence speed and final accuracy) under different inputs and sampling configurations.

**Schedule Transformation for Dense Communication:**

The third type is to transform irregular communication to regularized communication (e.g., AlltoAll, P2P), which has been optimized by existing communication kernels (Figure 2(b)). ROC [18] delegates communication to its underlying NVIDIA Legion runtime [5], which manages irregular remote neighbor access via a DMA engine. It batches fine-grained embeddings into large embedding tiles on CPUs to facilitate coarse-grained data movement between the host and GPUs. NeuGraph [26] tiles the large node embedding matrices by rows (as embedding chunks) and then forwards each chunk to GPUs sequentially via coarse-grained P2P communication. P3 [12] spots the potential of transforming irregular embedding communication to regular all-to-all communication for embedding column tiles. However, this type of effort would introduce many unnecessary data movements and non-trivial overhead to transform original algorithms and data inputs.

To sum up, existing designs explore solutions in a limited scope and have yet to extend their solution search to a broader context by exploring the synergy between the multi-GPU GNN workloads, GPU execution paradigms, and communication patterns. Therefore, these designs could hardly enjoy the full potential of multi-GPU platforms.

**3 Motivation**

Different from prior solutions, we propose a new view for multi-GPU GNN workload. We spot that by removing the explicit barrier between the computation and communication stage in multi-GPU GNNs, we can co-schedule the operations from both stages in a holistic way that can reduce the GPU resource idleness and promote performance (Figure 2(c)). For example, when GPUs initiate remote access requests and are waiting for the arrival of remote data, the idle cycles of GPUs can be fulfilled by other local computing workloads. Such insight enables us to abstract the multi-GPU GNN workload as a fine-grained dynamic software pipeline for communication and communication overlapping. Specifically, “Fine-grained” means that the operations at each pipeline stage are tiny (e.g., the aggregation of one neighbor’s embeddings) versus DNN layers. “Dynamic” means that the division of computation into pipeline stages would vary among different inputs in contrast to DNNs with a relatively fixed pipeline. Such a new design is motivated by our three major observations.

**GNN Workload Speciality:**

The first observation reveals the specialty of GNN workloads, which feature two major types of partial dependency that facilitate pipelining [1]. The first type is the fine-grained neighbor aggregation dependency, where the neighbor embeddings of individual graph nodes are aggregated either sequentially or in parallel with proper synchronization. The second type is the dynamic execution

Listing 1: NVSHMEM APIs in CUDA C.

4 int gpu_id = nvshmem_team_my_pe(NVSHMEMX_TEAM_NODE);
5 // Set the GPU based on its device ID on CPUs.
6 cudaSetDevice(gpu_id);
7 // Define NVSHMEM memory visible for all GPUs on CPUs.
8 d_shared_mem = (void*) nvshmem_malloc (num_bytes);
9 // Define global memory visible only for the current GPU.
10 cudaMalloc((void**) &d_mem, num_bytes);
11 // Remote access API called by a thread/warp/block.
12 __device__ nvshmem_float_get_{warp/block}(void *dst, const
    void *src, size_t nelems, int src_gpu_id);
13 // Sync all GPUs within an NVSHMEM context on CPUs.
14 nvshmem_barrier_all();
15 // Release NVSHMEM objects on CPUs.
16 nvshmem_free(d_shared_mem);
17 // Terminate the current NVSHMEM context on CPUs.
18 nvshmem_finalize();

```

dependency on limited processing units, where different operations would compete for limited GPU resources (e.g., SMs) during the runtime. Such two types of dependencies expose new opportunities for us to amortize communication costs by overlapping neighbor aggregation from different nodes.

**GPU Execution Characteristics:** The second observation highlights the characteristics of the GPU execution paradigm. One key design principle of GPUs is their massive computation/communication parallelism to amortize the unit cost of individual computation/communication operations [40]. The underlying mechanism of GPU hardware design to facilitate this is to simultaneously schedule multiple logical processing units (e.g., threads/warps/blocks) to share the hardware processing units (i.e., GPU SMs). Such a design provides the essential ingredient for pipelining, which is that computation and communication operations can co-run on the same units at the same time to fulfill the idle GPU cycles and maximize the utilization of the GPU hardware processing units. Moreover, with the precise control of GPU kernel launching parameters (e.g., the size of the block and shared memory), the effectiveness of co-running heterogeneous operations can be adjusted so that we can flexibly accommodate different inputs while maintaining high-performance delivery.

**Multi-GPU Programming Support:** The third observation features the recent advancement of the GPU communication technique and its programming support. The one highlighted most is the NVSHMEM [36], which provides GPU intra-kernel APIs for fine-grained (several to tens of bytes) inter-GPU communication (Listing 1). NVSHMEM is the main communication backend for MGG. Other existing techniques such as Zero-copy memory can also serve as an alternative to NVSHMEM for fine-grained communication. The performance will be similar while NVSHMEM offers better programmability. Some other traditional strategies for inter-GPU communication, would either offer too

coarse-grained communication solutions (e.g., unified virtual memory [38] uses KB-level communication granularity) or resort to the default communication strategies of existing multi-GPU-based runtime system (e.g., NVIDIA Legion [5]) without GNN-tailored communication optimization.

These observations and insights motivate MGG, a holistic multi-GPU GNN system with a novel view of GNN workloads as an operation pipeline. MGG automates the pipeline construction, detailed pipeline mapping, and dynamic input-driven pipeline adaption, to improve the GNN scaling.

## 4 GNN-tailored Pipeline Construction

Constructing a GNN-tailored pipeline are facing two major challenges: 1) *How to effectively partition and schedule multi-GPU GNN workloads* so that pipeline efficiency can be maximized; 2) *How to properly layout input* so that the hierarchy of GNN inputs and the memory/storage of multi-GPU systems can be carefully matched to facilitate pipeline execution. MGG addresses these challenges with *Pipeline-aware Workload Management* and *Hybrid GNN Data Placement*.

### 4.1 Pipeline-aware Workload Management

Managing irregularly sparse GNN workloads for pipelining is challenging and could hardly benefit from the prior practice and exploration of the DNN pipeline [29, 30].

**Difference from DNN pipeline** *First*, balancing the GNN workloads among GPUs has to jointly optimize the computation capacity and the computation/communication irregularity. While the DNN pipeline only needs to balance the computation/memory capacity, since its pipeline stages are well-structured and their inputs are regularly dense. Distributed DNNs require dense regular communication (e.g., Allreduce) that is naturally fit for existing GPU interconnects optimized for throughput and has been optimized by many libraries (e.g., NCCL). In contrast, distributed full-graph GNN (with the entire graph cached on GPUs) is much more challenging since it requires sparse irregular communication that is naturally at odds with the existing hardware interconnects, and fewer efforts have optimized its performance. *Second*, the GNN pipeline workload is more irregular and non-structural and can easily cause pipeline stalls/bubbles. For example, remote neighbor aggregation would have different stages (remote access + aggregation) compared with local neighbor aggregation (local access + aggregation), making it challenging to mix those two heterogeneous workloads. While in the DNN pipeline, all inputs should consistently pass through the same pipeline stages. *Third*, GNN pipeline stages are more fine-grained (e.g., fetching individual embeddings) compared with coarse-grained layers (e.g., GEMMs and Convolutions) in the DNN pipeline. Such small workload granularity enables different pipeline stages to overlap with each other on GPU processing units, like Streaming Multiprocessors (SMs). In

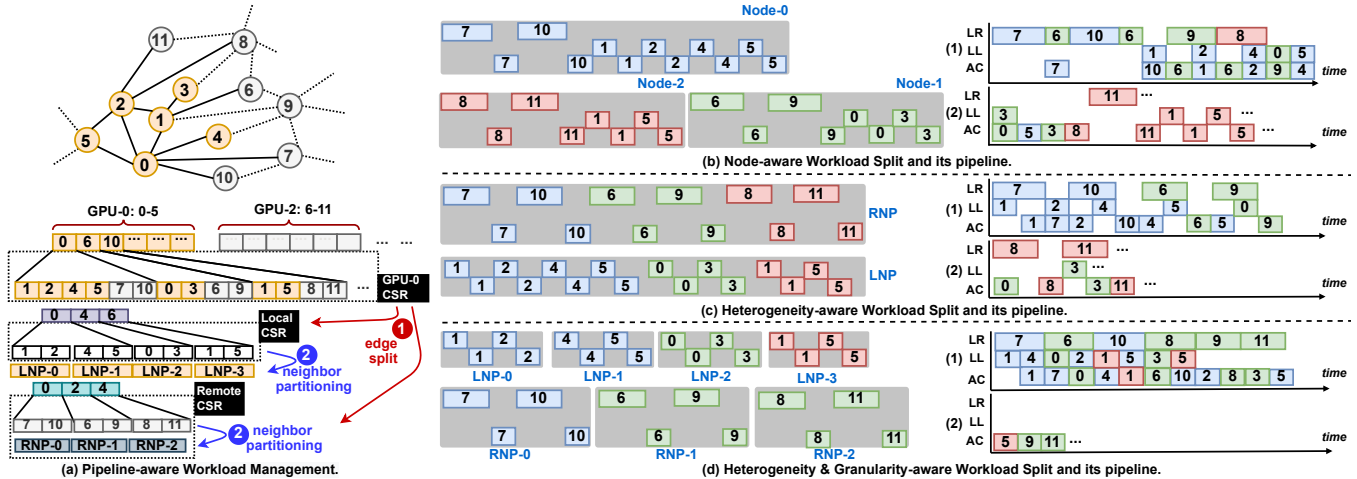

Figure 3: (a) Pipeline-aware workload management. “LNP”/“RNP” indicate local/remote workload partitions. (b)(c)(d) Different strategies of workload decomposition and pipelining. Each box indicates a certain (local/remote) aggregation workload and its length indicates its relative latency. “LR”: loading remote neighbors, “LL”: loading local neighbors, “AC”: aggregation computation. Each grey rectangular shadow indicates a workload partition to be processed by one GPU processing unit. (1) and (2) indicate that the same pipeline is chunked into two parts along its time axis due to space limitations.

contrast, DNN pipelines can only overlap layer-wise computation and communication operations among different GPUs.

With the above insights, we propose a three-stage dynamic software pipeline design. The three stages include *loading remote neighbors (LR)*, *loading local neighbors (LL)*, and *aggregation computation (AC)*. Aggregation of a certain neighbor will only take two stages. The remote neighbor aggregation will take the stage LR and AC while local neighbor aggregation will take the stage LL and AC. The stage-wise pipelining is achieved with two steps: 1) assigning aggregation workload to different GPU logical processing units (LPUs), like warps and blocks, and 2) scheduling different LPUs on the same GPU SM to overlap their execution. Three-phase pipeline can generalize to different GNN models, which essentially consist of the different numbers of basic remote and local operations. For example, GCN has a lower local-versus-remote operation ratio while GAT features a higher local-versus-remote operation ratio. Three-phase pipeline can also capture differences among inputs. For instance, a more sparse graph will have a higher remote-to-local operation ratio.

However, the direct construction and execution of such three-stage pipelines would be inefficient, because of its ignorance of GNN workload heterogeneity and irregularity on multi-GPU platforms. To address these challenges, MGG highlights a GNN-tailored pipeline construction strategy to build and optimize the software pipeline in three steps.

**Step-1: Workload-aware inter-GPU pipeline workload balancing.** This step aims to construct the “raw” pipeline and balance workloads among pipelines on different GPUs. Our insight is that GPUs with massive processing units (e.g., SMs) will serve many pipelines concurrently, and the key to maximizing GPU performance and utilization is to en-

sure that each pipeline will get a similar amount of workload, thereby avoiding execution critical path on certain “long” pipelines. We, therefore, develop a *range-constrained binary search algorithm* (Algorithm 1) based on prior graph partitioning exploration [3]. Our solution features a lower runtime cost to split the GNN input graph into chunks (one chunk per GPU) while balancing the number of edges within each chunk. Then the workload from the same chunk is grouped by nodes as *workload partitions* mixed local and remote neighbors (Figure 3(b)). From its potential execution pipeline, we can see many idle cycles (indicated by blank spaces in different pipeline stages) which would result in low pipeline efficiency and GPU resource occupancy. Note that in the software pipeline, workloads from different partitions can be overlapped as they will be processed by different LPUs. While the workloads from the same partition are sequentially processed by one LPU and their relative order should be maintained even after being mixed with other partitions.

**Step-2: Heterogeneity-aware pipeline bubble reduction.** The pipeline constructed from the previous step is still inefficient due to its scattered workloads among stages, namely pipeline bubbles. The optimization in this step is to minimize such pipeline bubbles for better pipeline efficiency. The key is to reduce the heterogeneity of workload partitions that hinders effective overlapping. To achieve this, we categorize the sparse multi-GPU GNN computation into two types. The first type has local neighbor access only, which has shorter execution latency. The second type has remote neighbor access, which features high latency overhead. We delicately handle different types of workloads via grouping (Figure 3(a)-1), where two separate CSRs for *local* and *remote* subgraphs will be built. The aggregation will be conducted on local and

        (eList), and the number of GPUs (numGPUs).
output :list of graph edge split points (numGPUs - 1).
1  outList = {};
2  lastPos = 0;
   /* Compute approximated #edges per GPU.          */
3  ePerGPU = (len(eList) + numGPUs - 1) / numGPUs;
4  for sId in [0, 1, ..., numGPUs - 1] do
5  |   nid = binSearch(nPtr, ePerGPU, lastPos, numNodes);
6  |   lastPos = nid;
7  |   outList[sId] = nid;
8  end
9  return outList;

   /* Search split points on nPtr.                  */
10 Function binSearch(nPtr, ePerGPU, lastPos,
    numNodes):
11 |   i = lastPos;
12 |   j = numNodes;
13 |   target = min(nPtr[i] + ePerGPU, nPtr[numNodes]);
14 |   while i < j do
15 | |   mid = (nPtr[i] + nPtr[j]) / 2;
16 | |   if mid > target then
17 | | |   j = (i + j) / 2;
18 | | |   else
19 | | |   i = (i + j) / 2;
20 |   end
21 |   return i;
```

---

remote subgraphs separately and followed by a result synchronization at the end. Such a remote-local split is also backed by the fact that on platforms with all-to-all GPU interconnections (e.g., DGX-A100/H100), accessing different GPUs under the same data granularity has approximately equal communication cost [24]. Such heterogeneity awareness in workload partitioning (Figure 3(c)) enables a more densely overlapped workload between the stage LR and LL/AC.

**Step-3: Granularity-aware intra-GPU pipeline enhancement.** While the second optimization improves pipeline efficiency by reducing the workload heterogeneity, there is still plenty of room for further enhancement. The optimization in this step is to facilitate a more balanced workload distribution among pipeline stages. This key is to find the proper workload granularity for local and remote subgraphs so that those originally sequentially processed workload partitions can be overlapped. Our key observation is that nodes in the local/remote subgraphs would have a diverse number of neighbors. Such a specialty makes it challenging for massively parallel GPUs to harvest the real performance gains due to the imbalance workload and diverged execution flow. Therefore, we approximate such coarse-grained irregular workloads with fine-grained fixed-sized partitions so that the workload imbalance across nodes can be amortized. For example, with 2 neighbors per partition (Figure 3(a)-②), we can get a more balanced workload among nodes in their local and remote

neighbor aggregation. With such granularity awareness, the individual pipeline can be further condensed along its time axis with more overlapping of the LL and AC stage. (Figure 3(d)). Meanwhile, the irregular workload can be more evenly distributed to GPU SMs for higher GPU utilization. On the other side, partition granularity should also be balanced with synchronization overhead, since more fine-grained partitioning can bring more parallelism at the cost of more synchronization overhead. This is because workloads from different partitions for the same target node need to be reduced via synchronization, like inter-thread shuffling and atomics.

MGG design can also be generalized to multiple machines with a minor adaptation. For example, in Figure 3(d), when there are inter-node (over Inifite-Band) remote neighbors (longer latency due to lower inter-node communication speed), the size of remote neighbor partitioning (RNP) should be adjusted to a smaller size (e.g., from 2 to 1 remote neighbor) to facilitate better overlapping with local computation.

## 4.2 Hybrid GNN Data Placement

In collaboration with our multi-step pipeline construction, we introduce a *hybrid GNN data placement* strategy to exploit the benefits of different types of memory in SHMEM-enabled multi-GPU systems. The major impact of such hybrid placement on pipelining is two-fold. First, placing GNN data in different memory spaces will lead to different ratios of local and remote workloads, thus, affecting workload balance among pipelines. Second, different memory spaces will offer different access performances (e.g., latency), thereby, affecting the execution efficiency of the individual pipelines, such as the number of pipeline bubbles.

Our strategy focuses on two major aspects. Firstly, for workload balance among pipelines, we leverage NVSHMEM “shared” global memory to store the node embeddings (NEs) of the whole graph (Figure 4 left). Our major consideration here is that such shared global memory space can be accessed by all GPUs with the approximated equal access speed, which is vital to facilitate a more even distribution of remote workloads to GPUs in terms of their size and unit access costs. In addition, NEs are generally large in terms of size (due to high dimensionality), which are beyond the device memory limit of a single GPU. Therefore, NEs are ideal to be placed in shared global memory space with sufficient space (with aggregated memory of different GPUs), which also provides direct remote access support across GPUs. Specifically, we will partition the NEs of input graphs into *n* equal-sized partitions (where *n* is the number of GPUs) and place each of them in one GPU’s shared global memory space.

Secondly, for the efficiency of individual pipelines, we allocate the “private” global memory space for storing partitioned graph structure (GP) data, which is only visible to kernels on the current GPU. Our key insight is that GP (e.g., edge lists), is all scalar values and usually small in size, and will only

Figure 4: MGG Storage Layout and Communication Pattern. Note that “NE-*i*” is the node embedding partition stored on the *i*-th GPU. “GP-*i*” is the neighbor partition processed by the *i*-th GPU. “GPU-*i* [lb, ub]” is the node-id range [lowerbound, upperbound] of the node embeddings on the *i*-th GPU.

be accessed by the local GPU. Therefore, GP is ideal to be placed in individual GPUs’ DRAM. Such a placement is also important to reduce unnecessary and inefficient remote access on those tiny scalars for fewer pipeline bubbles. In our design, GP data (e.g., edges) from private GPU global memory will be processed by a *address translation* unit for fetching correct NEs on local/remote GPU since the NE indices are rebased to zero on each GPU (Figure 4 right).

## 5 GPU-aware Pipeline Mapping

Efficient pipelining also demands effective mapping of well-constructed pipeline workload and their schedules to the low-level GPU logical processing units (e.g., GPU threads/warp-s/blocks) to overlap computation and communication. To achieve this, we propose *Warp-based Mapping & Pipelining* and *Specialized Memory Design & Optimization* to jointly optimize the pipeline execution efficiency, GPU utilization, and end-to-end design flexibility.

### 5.1 Warp-based Mapping & Pipelining

An effective pipeline mapping demands comprehensive consideration of two major aspects. 1) *Which type of GPU logical processing units (e.g., warps, blocks) should be used for pipeline workload partitions?* We choose GPU warp as the basic working unit to handle the workload of each partition. This is because threads in a warp can collaboratively work on different dimensions of a node embedding simultaneously. Whereas using a single or several threads (less than the size of a warp, 32 threads) would hardly explore the computation parallelism and would cause warp-level divergence. Besides, NVSHMEM remote access initiated by a warp of threads would merge the requests into one remote memory transaction to amortize the overhead. 2) *Which pattern of mapping should be used for benefiting pipeline execution efficiency?* The most straightforward way is to continuously map the neighbor partitions from the local and remote workload list to GPU warps with continuous IDs (Figure 5). However, this strategy would easily suffer from workload imbalance among GPU SMs. This is because warps with continuous IDs are

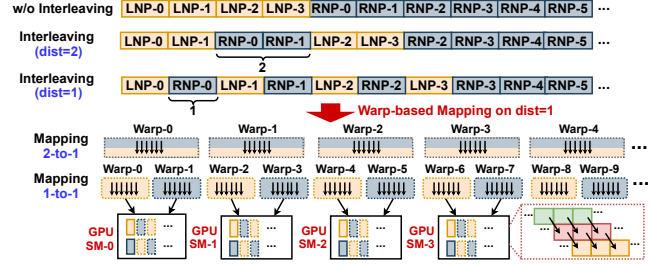

Figure 5: Warp-based Mapping and Pipelining. Note that “LNP” refers to the local neighbor partitions; “RNP” refers to the remote neighbor partitions. Workload and Warps are matched based on colors. Tiny boxes in GPU SM indicate decomposed workload operations for overlapped execution.

more likely to be placed into the same thread block, which is assigned to one SM for LNP processing. Therefore, SMs assigned with warps for handling remote neighbor partitions would lead to much longer latency than SMs assigned with warps for processing local neighbor partitions. Such a workload imbalance would lead to poor GPU utilization and runtime execution performance.

To this end, we introduce our novel *workload interleaving* strategy to balance the workload among SMs on GPUs. Each warp of threads running on GPU would handle one or more pairs of local/remote workload partitions. To more precisely calibrate the warp-to-SM mapping for different pipeline stages to achieve efficient pipelining, we introduce a new metric – *interleaving distance*. We give examples with the interleaving distance equals 1 and 2 for illustration (Figure 5). By mixing different types (both local and remote) of workload together, better GPU utilization can be achieved since when one warp is blocked for high-cost remote access, other warps that are working on local computation can still be served by the SMs warp scheduler for filling up these idle GPU cycles. Moreover, such a design would improve design flexibility. For instance, given an input graph with a selected neighbor partition size, we can adjust the size of interleaving distance and the workload per warp so that waiting cycles of the remote access can be hidden by the computation cycles of the neighbor aggregation. Thus, each warp can be fully utilized while the design can achieve sufficient parallelism.

MGG currently processes the neighbors of adjacent nodes (based on node-ids) to the same thread block where the same block will be scheduled on the same SM. If there are common remote neighbors for those adjacent nodes, their remote requests will be merged. Improving such locality requires reordering the graph nodes to maximize their common neighbors. Such an exploration is orthogonal to our current contribution. In future GPUs, there is a trend to explore the locality among independent processing units. For instance, in Hopper, several thread blocks can be grouped together as thread-block groups. We can explore the tradeoff between the locality benefits and group synchronization overhead.

## 5.2 Specialized Memory Design & Optim.

Efficient software pipelining also demands careful management of high-bandwidth shared memory for promoting data access efficiency and asynchronous primitives for exploiting intra-warp operation pipelining.

**GPU SM Shared Memory Layout:** Based on our MGG’s warp-based workload design, we propose a *block-level shared memory orchestration* to maximize the performance gains. We have several key insights for such a dedicated memory layout design within each thread block. *First*, our neighbor-partition-based workload will generate the intermediate results that can be cached at the high-speed shared memory for reducing the frequent low-speed global memory access. *Second*, NVSHMEM-based remote data access demands a local scratch-pad memory (e.g., registers, shared and global memory) to hold the remote data for local operations.

For the *local* neighbor aggregation, we reserve a shared memory space with  $D$  ( $D$  is the embedding dimension) floating-point numbers for embeddings of the target node in each neighbor partition so that threads from a warp can cache the intermediate results of partial reduction in shared memory. For the *remote* neighbor aggregation, the shared memory space is doubled  $2 \times wpb \times D$  ( $wpb$  is the warps per block). The reason is that we need the first half  $wpb \times D$  for caching the partial aggregation results of each warp and the remaining for the remotely accessed neighbor embeddings. For each MGG kernel design, we will first identify the warp-level information, like warp IDs. Then within each thread block, we define the customized shared memory layout by splitting the contiguous shared memory address into three different parts for neighbor ids, partial aggregation results, and the remotely-fetched node embeddings. We use the dynamic shared memory for design flexibility since those parameters (e.g.,  $wpb$  and  $D$ ) can only be determined at runtime. During execution, we will first calculate the total shared memory size per block and then pass it as a kernel launching parameter.

**Pipelined Memory Operation:** §5.1 has discussed assigning local (LNP) and remote (RNP) neighbor aggregation workloads to warps so that different warps can overlap their computation and communication to fully saturate the active cycles of the GPU SM scheduler. However, only exploiting the inter-warp communication-computation overlap is not enough to maximize the utilization of GPU resources. We further explore the overlapping of the computation and communication at the intra-warp level by carefully scheduling the memory operations. Figure 6(a) shows the case with two LNPs and two RNPs by using the synchronized remote access, we can just sequentially process the two LNPs and the two RNPs. The long-latency remote access can happen only after the completion of its preceding LNP. This could lead to a longer GPU stall for memory operations and low GPU SM utilization. Our profiling also shows that without overlapping, the remote access usually dominates the overall execution

Figure 6: Illustration of (a) w/o and (b) w/ asynchronous primitives for overlapping computation and communication of an individual warp. Note that the length of each rectangular box indicates the estimated latency cost of each operation.

(around 60% of overall latency) compared to the time for local data access plus the time for aggregation computation (around 40% of overall latency). Such observation justifies our design to mainly hide the latency from remote access.

To amortize the cost of remote access for each warp, we introduce *asynchronous remote memory operations* (Figure 6(b)). This improved design consists of two major steps. First, we can simultaneously launch the local memory access while initializing the remote memory access for fetching the node embedding (❶), therefore, the time for remote access can be amortized by the processing of LNP. Second, once the remote access is completed, the current warp will start aggregation on the remotely-fetched node embedding data (❷). The next step will start the new iteration of the previous two steps, which will process a new pair of LNP and RNP.

## 6 Intelligent Runtime Design

In this section, we will discuss our intelligent runtime design with performance/resource analytical modeling and heuristic-based cross-iteration optimization strategy.

**Performance-Resource Analytical Modeling:** The performance/resource model of MGG has two variables: *workload per warp (WPW)* and *shared memory usage per block (SMEM)*, which can be measured by

$$\begin{aligned} WPW &= 2 \cdot ps \cdot D \cdot dist, \\ SMEM &= ps \cdot wpb \cdot IntS + 2 \cdot wpb \cdot D \cdot FloatS \end{aligned} \quad (1)$$

where  $ps$ ,  $wpb$ , and  $D$  are the sizes of neighbor partition, warp per block, and node embedding dimension, respectively;  $dist$  is the interleaved distance of local/remote workloads (§5.1);  $IntS$  and  $FloatS$  are both 4 bytes on GPUs. To determine the value of the  $ps$ ,  $wpb$ , and  $dist$  of a given input graph, we will first compute the total number of warps by using

$$numWarps = \frac{\max\{local, remote\}}{dist} \quad (2)$$

where *local* and *remote* are the number of local and remote partitions, respectively. Then we compute the total number of

blocks and the estimated block per SMs by using

$$\begin{aligned} numBlocks &= \frac{numWarps}{wpb}, \\ blocksPerSM &= \frac{numBlocks}{numSMs} \end{aligned} \quad (3)$$

Later, based on our micro-benchmarking results on diverse datasets, we define our parameter search space and constraints: 1)  $ps \in [1 \dots 32]$  to balance the computation parallelism and synchronization overhead; 2)  $dist \in [1 \dots 16]$  to effectively overlap the computation and remote memory access; 3)  $wpb \in [1 \dots 16]$  to maintain SM warp scheduling flexibility for better occupancy and throughput; 4)  $numSMs \leq c_1$ ,  $SMEM \leq c_2$ , where  $c_1$  and  $c_2$  are hardware constraints [48], e.g., NVIDIA A100 has 108 SMs and 164KB shared memory per SM.

**Heuristic-based Cross Iteration Optimization** To optimize the design of MGG, the parameter  $ps$ ,  $dist$ , and  $wpb$  are initialized as the value 1 at the beginning. Then we optimize one parameter in each of the following iterations. *First*, we increase the  $ps$  to maximize the warp utilization. When further increasing the  $ps$  would also increase the latency, we would stop the search on  $ps$  and switch to  $dist$ . *Second*, we apply a similar strategy to locate the value of  $dist$  that can maximize the overlap of local computation and remote access. *Third*, we increase  $wpb$  to maximize the utilization of the entire SM. If any increase of  $wpb$  would increase the latency, we know that there may be too large thread blocks or too heavy workloads on individual warps that lower SM warp scheduling efficiency or computation parallelism. We would “retreat” (i.e., decrease)  $ps$  to its second-highest value if necessary and restart the increase of  $wpb$ . This optimization algorithm will stop when any decrease of  $ps$  and increase of  $wpb$  would lead to higher latency than the top-3 lowest latency. The latency of each iteration during the optimization will be recorded by a configuration lookup table. Finally, the configuration with the lowest latency will be applied.

This particular optimization order of parameters ( $ps$ ,  $dist$ , and  $wpb$ ) is based on two major aspects: (i) *Spatially speaking*, the granularity is from coarse-grained algorithm-level partitioning through  $ps$ , to medium-grained pipeline construction through  $dist$  (according to the partition plan), to fine-grained pipeline-to-warp fine-tuning through  $wpb$  (according to the pipeline design). (ii) *Temporally speaking*, the three optimizations are applied at loading-time ( $ps$  to decide layout), kernel initialization ( $dist$  to decide pipeline), and runtime ( $wpb$  to decide pipeline mapping), respectively.

The above parameter adaption for dynamic pipelining is vital for design/optimization generality. This is because the characteristics of graphs (#nodes/edges and embedding sizes) would lead to different efficiency of kernel pipelines. Our later experimental studies (as shown in Figure 11) demonstrate its benefits with up to 70% of performance improvements.

## 7 Evaluation

**Benchmarks & Datasets** Despite the diversity of GNN models, the fundamental computation and communication paradigm (vector-based scatter-gather operation) in multi-GPU GNNs remains the same. We evaluate two distinctive and representative GNN models on *node classification* tasks:

The first type of GNN model uses a *non-discriminated* neighbor aggregation strategy, where all neighbors contribute equally when doing the aggregation. We choose **Graph Convolutional Network (GCN)** [21], which is the most popular GNN model and is also the key backbone network for many other GNNs, such as GraphSAGE [16] and Differentiable Pooling [52]. We use *2 layers with 16 hidden dimensions* for GCN, which is also the setting from the original paper [21]. The computation of a 2-layer GCN can be expressed as

$$Z = \text{Softmax}(\hat{A} \text{ReLU}(\hat{A}XW^1)W^2). \quad (4)$$

where  $\hat{A}$  is the adjacent matrix of the input graph with self-loop edges, and  $X$  is the input node embedding matrix, where  $X \in R^{N \times D}$ ;  $N$  is the number of nodes in a graph;  $D$  is the size of node embedding dimensions.  $W^1$  and  $W^2$  are trainable weight matrices in layer-1 and layer-2, respectively.

The second type uses a *discriminated* neighbor aggregation strategy, where neighbors would contribute differently depending on their calculated edge-specific features. We choose **Graph Isomorphism Network (GIN)** [49], which aims to distinguish the graph structure that cannot be identified by GCN. Each layer of GIN can be expressed as

$$h_v^{l+1} = MLP^l((1 + \varepsilon^l)h^l + \sum_{u \in N_{(v)}} h_u^l). \quad (5)$$

where  $l$  is the layer ID and  $l \in \{0, 1\}$ ,  $MLP$  is a fully-connected neural network,  $h_v$  is the node embedding for node  $v$ , and  $N_{(v)}$  stands for the neighbors of node  $v$ . GIN mainly differs from GCN in its aggregation function, which introduces a weight parameter as the ratio of contribution from its neighbors and the node itself. In addition, GIN is the reference architecture for many other advanced GNNs with more edge properties, such as Graph Attention Network [43]. For GIN evaluation, we use *5 layers with 64 hidden dimensions*, which is also the setting used in the original paper [49]. Graphs (Table 1) used in our evaluation are large in their number of nodes and edges that demand multi-GPU capability for effective GNN computation. #Class is the output dimension

Figure 7: Performance comparison with DGL. Note that full-graph PAPER on DGL requires A100-80GB.

(#labels) for the node classification task. #Dim is the embedding dimension of the input graph.

**Baselines** In this evaluation, we compared MGG with several existing systems that support large full-graph GNN (i.e., caching the entire graph on GPUs) on multi-GPU platforms.

**1) Deep Graph Library (DGL)** [45] is the state-of-the-art framework for large-scale GNNs across GPUs. It leverages PyTorch-Direct [27] as the communication backend for GPU-initiated zero-copy memory access [41] to fetch neighbors embedding from the CPU host. **2) MGG-UVM** [20] is a GNN design by adapting MGG to leverage unified virtual memory (UVM). UVM has been highlighted in handling irregular graph computations (such as PageRank) on large graphs [20]. However, [20] is not open-sourced, we thus generalize the pipeline kernel designs and optimizations (§4 and §5) of MGG to build such a UVM baseline and incorporate optimizations from [20]. Note that UVM and zero-copy memory are different communication backends [1]. Thus, MGG-UVM does not implement zero-copy data transfer. We remark UVM is the key communication protocol before the new hardware support for fine-grained direct GPU-GPU communication (e.g., NVSHMEM). UVM is more coarse-grained and will require the engagement of CPUs (e.g., host memory management) for communication. The reason to use MGG-UVM is to show that if there is no advanced hardware support (e.g., NVSHMEM) for fine-grained direct GPU-GPU communication, the benefits of our elaborated pipeline can be offset by UVM communication overhead. **3) ROC** [18] is a popular distributed multi-GPU system for full-graph computation. ROC highlights its learning-based partitioning and leverages NVIDIA Legion [5] runtime for communication and task scheduling.

Other multi-GPU GNN designs, like NeuGraph [26] and P3 [12], are not publicly available. Initially, we plan to evaluate MGG on AMD ROC\_SHMEM [2]. However, as indicated in its document, the existing ROC\_SHMEM is an experimental prototype and is not officially ready to be applied in prac-

tice due to very strict software limitations (e.g., only supports ROCm v4.3) and hardware (e.g., only supports AMD GFX9 GPUs), which are quite challenging to find and deploy and not supported by any existing GNNs frameworks [6, 18, 28] for comparison. We believe that once ROC\_SHMEM becomes ready and generally applicable, MGG can be easily migrated to AMD multi-GPU platforms.

There is no existing design that can leverage GPU-to-GPU communication only for distributed full-graph GNN computation. We try our best to measure the best-possible baseline performance. DGL and ROC have longer latency in the earlier iteration due to cache warmup for node embedding on GPU memory. We thus perform warm up iterations until their per-iteration latency becomes stable, and then measure their performance with minimized CPU-GPU data movements.

**Platforms & Tools** The implementation of MGG consists of ~9K LoC. We compile and link MGG with CUDA (v11.2), OpenMPI (v4.1.1), NVSHMEM (v2.0.3), and cuDNN (v8.2) library. Our major platform is an NVIDIA DGX-A100 with dual AMD Rome 7742 processors (each with 64 cores, 2.25 GHz), 1TB host memory, and 8×A100 GPUs (40 GB) connected via NVSwitch, which offers 600 GB/s GPU-to-GPU bi-directional bandwidth. For the modeling study, we also leverage DGX-1 with 4×V100 GPUs connected via NVLinks. We use NVIDIA NSight Compute to get the kernel-level profiling metrics. Speedup is averaged over 100 runs.

## 7.1 End-to-End Performance

**Compared with DGL** In this section, we will compare with the state-of-the-art DGL framework, which leverages PyTorch-Direct for cross-GPU communication. We evaluate different datasets and platform settings (with 4 and 8 A100 GPUs). As shown in Figure 7, MGG outperforms DGL with averaged  $4.25\times$  and  $4.57\times$  speedups on GCN and GIN models, respectively. We also notice a trend that MGG demonstrates a more pronounced speedup with more GPUs. With the increasing number of GPUs, DGL suffers from heavy memory access contention, since multiple GPUs are initiating massive requests to access the neighbor embeddings on the CPU host memory. Another observation is that on GIN ( $D = 64$ ) with higher hidden dimensionality for smaller datasets (e.g., PROD and PROT), the performance gap between DGL and MGG is smaller compared to GCN ( $D = 16$ ) since as indicated in [28], zero-copy memory would be beneficial from more coarse-grained data movement (with larger embedding vector) that can saturate the PCIe cache line (128 Bytes). While such an advantage of DGL diminishes for those larger datasets (e.g., IT04 and PAPER) on GIN due to significantly increased sparsity and irregularity. In addition, compared with MGG, DGL assumes the one-size-fits-all communication strategy would work well for all input datasets. Therefore, it ignores the importance of the inputs and hardware properties, which would bring non-trivial (more than 30%) benefits (§7.2).

(a) GCN Model.

(b) GIN Model.

Figure 8: Performance comparison with MGG-UVM.

Table 2: Additional performance comparison of MGG and DGL on GraphSAGE and GAT.

Model	RDD	ENWIKI	IT04	PAPER	PROD	PROT	ORKT
SAGE	4.97×	1.76×	1.99×	3.53×	7.05×	3.39×	3.53×
GAT	2.65×	1.62×	2.06×	3.04×	2.06×	3.39×	3.04×

MGG can also be extended to cover other GNN models. The following results show the speedups of MGG over DGL on GraphSAGE with layerwise node neighbor sampling and GAT with dot-product edge attention. Table 2 shows that the performance results of GAT and SAGE also agree with our prior observations on the GCN and GIN, demonstrating the generality and effectiveness of our proposed design and optimizations to handle more complex dataflow (e.g., edge attention and softmax) in multi-GPU GNN computation.

Despite that MGG (NVSHMEM) and DGL (with CPU-GPU zero-copy memory [41]) both rely on GPU-initiated communication and overlap communication with computation, their underlying mechanism is different, and MGG shows more performance advantages. MGG can leverage inter-GPU communication while DGL can only rely on CPU-GPU communication with limited bandwidth. This makes the communication costs pronounced in DGL and offsets the performance gains from massive thread-level parallelism. This experiment also shows that MGG can serve as a drop-in replacement for the existing communication backend of DGL to improve large-scale full-graph GNN computation.

**Compared with MGG-UVM** In this experiment, we compare MGG with its UVM-based counterpart, MGG-UVM, which uses UVM in place of NVSHMEM for remote communication. Figure 8 shows that MGG achieves  $4.58\times$  speedup and  $5.04\times$  speedup on average compared to MGG-UVM on GCN and GIN, respectively. The MGG-UVM leverages the page-faulting-based remote data access that is more coarse-grained (around 4 KB) in comparison with a single node embedding size (less than 0.4KB), which leads to higher overhead and lower effective bandwidth usage per embedding

Figure 9: Performance comparison with ROC with  $8\times$ A100.

transfer. Such an overhead would exacerbate with more GPUs and also make MGG-UVM challenging for GPU SM schedulers to effectively dispatch instructions for the next available warps. This is mainly because most of the warps wait for the long-cycle page-faulting and migration.

We notice that with the increase of the dimension size (i.e., data movement granularity), the speedup over MGG-UVM becomes higher. We later found out that the increase of data-movement granularity actually increases the overall page-fault counts. This is because embedding vectors are generally stored continuously for memory efficiency instead of aligning with the size of memory pages. Therefore, increasing the size of individual embedding also increases the likelihood of triggering multiple pagefaults per embedding transfer.

Comparing among datasets, for graphs (e.g., PAPER) with more nodes/edges and lower average node degree, MGG would demonstrate more speedups since these graphs exhibit more irregular and sparse access that can not well fit into regular fix-sized pages. This also indicates the importance of amortizing communication overhead. Thanks to pipeline-centric workload management, we can effectively amortize such costs with careful operation scheduling.

We further measure two performance-critical GPU kernel metrics that are the key indicators of our pipeline efficiency (§4.1): *Achieved Occupancy* (the ratio of the average active warps per active cycle to the maximum number of warps supported in an SM) and *SM utilization* (the utilization of all available SMs on a single GPU). MGG improves SM utilization (by 21.15% on average) and occupancy (by 39.20% on average) compared to MGG-UVM. This indicates that MGG can effectively 1) distribute irregular workloads to SMs to balance workloads among pipelines and improve the overall GPU utilization, and 2) overlap the remote access and local aggregation computation from different warps to reduce pipeline bubbles and maximize SM occupancy.

**Compared with ROC** In this experiment, we compare MGG with ROC [18] on their officially released GCN model implementation. We originally plan to evaluate both 4 and 8 GPU settings. However, ROC reports many out-of-memory (OOM) errors for those large graphs on GCN/GIN model and medium graphs on the GIN model due to its aggressive caching of those intermediate tensors on GPUs. Therefore, we keep our comparison to 8 GPUs. Performance-critical ROC runtime configurations (e.g., #CPU cores, GPU/host memory size) are optimized to fully utilize the DGX-A100.

Figure 10: Optimization Analysis: (a) Neighbor Partitioning; (b) Workload Interleaving; (c) Choice of Communication Primitives.

Figure 9 shows that MGG achieves averaged  $12.30\times$  and  $9.35\times$  speedups over ROC on GCN and GIN, respectively. MGG demonstrates a more pronounced speedup over ROC on the larger graph (e.g., IT04 and PAPER), which has more irregular neighbor embedding access. The Legion runtime of ROC relies on the DMA engine for bulky data (batched embeddings) transfer between host and GPU memory, leading to higher throughput but inferior latency performance. Besides, ROC relies on a separate communication-computation design, where computation happens after the full completion of communication. Such a design eliminates the opportunity to fill idle GPU cycles with computation during communication. In addition, the learning-based partitioning (to reduce communication) of ROC shows benefits on relatively smaller datasets (e.g., RDD and PROT) but hard to find optimal partition plans for large graphs due to the input structure complexity.

## 7.2 Optimization Analysis

**Neighbor Partitioning (NP)** We compare MGG with a baseline design without applying the neighbor partitioning technique (*i.e.*, each aggregation workload consists of all local/remote neighbors) on  $4\times A100$ . We apply the workload interleaving for both implementations and fix the warp-per-block size to 2 to eliminate the impact from other performance-related factors. Figure 10(a) shows higher latency (averaged  $2.26\times$ ) for designs without applying neighbor partitioning, since the workload imbalance becomes more severe across different warps without neighbor partitioning, especially for those graphs with many remote access demands, leading to limited computing parallelism and GPU underutilization.

**Workload Interleaving (WL)** We compare MGG with a baseline design without workload interleaving (*i.e.*, remote neighbor aggregation and local neighbor aggregation are mapped separately to the GPU warps). We fix the neighbor partition size to 16 and the warp-per-block size to 2. Figure 10(b) shows that MGG consistently outperforms the non-interleaved baseline with an average of  $1.89\times$  speedup. Without interleaving the local/remote workload, the workload distribution would be highly skewed, where the heavy and intensive remote aggregation would be gathered on certain warps close to each other while the lightweight local aggregation would be gathered on some other warps close to each other. This leads to inefficient warp scheduling and higher latency.

Figure 11: Parameter selection for three different settings. (a), (b), and (c) are for setting I, II, and III, respectively. Note that the left-side figures show the runtime latency for different combinations of  $ps$  and  $dist$ , while the right-side figures show the latency for different combinations of  $wpb$  and  $dist$ . The solid black triangle with “E” is the searched “optimal” combination for  $ps$  and  $dist$ , while the black solid star with “E” is the searched “optimal”  $wpb$  given  $dist$  and  $ps$ .

**Communication Primitives** We adopt MGG with different NVSHMEM primitives at the *thread*, *warp*, and *block* levels. We fix the number of GPUs to 2, the hidden dimension to 16, the neighbor partition size to 2, and the distance of workload interleaving to 2. Figure 10(c) shows that warp-level NVSHMEM primitives (*e.g.*, `nvshmemx_float_warp_get`) for remote accessing can bring the lowest latency. For thread-level NVSHMEM primitives (*e.g.*, `nvshmem_float_get`), it would not coalesce the remote memory access to reduce unnecessary transactions. For the block-level NVSHMEM primitives (*e.g.*, `nvshmemx_float_block_get`), the higher overhead comes from collaborating a block of threads for remote access, since thread blocks (usually consisting of multiple warps) is larger than a single warp, thus, leading to higher synchronization and scheduling cost. This study also shows that our choice of warp-level primitives strikes a good balance between memory access efficiency and scheduling flexibility.

**Modeling and Optimization** We further analyze the effectiveness of our lightweight analytical model for design space

Table 3: Accuracy-Latency of GNNs w/ and w/o sampling.

Dataset	Accuracy w/ sampling	Accuracy w/o sampling	Latency (w/o vs. w/ sampling)
RDD	0.937	0.957	1.07×
PROT	0.776	0.825	1.25×

search. Specifically, three key parameters are studied, the size of neighbor partitioning ( $ps$ ), the interleaving distance ( $dist$ ), and the warps per block ( $wpb$ ). We consider three different settings on a 2-layer GCN model: I: RDD on  $4 \times A100$  as the basic setting. II: RDD on  $8 \times A100$  to demonstrate the adaptability toward the different numbers of GPUs. III: RDD on  $4 \times V100$  [37] to demonstrate the adaptability toward the different types of GPUs. We decompose searching results into two parts corresponding to the output of the *second* and *third* steps of the optimization discussed in §6.

Figure 11 shows that our performance modeling and parameter selection strategy can pinpoint the low-latency design for the above three settings. The overall searching process only requires about 10 iterations to reach the final “optimal” settings. Note that here we show latency results for all possible settings for comparison. While in practice, we only need to traverse a small part of the whole design space (as indicated by the boxes touched by the dot lines). By comparing the final optimal runtime configuration setting and the initial configuration, we can see that modeling and cross-iteration optimization can decrease the execution time by up to 68%. In the end-to-end GNN training (usually more than 100 iterations), such a latency saving would also be significant.

### 7.3 Additional Study

**Accuracy-latency Tradeoff** This study will analyze the accuracy-latency tradeoff between GNNs with sampling and full-graph (w/o sampling) on  $8 \times A100$ . Table 3 shows an evident node classification accuracy increase (2% to 5%) of GNN w/o sampling over GNN w/ sampling. The accuracy of sampling-based GNN would be affected by many factors (e.g., sampling rate at each GNN layer and graph structure). It is thus highly tricky to choose the “optimal” value for those factors. Here we follow the conventional way for GNN sampling [45]. The accuracy difference agrees with previous GNN algorithmic work [16]. In many real-world applications (e.g, e-commerce), such an accuracy advantage of full-graph GNNs are be more preferred by users. Because even 1% accuracy would make significant profit gains when deploying services at scale while the latency penalty is relatively minor.

**Generality to other applications** The design of MGG can be generalized to other similar applications. We demonstrate the typical and popular deep-learning recommendation model (DLRM) [31, 47, 54] that has been widely used in the industry. In multi-GPU DLRM, the large embedding tables are partitioned by rows and stored in different GPUs. The DLRM inputs (embedding access queries) will request embeddings

Table 4: DLRM [31] with MGG in Embedding Lookup.

Implementation	DLRM [31]	DLRM (MGG)
Time (ms)	315.27	119.66

from tables on different GPUs and then apply operations (e.g., elementwise addition or dot product) on those fetched embeddings. Such embedding lookup is highly sparse and irregular and dominates ( $> 80\%$  latency [15, 54]) the overall DLRM computation. We improve the mainstream DLRM system [31] with the design and optimizations of MGG to accelerate embedding lookup and element-wise addition and compare with the original system (which relies on NCCL) [31] under 4-GPU settings on the popular Criteo Kaggle [9] dataset. Table 4 shows that DLRM with MGG effectively reduces the lookup time (2.64 $\times$ ). The fine-grained remote access of MGG can reduce redundant inter-GPU traffic by using NCCL and offset the cost by massively parallel GPU-initiated communication.

## 8 Discussion

**Deep Learning Pipelines:** Despite the popularity of the pipeline concept in the conventional dense DL, the generalization of such a technique in sparse GNN computation is yet to be explored in-depth. PiPAD [44] overlaps the communication (CPU-to-GPU) and processing (on GPUs) between adjacent graph partitions. Adopting this strategy, we will get designs as Figure 3(c), which would still suffer from pipeline bubbles due to workload imbalance. vPipe [56] dynamically assigns a DNN layer to certain pipeline stages during the runtime. It improves pipeline efficiency and GPU utilization for DNN models. However, adopting this approach in our fine-grained kernel pipeline would incur high overhead due to frequent workload reassignment and context switching. In addition, the pipeline bubbles in dense DNN are predictable, input-agnostic, and can be reduced offline. However, the pipeline bubble for GNN can only be figured out at runtime due to input dependency. It, therefore, demands careful online workload balance and a pipeline schedule/mapping.

**Graph Partitioning Strategies:** Besides our current ID-based graph partitioning, our designs/optimizations could also be extended to support other graph partitioning strategies from prior graph processing and GNN work. There are several major categories. 1) *Locality-driven partitioning* (e.g., Gemini [57] and Rabbit order [4]) minimizes the communication/synchronization cost in distributed graph processing/GNN computing. Such partition strategies are orthogonal to our current design optimization. Despite it will reduce the total size of communication, the communication pattern remains the same with irregular, sparse, and fine-grained data movements. Our MGG design can be modified to accommodate such reduced-communication cases through dynamic kernel re-configuration (e.g., fine-tuning the interleaving distance and warp-to-block mapping) to maximize

communication and computation efficiency. 2) *Workload-driven partitioning* (e.g., NeuGraph [26] and CUBE [53]) balances the irregular graph/GNN workload among different devices. This type of strategy typically maintains multiple replicas of nodes and node properties on different devices and synchronizes partial results in replicas after local computation on each device. Our current design be adapted to handle such cases by inserting device synchronization primitives (NVSHMEM collective communication primitives, such as `nvshmem_float_sum_reduce`) for maintaining data consistency among different replicas. 3) *Learning-based partitioning* (e.g., ROC [18]) dynamically learns an “optimal” partitioning strategy that can maximize the computation performance. Our current design/optimization can also support this partitioning strategy by incorporating the overhead of NVSHMEM remote memory access in the runtime prediction model when optimizing partitioning strategies online.

## 9 Conclusion

This paper presents MGG, a novel multi-GPU system design, and implementation to exploit the potential of leveraging GPU intra-kernel software pipeline for accelerating GNNs. MGG consists of GNN-tailored pipeline construction and GPU-aware pipeline mapping to facilitate workload balancing and operation overlapping, and an intelligent runtime design to dynamically improve the GNN runtime performance. Experiments show the advantages of MGG over state-of-the-art solutions and its generality towards other DL applications.

## 10 Acknowledgment

We would like to appreciate the great help and support from OSDI shepherd and anonymous reviewers. This work was supported in part by NSF-2124039 and CloudBank [32]. We also appreciate the generous help and support from Amazon Faculty Research Award 2021 for Professor Yufei Ding and NVIDIA Graduate Fellowship 2022-2023 for Yuke Wang.

## A Artifact Appendix

MGG is a holistic runtime for exploiting intra-GPU-kernel communication-computation pipelining to accelerate multi-GPU GNNs. MGG consists of two parts. The first part is the host-side CPU program. It is responsible for dataset loading, runtime configuration generation, and invoking the GPU-side program. The second part is the device-side GPU program, called kernels. It is responsible for the major computation and communication of the GNN model on sparse neighbor-aggregation across GPUs and dense node-update phase within each GPU. MGG introduces GNN-tailored pipeline construction and GPU-aware pipeline mapping to facilitate workload balancing and operation overlapping.

- **Hardware, OS & Compiler:**
  - NVIDIA DGX-A100 with dual AMD Rome 7742 processors (each with 64 cores, 2.25 GHz), 1TB host memory, and 8×A100 GPUs (40 GB) connected via NVSwitch (600 GB/s).
  - Operating systems: Ubuntu 20.04+.
  - Compilers: NVCC (v11.2), GCC (v7.5.0),
  - Libraries: CUDA (v11.2), OpenMPI (v4.1.1), NVSHMEM (v2.0.3), cuDNN (v8.2).
  - Datasets: SNAP [23] and OGB [17].

### Environment Setup

#### Step-1: Download libraries and datasets.

##### – 1.1. Download libraries.

```
wget storage.googleapis.com/mgg_data/local.tar.gz
tar -zxvf local.tar.gz
tar -zxvf local/nvshmem_src_2.0.3-0/build_cu112.tar.gz
```

##### – 1.2. Download datasets and Setup Baselines.

```
wget storage.googleapis.com/mgg_data/dataset.tar.gz
tar -zxvf dataset.tar.gz
cd dgl_pydirect_internal/
wget storage.googleapis.com/mgg_data/graphdata.tar.gz
&& tar -zxvf graphdata.tar.gz
&& rm graphdata.tar.gz
cd ..
gsutil cp -r gs://mgg_data/roc-new/ .
```

##### – 1.3. Launch Docker for MGG.

```
cd docker
./launch.sh
```

##### – 1.4. Compile MGG implementations.

```
mkdir build && cd build && cmake .. && cd ..
./0_mgg_build.sh
```

<sup>2</sup><https://github.com/YukeWang96/MGG-OSDI23-AE.git>

<sup>3</sup><https://doi.org/10.5281/zenodo.7853945>

### Step-2. Run Initial Tests.

Please try below Section-3.4 and Section-3.5.

### Step-3: Experiments.

#### – 3.1. Compare with UVM (Fig.8a and Fig.8b).

```
./0_run_MGG_UVM_4GPU_GCN.sh
./0_run_MGG_UVM_4GPU_GIN.sh
./0_run_MGG_UVM_8GPU_GCN.sh
./0_run_MGG_UVM_8GPU_GIN.sh
```

Results can be found at Fig\_8\_UVM\_MGG\_4GPU\_GCN.csv, Fig\_8\_UVM\_MGG\_4GPU\_GIN.csv, Fig\_8\_UVM\_MGG\_8GPU\_GCN.csv, Fig\_8\_UVM\_MGG\_8GPU\_GIN.csv

#### – 3.2. Compare with DGL (Fig.7a and Fig.7b).

```
cd dgl_pydirect_internal/
./launch_docker.sh
cd gcn/
./0_run_gcn.sh
cd ../gin/
./0_run_gin.sh
```

Results of DGL can be found at 1\_dgl\_gin.csv and 1\_dgl\_gcn.csv. MGG reference is in MGG\_GCN\_8GPU.csv and MGG\_8GPU\_GIN.csv.

#### – 3.3. Compare with ROC on 8xA100 (Fig.9).

```
cd roc-new/docker
./launch.sh
```

Results can be found at Fig\_9\_ROC\_MGG\_8GPU\_GCN.csv, Fig\_9\_ROC\_MGG\_8GPU\_GIN.csv.

#### – 3.4. Compare NP with w/o NP (Fig.10a).

```
python 2_MGG_NP.py
```

Note that the results can be found at MGG\_NP\_study.csv.

#### – 3.5. Compare WL with w/o WL (Fig.10b).

```
python 3_MGG_WL.py
```

Note that the results can be found at MGG\_WL\_study.csv.

#### – 3.6. Compare API (Fig.10c).

```
python 4_MGG_API.py
```

Note that the results can be found at MGG\_API\_study.csv.

#### – 3.7. Design Space Search (Fig.11a).

```
python 5_MGG_DSE_4GPU.py
python 5_MGG_DSE_8GPU.py
```

## Abstract

Dynamic neural networks (NNs), which can adapt sparsely activated sub-networks to inputs during inference, have shown significant advantages over static ones in terms of accuracy, computational efficiency, and adaptiveness. However, existing deep learning frameworks and compilers mainly focus on optimizing static NNs with deterministic execution, missing optimization opportunities brought by non-uniform distribution of activation in dynamic NNs. The key to optimizing dynamic NNs is the traceability of how data are dynamically dispatched to different paths at inference. Such dynamism often happens at sub-tensor level (e.g., conditional dispatching tokens of a tensor), thus hard for existing tensor-centric frameworks to trace due to misaligned expression granularity.

In this paper, we present Brainstorm, a deep learning framework for optimizing dynamic NNs, which bridges the gap by unifying how dynamism should be expressed. Brainstorm proposes (1) *Cell*, the key data abstraction that lets model developers express the data granularity where dynamism exists, and (2) *Router*, a unified interface to let model developers express how *Cells* should be dynamically dispatched. Brainstorm handles efficient execution of routing actions. This design allows Brainstorm to collect profiles of fine-grained dataflow at the correct granularity. The traceability further opens up a new space of dynamic optimization for dynamic NNs to specialize their execution to the runtime dynamism distribution. Extensive evaluations show Brainstorm brings up to  $11.7\times$  speedup ( $3.29\times$  on average) or leads to 42% less memory consumption for popular dynamic neural networks with the proposed dynamic optimizations.

## 1 Introduction

As deep neural network models become large and complex, it is more and more challenging to sustain the growth of model size due to the increased computing requirement. The key

limitation is the static activation of a whole network regardless of inputs, which is much less efficient than a human brain that can dynamically and sparsely activate neurons related to perceived information. Therefore, there have been numerous efforts by machine learning researchers to design *dynamic* neural networks that can feed inputs into different sub-neural structures or parameters of a large model during inference. Dynamic neural networks have shown favorable properties including efficiency [1–8], adaptiveness [1, 9, 10], generality [1, 9, 11, 12], and interpretability [9, 13]. For example, by designing a large number of expert sub-networks but only conditionally activating a small subset of them, Mixture-of-Expert (MoE) has helped to scale Transformer to trillions of parameters and achieve superior performance [14, 15].

Unfortunately, existing deep learning (DL) frameworks are not yet effective for running dynamic neural networks. Their optimization mainly focuses on static neural networks, whose operator execution order is deterministic for all inputs. It has been widely studied in compilers for general programs (e.g., Java, C#) to leverage runtime characteristics of programs to dynamically optimize their execution [16, 17]. By analyzing runtime profiles of dynamism, we find many dynamic NNs have similar opportunities due to their non-uniform distribution of branch activation or token dispatching, which can be further utilized for dynamic optimization.

However, existing tensor-centric programming models cannot support dynamic optimization well. The major challenge is the misaligned expression granularity, i.e., tensor-centric compilers can only trace how data flows at the tensor level in a static dataflow graph (DFG), but dynamism often happens at the sub-tensor level in dynamic NNs. For example, Mixture-of-Experts (MoE) networks use hidden dimensions within input tensors to represent the concept of “tokens”, which are dynamically reordered to activate parallel expert sub-networks with different tokens. It is critical for dynamic optimizations to collect profiles of dynamism, which is hard for existing compilers because they have no knowledge about what “tokens” are and how they are dynamically dispatched.

In this paper, we present Brainstorm, the first framework to

\*This work is done while Weihao Cui and Lingji Ouyang are interns in Microsoft Research

Figure 1: Examples of dynamic neural networks routing at token-level, patch-level, and pixel-level.

optimize the execution of dynamic NNs. Brainstorm unifies the expression of dynamic NNs to make their dynamism easy to trace. At the core of Brainstorm is a new data abstraction called *Cell* that lets model developers describe the granularity of dynamism, e.g., a token inside a tensor. To make *Cell*-level dataflow traceable, Brainstorm unifies the *Router* interface to let model developers express how *Cells* should be dynamically dispatched among multiple branches. Brainstorm can collect the runtime profiles of *Routers* with negligible overhead. Inspired by profile-guided optimization of programming languages [16–20], Brainstorm proposes four dynamic optimizations with statistical analysis of *Cell*-level dataflow: (1) by analyzing the number of *Cells* routed to branches, horizontally fuses multiple branches with GPU kernels optimized for frequent *Cell* loads; (2) with cross-layer *Cell*-level analysis, optimizes distributed placement of parallel branches to minimize inter-GPU communication; (3) with branch activation profiles, speculatively launches branch operators to hide routing overhead; and (4) speculatively preloads branch weights to save GPU memory.

We implement Brainstorm based on PyTorch by extending it with *Cell* and *Router*. We have implemented 6 state-of-the-art dynamic NNs using Brainstorm’s APIs, which are extensively evaluated on Nvidia GPUs. With the proposed dynamic optimizations, our evaluation shows Brainstorm achieves up to  $11.7\times$  speedup ( $3.29\times$  on average) or reduces memory consumption by 42%, compared with state-of-the-art solutions. We open-source Brainstorm to encourage more optimizations for dynamic NNs<sup>1</sup>. The key contributions are as follows.

- We identify a new space of optimization for dynamic NNs by leveraging the statistical profiles of dynamism to specialize model execution to runtime dynamism distribution.
- We identify the major challenge of optimizing dynamic NNs in existing DL frameworks is the misaligned granularity between the tensor-level programming and the fine-grained dataflow required to trace.

<sup>1</sup>Code available at <https://github.com/Raphael-Hao/brainstorm>

- We unify the programming of dynamic NNs with *Cell* and *Router* abstraction, making dynamism easy to trace.
- We propose multiple dynamic optimization strategies, leveraging the *Cell*-level dataflow analysis, which are shown effective for popular dynamic NNs.

We explain background and motivation in §2. We introduce Brainstorm’s key abstraction in §3. Four dynamic optimizations are proposed in §4. We present Brainstorm’s *Cell*-level dataflow analysis in §5. We explain the implementation in §6. We show the evaluation results in §7. We discuss handling distribution drift and other opportunities in §8. We compare with related works in §9. We conclude this paper in §10.

## 2 Background and Motivation

**Dynamic Neural Networks.** To mimic how the human brain works, the machine learning community actively works on how dynamic NNs should be designed. Various types of dynamism have been proposed to adapt the model structures and parameters to different inputs. Figure 1 illustrates representative patterns of dynamic NNs. The most common way of building a dynamic NN is to adaptively dispatch (parts of) inputs to different sub-networks with a routing mechanism. A common functionality, referred to as a *router* in this work, predicts which sub-network the input values should go through. Many routing policies have been proposed for different tasks, e.g., top-k router [3]. Sub-networks in different branches could have different weights, architectures, or the number of parameters to better fit the routed inputs. For example, MoE networks train parallel experts and dispatch input tokens into different expert sub-networks, each of which is expected to specialize in certain input categories [14, 15, 21, 22]. ClassSR [10] routes image patches to heterogeneous branches based on super-resolution difficulty. Skip-Conv [23] routes new pixels to computation and skips duplicated pixels of previous frames. Model developers often use a tensor to store multiple tokens/patches/pixels, and program sub-tensor dynamism using data movement operators like einsum [24].

**Dynamic optimization opportunities.** It has been widely studied in programming languages [25, 26] to leverage statistical profiles of program dynamism for just-in-time (JIT) optimization, e.g., HotSpot JVM speculatively trims paths never executed in collected runs [16]. However, optimizations in existing DL frameworks mainly focus on static NNs. They miss a lot of dynamic optimization opportunities brought by neural network dynamism.

Figure 2 illustrates routing distribution of four dynamic NNs. Figure 2a and Figure 2b are two dynamic NNs dispatching tokens and patches to different branches, respectively. We observe their distribution of tokens/patches is imbalanced: some branches receive non-negligibly more data than others. They have opportunities to tune efficient GPU kernels to

Figure 2: Distribution of routing in four dynamic NNs.

fit their shapes to load distribution, which could potentially bring over  $10\times$  speedup. Also, these parallel branches can be horizontally fused for concurrent execution (§4.1).

We also identify optimization opportunities by analyzing statistics of multi-layer correlation. Figure 2c illustrates the multi-layer correlation of TaskMoE [27], which is the portion of tokens from an expert at Layer-0 routed to another expert at Layer-1. We find the branch activation of two consecutive layers is correlated, e.g., it has a high probability that Expert-14/15 of Layer-1 will be activated after Expert-0 of Layer-0. Up to 87% of inter-GPU communication can be saved by co-locating correlated experts on the same GPU (§4.2).

Figure 2d shows branch activation of selected routers from DynamicRouting [28], which has 186 routers trained to forward images to one or two branches among three branches. Our measurement shows it spent over 44% time on routing. However, many routers have a biased distribution that tends to activate the same branch at different runs. E.g., Router-3 has a high probability of choosing Branch-1 and Branch-2. They create an opportunity for speculative execution, e.g., skipping routing computation to reduce routing overhead (§4.3), or opportunistically preload weight to GPU memory (§4.4).

Moreover, we find many dynamic NNs can be optimized by multiple dynamic optimizations simultaneously. The key requirement of these optimizations is the ability to collect statistical profiles at the granularity where dynamism happens, which is not explored by existing DL frameworks.

**Misaligned programming model.** The misaligned programming model is the major obstacle to tracing dynamism profiles in existing frameworks. As shown in Figure 1, language tasks typically route at the granularity of tokens from input sentences; vision tasks route patches from input images; video models partially reuse previous pixels depending on inter-frame similarity. All the dynamism happens inside the tensor of sentences, images, or frames. Existing frameworks

optimize models with a static dataflow graph, which expresses only the relation of tensors and operators. They have no ability to collect necessary profiles at runtime. Without explicit specification by model developers, they cannot understand what tokens are and how they are dynamically dispatched, let alone trace the complex token-level dataflow as Figure 2c requires. Moreover, tensor-level programming can only be applied with operator-level optimization (e.g., operator fusion) without the ability to optimize more fine-grained data movement or computation. These challenges motivate Brainstorm to propose a principled design to let model developers expose the information that needs to be traced and leverage the collected profiles for dynamic optimizations.

### 3 Cell and Router as the Core Abstraction

For model developers to express dynamic NNs in a traceable manner, Brainstorm unifies the model expression with *Cell* and *Router* to build dynamism at the correct granularity.

**Cell.** To let model developers define the data granularity where dynamism happens, Brainstorm augments a traditional tensor with a data abstraction called *Cell*. The *Cell* is the basic unit to be dynamically dispatched among multiple branches. Model developers can annotate any tensor using the `brt.annotate_cell` API to specify the granularity of *Cells* in a tensor (`brt` is the package name of Brainstorm).

```
brt.annotate_cell(tensor, dims, shape)
```

Model developers need to specify the values in which dimensions (`dims`) and which shape (granularity) to route. Figure 3 shows three examples that route values in *Cells* at the granularity of token, patch, and pixel, respectively. The first example routes a tensor with three tokens located at the 0-th dimension (`dims=(0)`), each represented by a vector of 768 float values (`shape=(1, 768)`). The second and third examples route  $32\times 32$  patches (`shape=(32, 32)`) and  $1\times 1$  pixels (`shape=(1, 1)`) in a 2D image tensor (`dims=(0, 1)`).

**Router.** To dynamically dispatch *Cells*, Brainstorm introduces a unified *Router* API that supports customized rules via `router_fn` to decide the dynamic placement of *Cells* among multiple branches. The API definition of *Router* and `router_fn` are elaborated as follows<sup>2</sup>.

```
class Router:
    def __init__(router_fn : Func)
    def forward(x : Tensor, kwargs) : Tuple[Tensor], Routes

def router_fn(x : Tensor, kwargs) : Routes
```

When initializing a *Router*, the `router_fn` should be specified to define the routing rule, i.e., how *Cells* should be routed among multiple branches. The `router_fn` takes the tensor

<sup>2</sup>We only show routing *Cells* of a single tensor. Multi-tensor routing has similar APIs, which are omitted due to the limited space.

Figure 3: Examples of routing *Cells* at token-level, patch-level, and pixel-level. `router_fn` generates routing decisions indicating branch IDs should *Cells* be routed to (-1 for dropping), collected by the JIT profiler for dynamic optimization.

annotated with *Cells* as inputs and generates a special tensor *Routes*, whose value indicates which branch should *Cell* go. The shape of *Routes* has the same layout as *Cells* of the source tensor to route. E.g., the second example in Figure 3 has  $6 \times 4$  patches, thus `router_fn` should also generate  $6 \times 4$  *Routes*. Auxiliary inputs can be set in `kwargs` when making routing decisions. In the forward process of a model, *Router* feeds the input tensor to `router_fn` to get routing decisions for *Cells*, then dispatch *Cells* to corresponding branches. It is easy to port existing code of dynamic NNs to Brainstorm, e.g., we modify only 12 lines of code to port the official PyTorch implementation of SwitchTransformer [14] to Brainstorm.

Brainstorm’s *Router* abstraction decouples control-flow of deciding how *Cell* should be dynamically dispatched from its execution. Depending on runtime profiles, the optimal execution strategy varies greatly. Brainstorm eases model developers from challenging execution optimizations. They only need to focus on designing routing logic and leave execution optimizations to Brainstorm. The *Routes* given by `router_fn` are collected by JIT Profiler to get statistical profiles. Brainstorm’s dynamic optimizations analyze these statistics to find the most efficient execution strategy (§4).

Behind *Router* are a series of efficient GPU operations to realize the routing actions specified by `router_fn`. When branches receiving *Cells* are located on the same GPU, Brainstorm uses an efficient data rearrangement GPU kernel to generate multiple tensors containing *Cells* routed to each branch. Unlike existing solutions that heavily use computation operators (e.g., `einsum`) for fine-grained dynamic data rearrangement, Brainstorm uses a GPU kernel to directly move data to avoid unnecessary computation. When *Cells* are distributed to multiple GPUs, Brainstorm has a sparse communication primitive to efficiently scatter and gather *Cells*. Compared with the commonly used all-to-all primitive in existing DL

Table 1: The statistical information used by different dynamic optimization strategies in Brainstorm.

frameworks [22, 29], Brainstorm’s sparse communication is more efficient when *Cells* are routed unevenly to multiple GPUs because it avoids unnecessary communication due to padding (refer to §6 for implementation details).

**Comparison to IR with control-flow.** Different from intermediate representations (IR) of existing DL frameworks that mix control-flow and dataflow together, Brainstorm chooses a decoupled design with *Router*. Brainstorm’s dataflow graph hides complex control-flow of *Router* behind `router_fn`. A *Router* can be regarded as a data distribution operator dynamically dispatching *Cells* of tensors to multiple branches. This greatly eases the tracing and analysis of *Cell*-level dataflow because compilers no longer need to separate dynamism-related operators from dataflow graphs, which is hard for DL frameworks [30–32]. Actually, instead of knowing how routing logic is constructed, it is more useful for compilers to know statistical information about routing decisions, which is sufficient to be captured by Brainstorm’s *Router*.

Moreover, Brainstorm further enhances control-flow operators in existing IR with *Cell*-level routing ability. Brainstorm’s *Router* itself can be regarded as a switch-case operator to route *Cells* to different branches for conditionally applying different functions. Together with a while-loop operator, a dynamic NN can route some *Cells* back to loop entry for the next iterations, and drop others to the output, which is commonly used by auto-regressive decoding of language tasks.

## 4 Dynamic Optimizations

Brainstorm analyzes the collected program execution profiles to improve runtime performance. Different from traditional dynamic optimization that analyzes the invocation of program functions or code blocks, the key for optimizing dynamic NNs is to profile and analyze *Cell*-level dataflow to specialize model execution to runtime dynamism distribution. In this section, we introduce four dynamic optimizations we identified for dynamic NNs. More optimizations are possible with Brainstorm’s *Cell* and *Router* abstraction. Table 1 lists the required information to conduct each dynamic optimization.

### 4.1 Dynamic Horizontal Fusion

Horizontal fusion is a compiler optimization to fuse concurrent branches of a model into a fused operator to improve

Figure 4: Operators of multiple branches are horizontally fused into one kernel. Only activated operators are executed. Each branch uses the nearest tuned kernel for least padding.

GPU Compute Unit (CU) utilization and reduce launching overhead. Existing approaches [33, 34] cannot be applied to dynamic NNs, because they assume a static dataflow graph whose branches are all activated with the same input. Brainstorm introduces a dynamic horizontal fusion optimization that supports dynamically and sparsely activated branches so that they can be executed on GPU simultaneously.

Especially, as we have shown in Figure 2, the *Cell* distribution can be very imbalanced for dynamic NNs. Even for large batch size, it can still accelerate the model execution by dynamical horizontal fusion of branches receiving a few numbers of *Cells*. Brainstorm leverages the profiles collected from *Router* to extract the statistical loads of each branch, i.e., how many *Cells* are routed to each branch. Brainstorm finds multiple percentiles (e.g., 50%, 90%, 100%) of the *Cell* load distribution, and tunes GPU kernels for these shapes. All tuned kernels are fused into one operator. At inference, Brainstorm pads the input of each branch to the nearest tuned kernel. This requires the traceability of the dynamic *Cell*-level dataflow at runtime that we explain how Brainstorm achieves it in §5.2. Note that the dynamically fused GPU kernel only uses the weights of activated branches without needing to load the weights of all branches into the GPU memory.

Figure 4 shows an example of routing 112 *Cells* among four parallel branches. Only three of the branches (only known at runtime) are activated. Before horizontal fusion, the three activated branches have to be executed sequentially, which may not saturate the GPU CU utilization. After fusing all branches into one GPU kernel, GPU can execute the activated branches simultaneously at a higher CU utilization. Each branch is executed with the tuned kernel of the least padding for the most efficient execution. For example, the fused kernel contains two tuned kernels of Conv 3x3 for 32 *Cells* and 64 *Cells*, which is used by the first two Conv 3x3 branches in the network by padding 4 and 2 *Cells*, respectively.

## 4.2 Profile-Guided Model Placement

The cerebral cortex of human brain is organized into distinct areas, whose neurons of a function are located closely [35]. By analyzing statistical routing decisions, we observe similar effects in artificially designed dynamic NNs. As shown in Fig-

Figure 5: Profile-guided model placement. The example shows the default placement has 90% inter-GPU traffic, which is reduced to 10% by the optimized placement.

Figure 6: Speculative routing: skip routing computation and speculatively launch the branch w/ highest probability; unroll and relaunch to correct branches when mispredicted.

Figure 2c, experts from two layers are activated together with a high probability. The *Cell*-level communication between these highly-correlated experts is higher than the others. Figure 5 illustrates an example that, by analyzing the multi-layer correlation, Brainstorm can co-locate correlated sub-networks on the same GPU to reduce inter-GPU communication. Note that, in addition to dynamic *Cell*-level dataflow collected at runtime, the multi-layer correlation also needs to analyze static *Cell*-level dataflow to infer correct placement constraints. Our analysis in §5.1 shows each *Cell* of a sentence tensor depends on all *Cells* from the previous MoE layer. This implies a placement constraint that all *Cells* of a sentence should be gathered at the same GPU so that its self-attention operator can generate correct outputs. This presents a challenge requiring both dynamic and static *Cell*-level dataflow analysis to understand the inter-layer correlation of *Cells*. We explain Brainstorm’s static *Cell*-level dataflow analysis in §5.1.

In addition to cross-layer analysis, we find single-layer *Cell* distribution like Figure 2a can also help model placement. Some branches could take more *Cells* than others. Heavy branches can be co-located with light branches to balance the overall communication to avoid stalling on some GPUs.

## 4.3 Speculative Routing

Model developers often build routing logic involving control flows, which may require CPU processing and incur CPU-GPU synchronization overhead. Compared to their theoretical performance (based on FLOPs), routing overhead may dominate the inference latency. Our measurement shows MS-DNet [1] and DynamicRouting [28] spend 65% and 44% time in routing. We find these model often has a biased probability when selecting branches at inference. Our analy-

Figure 7: Speculatively preload weights with the highest probability; fallback to on-demand loading when mispredicted.

sis of Brainstorm’s *Router* profiles shows many *Routers* are highly predictable. Brainstorm can predict the decisions of DynamicRouting [28] with an accuracy over 90% by just choosing the most frequently appeared branches (§7.4.6). As Figure 6 shows, Brainstorm can predict the routing decisions of *Routers* in advance (based on statistical profiles) and skip `router_fn` to hide the routing overhead. To guarantee the correctness, Brainstorm uses a parallel thread to check the result of `router_fn`. When misprediction happens, the model execution will be unrolled to re-execute the correct branch with negligible misprediction overhead (§7.3).

#### 4.4 Speculative Weight Preloading

To run inference of a large model on a limited size of GPU memory, it often requires swapping weights of layers between GPU memory and host memory to reduce the GPU memory requirement [36]. To hide the memory migration latency, existing solutions need to know the execution order of layers to preload necessary weights while executing previous layers in a pipelined manner [37, 38]. However, dynamic NNs do not have a static order of layer execution. The execution of dynamically activated branches is only known when the routing decisions are made. This makes it hard for existing solutions to preload weights of dynamic layers. As shown in Figure 7, similar to speculative routing, Brainstorm leverages the statistical profiles of branch activation distribution to speculatively preload weights of branches that can be activated with a high probability. It falls back to on-demand loading with negligible overhead (§7.3) when the predictive preloading misses.

### 5 Tracing Cell-level Dataflow

To realize optimizations in §4, it is important to understand how *Cells* are transmitted along a network so that the compiler can leverage the *Cell*-level dataflow to optimize model execution. In dynamic NNs, there are two types of *Cell*-level dataflow: (1) static dataflow existing in most static operators (e.g., Conv2D), which is fixed for all inputs; and (2) dynamic dataflow, which is determined by *Routers* at runtime. The former is to understand *Cell*’s relationship across static layers; the latter is to identify the *Cell* routing among branches.

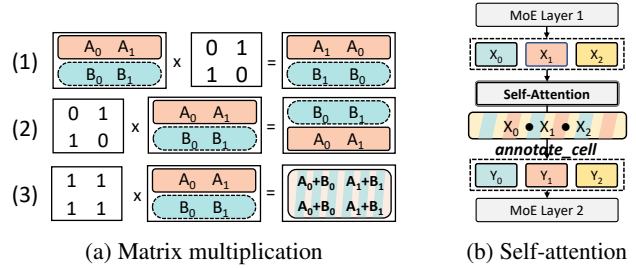

Figure 8: Different types of static dataflow at *Cell*-level.

#### 5.1 Static Cell-level Dataflow

Tensor-centric dataflow graphs only preserve relations between tensors without the information of *Cells*. To trace all possible *Cell*-level dataflow of static operators, Brainstorm uses symbolic execution at *Cell*-level to extract finer-grained relations in ahead-of-time compiling. With the annotated *Cells* of a tensor, Brainstorm initializes a symbolic version of the tensor, whose *Cells* are symbols. Tensor values belonging to one *Cell* share the same symbol. Brainstorm leverages the *tensor expression* of operators (widely used in DL compilers [39]) to build computation logic of operators. By checking the results of symbolic computation, Brainstorm understands how *Cells* are transmitted in static operators.

Figure 8a illustrates three examples of matrix multiplication between a tensor of multiple *Cells* and a constant matrix. The tensor has two *Cells* annotated as *A* and *B*. The first preserves *Cell* positions; the second reorders *Cells*; the third mixes all *Cells* in the output. This example shows the static *Cell*-level dataflow could vary when the tensor values are different. It is hard for tensor-level dataflow analysis to obtain this finer-grained relation. Figure 8b demonstrates the static *Cell*-level dataflow of the self-attention operator between two MoE layers. Because there is a matrix multiplication between two tensors in the self-attention operator and both tensors contain *Cells* of  $X_i$ , this self-attention operator mixes all *Cells* from input  $X$  to generate the output  $Y$ . With symbolic execution of *Cells*, we can derive the relations between the *Cells* in  $X$  and  $Y$ , i.e., every *Cell* in  $Y$  is derived from all *Cells* in  $X$ .

The static *Cell*-level dataflow analysis is necessary to derive cross-layer relations of *Cells*, which is important in data movement-related optimization. It allows Brainstorm to explore data movement at the *Cell*-level, breaking the limitation of tensor-level data movement when optimizing multi-GPU execution. For example, if *Cells* are only reordered without mixing (e.g., the first two types in Figure 8a), the framework has more freedom to dispatch *Cells* among multiple GPUs based on their data locality for better performance. For MoE-based models, because the tokens are mixed up in the self-attention layer, it introduces a constraint that requires aggregating all tokens of a sentence to the same GPU before self-attention to derive the output. As we have shown in §4.2, this requirement creates constraints of how *Cells* should be

Figure 9: The system architecture of Brainstorm. Shaded components are introduced by Brainstorm for dynamic NNs.

dynamically placed in optimization, which is only known after the static *Cell*-level dataflow is analyzed.

## 5.2 Dynamic *Cell*-level Dataflow

In Brainstorm, model developers express dynamism using *Router*. The routing logic is defined in `router_fn`, which generates routing decisions of *Cells* at runtime. Brainstorm’s *Router* abstraction makes it easy to trace the necessary information. Similar to dynamic optimization of traditional programming languages, Brainstorm focuses on collecting statistical profiles of routing decisions without caring about how they are generated.

If *Cell*-level profiling is enabled, when each time a *Router* is called, Brainstorm records its routing decision into a buffer. Brainstorm has a separate thread to stream the buffer to a profile file. Brainstorm supports multi-level profiling. Some optimizations only require local statistical profile of *Router* (e.g., branch load of *Cells*). Some optimizations require *Cell*-level dataflow across multiple layers, thus needing to dump raw decisions directly. As control signals, routing decisions are much smaller than other data tensors in dynamic NNs. Our evaluation in §7.3 shows the profiling overhead is negligible.

## 6 Implementation

We implement Brainstorm on Pytorch with 13,000 LOC: 3,000 lines for Brainstorm core abstraction, 3,000 lines for dynamic optimizations, 3,000 lines of C++ code for kernel scheduling and sparse *Cell* communication, and 1,500 lines for auto-transformation to support dynamic optimizations.

Figure 9 summarizes Brainstorm’s architecture. In addition to widely-used Tensor and Operator in existing frameworks, Brainstorm introduces *Cell* and *Router* to express dynamic NNs in a unified abstraction (§3). The programmed dynamic NNs will be optimized by the compiler with both static and dynamic optimizations (§4). Brainstorm’s dynamic optimization needs both static and dynamic *Cell*-level dataflow analysis (§5). Brainstorm first infers the static *Cell*-level dataflow in static operators (§5.1) in an ahead-of-time manner. When executing the compiled model, a JIT profiler collects *Router* profiles for further dynamic dataflow analysis (§5.2).

**Efficient *Cell* routing.** Brainstorm is responsible for dy-

Figure 10: Sparse All-to-All for distributed *Cell* routing. It saves redundant communication of extra padding.

amic *Cell* dispatching that is aware of dynamic optimization applied, leaving model developers to focus on designing the routing algorithm. For *Cell* routing on a single GPU, we use a custom GPU kernel to rearrange *Cells* inside a tensor according to the routing decisions. We borrow the idea from Tutel [22] for MoE models by rearranging *Cells* for all branches in parallel with a custom GPU kernel. But our implementation is general to all dynamic NNs in addition to MoE models. Moreover, our implementation is aware of the dynamic optimization applied. For instance, a dynamic horizontal fused operator may contain GPU kernels of varied sizes, thus requiring variable padding. For *Cell* routing across multiple GPUs, we provide a more flexible sparse communication primitive. As shown in the left of Figure 10, model developers often combine dense all-to-all primitive and permutation operations for distributed *Cell* routing. Its efficiency is restricted to balanced routing. With Brainstorm’s sparse communication, it only transmits *Cells* without extra padding. The underlying implementation of sparse communication is a collection of point-to-point communication. However, it can adapt to the dynamic optimization’s requirements and provide the most efficient communication mechanism.

**Excessive Candidates for Kernel Fusion.** Brainstorm fuses multiple branches into one kernel function, each comprising several potential candidates. At runtime, Brainstorm triggers suitable candidates based on the dispatched *Cells*. However, excessive kernel candidates derived from profiling analysis can lead to considerable time overhead when searching for them using auto-tuning tools [39]. To avoid issues in this case, Brainstorm only fuses a limited set of candidates of each branch. Meanwhile, kernel candidates are shared between branches if the fused branches are homogeneous (the same operator only with different weights). For instance, since SwitchTransformer uses the same feed-forward layer for its experts, Brainstorm only needs six candidate kernels to optimize the execution of 256 experts per layer (§7.4.1).

**Optimization Passes.** Most automatic transformations in Brainstorm are implemented with `torch.fx`. With the dataflow graph traced by `torch.fx`, Brainstorm uses the statistical profiles collected from *Routers* to manipulate the dataflow graph for optimization. E.g., in dynamic horizon-

Model	Dataset	Fusion	Place	Route	Load
Switch [14]	MNLI [40]	✓			
TaskMoE [27]	Synthetic		✓		
SwinV2-MoE [41]	ImageNet22k [42]		✓		
LiveSR	Iowa-DOT [43]	✓			
DRouting [28]	Cityscapes [44]			✓	✓
MSDNet [1]	Imagenet [42]	✓		✓	

Table 2: Benchmark specifications. (Fusion: Dynamic Horizontal Fusion; Place: Profile-Guided Placement; Route: Speculative Routing; Load: Speculative Weight Preloading.)

tal fusion, we replace operators of multiple branches in the dataflow graph with the generated fused kernel of multiple shapes and change *Router* to pad tensors to supported shapes while routing *Cells*. For speculative routing, we reorder operators in the dataflow graph to skip and unroll routing logic. For speculative weight loading, we collect parameters of branches, and insert extra operators for loading and unloading them at runtime. The profile-guided model placement is an exceptional case, as the loading of model weights falls outside the scope of `torch.fx`. Before inference, Brainstorm loads corresponding weights given by the placement plan derived from the statistical profiles. At runtime, Brainstorm’s *Router* will translate routing decisions given by `router_fn` according to the placement to route *Cells* to the appropriate devices.

**Selecting Dynamic Optimizations.** Given a dynamic model, we use a rule-based policy to select dynamic optimizations. Dynamic horizontal fusion is used for models with parallel branches when a single branch cannot saturate GPU cores. Profile-Guided model placement is used for multi-GPU inference. Speculative routing and weight preloading are enabled when routers block GPU kernel submission. Speculative weight preloading is used when GPU memory is limited, and paging is used. Table 2 has listed the dynamic optimizations applied to each model. For example, LiveSR is a lightweight super-resolution model, and a single branch may not saturate a GPU. Thus we apply dynamic horizontal fusion to it. Also, MoE-based models are usually large language models requiring multi-GPU deployment. Therefore we apply the placement optimization. The input for TaskMoE is sufficiently large for high GPU utilization, thus no need for horizontal fusion.

## 7 Evaluation

We evaluate the performance of Brainstorm (BRT) on six representative dynamic NNs. We compare Brainstorm with various approaches to execute and optimize dynamic NNs, including PyTorch-native static optimizations and model-specific optimizations (e.g., Tutel for MoE). Overall, Brainstorm achieves up to  $11.7\times$  speedup ( $3.29\times$  on average) or reduces GPU memory usage by 42%.

Model	Switch	TaskMoE	SwinV2-MoE
LOC	12	24	14
Model	LiveSR	DRouting	MSDNet
LOC	6	18	14

Table 3: Lines of code for porting the model to Brainstorm.

## 7.1 Experimental Setup

**Testbed.** We evaluate Brainstorm with two separate setups for single-GPU and multi-GPU experiments. The single-GPU evaluations use a server with AMD-EPYC-7V13 CPUs and one NVIDIA A100 (80GB) GPU running CUDA 11.3 and cuDNN 8.6. The multi-GPU evaluations use a server with Intel Xeon CPU E5-2690 v4 CPU and *eight* NVIDIA V100 (32GB) GPUs running CUDA 11.3 and cuDNN 8.2.

**Benchmarks and datasets.** Our evaluations are performed to run inference of six representative dynamic NNs, covering vision and natural language processing (NLP) tasks. Table 2 lists evaluated models, datasets, and dynamic optimizations we apply in Brainstorm. SwitchTransformer (Switch) [14] and TaskMoE [27] are two MoE models for NLP, whose *Cells* are defined at token level and sentence level, respectively; SwinV2-MoE [22, 41], LiveSR, DynamicRouting (DRouting) [28], and MSDNet [1] are four models for vision tasks. SwinV2-MoE and LiveSR define a *Cell* at image patch level. DynamicRouting and MSDnet use an image as a *Cell*. Statistical profiles used for Brainstorm’s dynamic optimizations are collected from training datasets and evaluated in test datasets.

**Baselines.** We mainly compare Brainstorm with PyTorch and Tutel in all experiments. As far as we know, PyTorch is a state-of-the-art framework that can flexibly support dynamic neural networks (thanks to the expressiveness of Python). The official implementation of all models we evaluated are based on PyTorch and thus are compared in all evaluations in this paper. Tutel is designed specifically for MoE. Thus we only compared Brainstorm with Tutel on MoE-based models. To evaluate the benefit of the new proposed dynamic optimizations, Brainstorm and all baselines use the same static optimizations (e.g., vertical kernel fusion) in all experiments.

## 7.2 Effectiveness of Brainstorm Abstraction
